20 **Abstract**

21 Topsoil field-saturated hydraulic conductivity, Kf_s , is a parameter that controls the partition of
22 rainfall between infiltration and runoff and is a key parameter in most distributed hydrological
23 models. There is a mismatch between the scale of local in situ Kf_s measurements and the scale
24 at which the parameter is required in models for regional mapping. Therefore methods for
25 extrapolating local Kf_s values to larger mapping units are required. The paper explores the
26 feasibility of mapping Kf_s in the Cévennes-Vivarais region, in south-east France, using more
27 easily available GIS data concerning geology and land cover. Our analysis makes use of a
28 data set from infiltration measurements performed in the area and its vicinity for more than
29 ten years. The data set is composed of Kf_s derived from infiltration measurements performed
30 using various methods: Guelph permeameters, double ring and single ring infiltrometers
31 and tension infiltrometers. The different methods resulted in a large variation in Kf_s up to
32 several orders of magnitude. A method is proposed to pool the data from the different
33 infiltration methods to create an equivalent set of Kf_s . Statistical tests showed significant
34 differences in Kf_s distributions in function of different geological formations and land cover.
35 Thus the mapping of Kf_s at regional scale was based on geological formations and land cover.
36 This map was compared to a map based on the Rawls and Brakensiek (RB) pedotransfer
37 function (mainly based on texture) and the two maps showed very different patterns. The RB
38 values did not fit observed equivalent Kf_s at the local scale, highlighting that soil texture alone
39 is not a good predictor of Kf_s .

44 **Introduction**

45 Distributed hydrological models are valuable tools for flood risk management at the
46 catchment or regional scale. Hydrological models generally distinguish two runoff generation
47 mechanisms: i) saturated excess runoff or Dunne runoff (Dunne and Black, 1970), when
48 runoff is generated over saturated areas, and ii) infiltration excess runoff or Horton runoff
49 (Horton, 1933), when rainfall intensity exceeds soil infiltration capacity. Topsoil field-
50 saturated hydraulic conductivity, K_{fs} , is a key parameter in controlling infiltration excess
51 runoff. This parameter is generally used in regional scale distributed hydrological models;
52 therefore mapping methods of this parameter are required. The task is difficult because the
53 model mesh scale is much larger (several hundreds m^2 to several km^2) than the scale of
54 available in situ measurements (hundreds of cm^2 to a few m^2) (Davis et al., 1999).
55 Pedotransfer functions, relating soil hydraulic properties to more easily accessible information
56 such as texture, dry bulk density and/or organic matter content, are often used for this
57 purpose. Examples of such pedotransfer functions are those of Clapp and Hornberger (1978),
58 Cosby et al. (1984), Rawls and Brackensieck (1985), the HYPRES functions (Wösten et al.,
59 1999) or ROSETTA (Schaap et al., 2001). Their ability to reproduce observed soil hydraulic
60 properties has been questioned (e.g. Verecken et al., 2010). Several authors have underlined
61 that those functions, often built using estimations made on undisturbed core samples in the
62 laboratory, may not be representative of in situ controls of soil hydraulic properties, as they do
63 not sample macropores correctly due to their small sample size (Jarvis et al., 2013). Several
64 papers have highlighted the impact of land cover on topsoil hydraulic conductivity (e.g.
65 Bonell et al., 2010; Gonzalez-Sosa et al., 2010). Recently, Jarvis et al. (2013) presented a
66 global data base of hydraulic conductivity measured in the field using tension infiltrometers.
67 They highlighted that topsoil hydraulic conductivity was only marginally related to soil

68 texture, but that organic carbon content, bulk density and land cover were better explanatory
69 factors of the variability of observed data (see also Jorda et al., 2015 for an update of the
70 study). Our study contributes to this effort of data collection and analysis of controlling
71 factors of Kf_s in the topsoil.

72 It was conducted in the Cévennes-Vivarais region, a region prone to intense Mediterranean
73 rainfall events that can lead to flash floods especially in the autumn. It was part of the
74 FloodScale project (Braud et al., 2014) aiming at understanding and simulating flash flood
75 generating processes. In this region, several hydrological models were proposed for flash
76 flood simulation and/or forecasting, such as models derived from TOPMODEL (Saulnier and
77 Le Lay, 2009; Vincendon et al., 2016), SCS based models (e.g. Gaume et Bouvier, 2004;
78 Naulin et al., 2013, Laganier et al., 2014), models based on the Richards equation (Vannier et
79 al., 2016) or infiltration excess runoff generation (Ayrat et al., 2005), modeling approaches
80 including infiltration excess and sub-surface flow such as the MARINE model (Roux et al.,
81 2011; Garambois et al., 2013). All of these models require mapping of the variation in
82 saturated hydraulic conductivity at regional scale. A first guess is generally obtained using
83 one of the above mentioned pedotransfer functions, but a hydrological model calibration is in
84 most cases performed starting from this first guess map. This is often achieved using a single
85 multiplicative factor of the map that retains the spatial variability and relative orders of
86 magnitude of the first guess map. For instance, Garambois et al. (2013) have shown that a
87 multiplicative factor ranging from 2 to 20 is needed for saturated hydraulic conductivity in the
88 region to reproduce observed hydrographs which implies that alternative solutions to
89 pedotransfer functions are required in order to provide more realistic maps of saturated
90 hydraulic conductivity that can be used in hydrological models.

91 In our paper, we take advantage of the large amount of in situ infiltration measurements
92 performed in the study area. However, those infiltration measurements were performed using
93 various techniques such as Guelph permeameters, double or single ring infiltrometers and
94 tension infiltrometers. Several studies have already compared different types of infiltration
95 methods (e.g. Angulo-Jaramillo et al., 2000; Mohanty et al., 1994; Ronayne et al., 2012;
96 Verbist et al., 2013; Bagarello et al., 2014) or some methods for analyzing the data (e.g.
97 Vandervaere et al., 2000; Verbist et al., 2013, Xu et al., 2012). Those studies agree that
98 different methods may lead to differences of several orders of magnitude in the estimated Kf_s ,
99 which in turn raises questions about the challenges of pooling our data sets. Thus, the
100 following questions are addressed in the present paper:

- 101 1/ Is it possible to pool the data from the infiltration measurements performed with
102 different techniques for the common analysis of Kf_s in the Cévennes-Vivarais region?
103 2/ Are geology and land cover relevant factors upon which the mapping of Kf_s can be
104 based?

105

106 **Materials and methods**

107 *Description of the available data sets*

108 The data used in this study were collected by different institutes and research teams between
109 2002 and 2012 in the Cévennes-Vivarais region in south-east of France (Figure 1). The main
110 catchments of the area (black contours in Figure 1) are characterized by steep slopes in their
111 upstream mountainous part (western parts of the catchments), corresponding mainly to granite
112 and schist geology, with a dominant forest land cover. Their downstream parts (eastern part)
113 are flatter, with sedimentary, marl or alluvium geology and are mostly farmed. Another data

114 set is included in this study (blue rectangle in Figure 1). It was collected in the Mercier
115 catchment, a forested and agricultural sub-catchment of the Yzeron periurban catchment,
116 close to the city of Lyon, France in 2008 (Gonzalez-Sosa et al., 2010). The geology is
117 dominated by gneiss and the catchment is prone to Mediterranean influence as is the
118 Cévennes-Vivarais region, with a hydrological response similar to that of the granite forested
119 catchments of the Cévennes-Vivarais. Figure 1 shows a simplified geology map of the
120 Cévennes-Vivarais region and the location of the infiltration measurements used in the
121 present study.

122

123 The first two data sets were obtained as part of a study conducted for the Schapi (Service
124 Central d'Hydrométéorologie et d'Appui à la Prévision des Inondations) in order to document
125 Kf_s for use in distributed hydrological models (BRGM data set). BRGM conducted several
126 infiltration measurements campaigns in the Gardons and Avène catchments between 2002 and
127 2008. Part of the data set is described in Desprats et al. (2010) and in several reports published
128 by Cerdan et al. (2004), Desprats et al. (2005, 2007, 2008), Baran et al. (2006). The
129 infiltration measurements were conducted with two types of devices: Guelph permeameter
130 (GP) (Figure 2a, 143 sampling points) and double ring (DR) infiltrometers (Figure 2b, 164
131 sampling points). These two data sets will be subsequently referred to as the “GP” and “DR”
132 data sets.

133 Guelph permeameter principles rely on the measurement of water flux from a cylindrical hole
134 (5 cm in diameter) into a homogeneous, non-saturated porous media. A Mariotte device
135 ensures constant pressure in the cylindrical hole and enables the infiltration rate to be
136 monitored. This device can estimate Kf_s and soil sorptivity (characterizing infiltration capacity
137 as a function of time and initial soil moisture). In our study, Kf_s data were derived from GP

138 measurements at a depth of 15 to 20 cm, using a constant head of 5-10 cm above the hole
139 bottom.

140 The double ring infiltrometer was composed of two concentric cylinders (40 cm diameter for
141 the inner cylinder) that were inserted into the soil to a depth of 5 cm. The water level was
142 maintained constant in both cylinders and the infiltration rate was measured in the inner
143 cylinder where the lateral diffusion effect was minimized. Kf_s was directly deduced from the
144 surface infiltration volume divided by the cylinder area when a constant flux was reached,
145 assuming that deeper horizons did not perturb the water flux and that the gradient governing
146 water flux was vertical.

147 For the GP and DR data sets, additional available information was the location, geology and
148 land cover at the sampling locations.

149

150 The third data set is the result of single ring (SR) or *Beerkan* infiltration measurements
151 (Figure 2c) performed in the Mercier sub-catchment of the Yzeron catchment, close to Lyon,
152 France in 2008 (see description in Gonzalez et al. (2010)) (57 sampling points) and from a
153 similar data set collected in the Claduègne sub-catchment, in the Ardèche catchment (Figure
154 1, 50 sampling points) in 2012 (described in Braud and Vandervaere (2015)). The
155 measurements were conducted using a single ring (40 cm inner diameter) positioned at the
156 soil surface after removal of vegetation. Twelve liters of water were introduced into the
157 cylinder without pre-wetting, and the infiltration was measured using a ruler and a
158 chronometer. The infiltration measurements were analyzed following the method proposed in
159 Lassabatère et al. (2006) which exploits the transient infiltration regime and provides
160 retention and hydraulic conductivity curves (see details in Gonzalez-Sosa et al. (2010) and

161 Braud and Vandervaere (2015)). Only Kf_s was considered in this study. This data set will be
162 referred to as the SR data set in the following discussion.

163

164 The fourth data set is Kf_s derived from tension infiltration measurements performed in the
165 Cévennes-Vivarais region (Figure 1, 26 sampling points) by the HSM (HydroSciences) and
166 LTHE (Laboratoire d'Etudes des Transferts en Hydrologie et Environnement) laboratories for
167 this study or other purposes. The tension infiltrometers (TI) used by those laboratories are
168 presented in Figure 2d and 2e respectively, with diameters of 25 and 20 cm. Hydraulic
169 conductivity was derived for the constant flux regime, using the multiple tension method
170 described in Vandervaere (1995) and derived from Ankeny et al. (1991) and Reynold and
171 Elrick (1991). For TI measurements performed with the infiltrometer in Figure 2e,
172 extrapolation of Kf_s from values close to saturation. was performed using linear interpolation
173 from a plot of logarithmic hydraulic conductivity as a function of linear tension (five values of
174 applied water potential between -100 and -10 mm). Another method to compute Kf_s was used
175 for the TI measurements performed with the infiltrometer in Figure 2d. As the disk was not
176 directly connected to the water column, the precise adjustment between the disk and water
177 column heights caused some technical difficulties, easily leading to a few mm of uncertainty
178 in the estimation of the applied tension. To overcome the problem, experiments were
179 conducted until a positive soil water head was obtained at the soil surface that could be
180 detected when leakage occurred at the bottom of the disk. The last measured tension was
181 assumed to be -0.1 mm of applied water potential and the hydraulic conductivity estimated at
182 this tension was assumed to be Kf_s . This data set will be referred to as the TI data set.

183 For the TI and SR data sets, additional information at each sampling site was location, soil
184 texture, organic matter content, dry bulk density, geology and land cover.

185

186 In our paper, the following land cover classification is used with the numbers indicated in
187 Table 1-4: cultivated grassland and crops (10), permanent grassland (11), broadleaf forest
188 (20), coniferous forest (21), lands and moors (22), vineyards and orchards (30). For geology,
189 the classification is: alluviums (100), volcanic rocks (200), granite and gneiss (300), marls
190 (400), schist (500), sedimentary (600).

191

192 ***Building a common pooled Kf_s data set***

193 Figure 3 shows a box plot of Kf_s as a function of the infiltration method. The Kruskal-Wallis
194 test shows that the differences between infiltration methods are significant ($p < 0.0001$). The
195 median DR is about one order of magnitude larger than that of GP, whereas the medians of
196 DR, SR and TI are closer (about a 0.5 order of magnitude difference). Individual values span
197 three to four orders of magnitudes. Several studies have compared different techniques for
198 estimating soil saturated hydraulic conductivity (e.g. Mohanty et al., 1994; Ronayne et al.,
199 2012; Verbist et al., 2013, Bagarello et al., 2014). Mohanty et al. (1994) reported
200 systematically lower values with GP than with TI, but they were dealing with infiltration
201 measurements performed at a depth of 15, 30 or 90 cm and not in the topsoil. Ronayne et al.
202 (2012) found larger values with the DR than with GP in a glacial till soil. In stony soils,
203 Verbist et al. (2013) reported larger values with SR than with DR, the latter being larger than
204 with TI. Bagarello et al. (2014) compared Kf_s values obtained with three methods: 1)
205 infiltration tests where a positive constant head is maintained at the soil surface, 2) infiltration
206 tests using a falling head, and 3) tension infiltrometers. They highlighted the fact that a
207 constant positive head may disturb the soil surface and provoke clogging that may reduce Kf_s
208 values. Differences in Kf_s may also occur because the devices have different infiltration areas

209 and thus cover different soil volumes. In our case, the SR and DR methods covered the largest
210 radii, whereas the GP and TI methods sampled a smaller area. Regarding the GP method, soil
211 compaction during hole excavation may occur and also clogging due to a constant positive
212 head during the infiltration while soil disturbance can be expected to be virtually absent with
213 TI methods. However, for the latter, an underestimation of Kf_s cannot be excluded since the
214 extrapolation to zero soil water pressure may neglect the potential influence of the macropores
215 network. All those differences in measurement protocols require caution when analyzing the
216 pooled data.

217

218 Pooling was conducted in two steps. In Figure 3, GP and DR data sets were significantly
219 different ($p < 0.0001$) and we chose to pool these two data sets first, trying to establish a
220 relationship between them. We first worked with the GP and DR data sets because the
221 sampling points from these methods spanned the largest combinations of geology and land
222 cover (Table 1). In addition, such pooling had already been performed successfully by
223 Desprats et al. (2010) for these two methods. They computed average values for different
224 combinations of geology and land cover and fitted the following relationship using the
225 averages per geology * land cover:

$$226 \quad Kf_{s_DR} = 47.422 \exp(0.0502 Kf_{s_GP}) \quad R^2 = 0.80 \quad (1)$$

227 In our study additional sample points were available so we updated this relationship. In
228 addition, as the distribution of Kf_s was found to be log-normal, we chose to compute the
229 relationship on $\log_{10}(Kf_s)$, expressed as $\log(Kf_s)$ in the following discussion, instead of using
230 the exponential relationship of Desprats et al. (2010). The advantage of our solution is that it
231 fits a linear relationship rather than a non-linear one which allows uncertainty on the
232 regression coefficients to be easily computed. Working with $\log(Kf_s)$ also allowed us to

233 reduce the differences in orders of magnitude among the data sets. Furthermore, the tests
234 described in the Results section were performed to choose the method (DR or GP) used to
235 compute the “equivalent” Kf_s used in the subsequent analysis. The DR method was chosen
236 after those tests which allowed us to reduce the data sets to three infiltration methods.
237 In the second step, Kruskal-Wallis tests were conducted to determine whether or not the
238 three remaining types of infiltration methods were significantly different. The DR and TI
239 values were not significantly different whereas the SR values were significantly different
240 from DR and TI. Therefore we tried to establish a relationship between the SR and DR + TI
241 data sets which would enable all the data to be pooled together for subsequent analysis. This
242 analysis consisted mainly in comparing various distributions, according to geology and land
243 cover information, as they were the only available common factors for all the sampling points.
244 The Kruskal-Wallis test was used to compare the distributions and statistical analyses were
245 performed using R software (R Core Team, 2014).

246

247 ***Mapping Kf_s***

248 A mapping procedure was proposed based on the statistical analyses for pooling the data
249 presented in the previous section. It relies on geology and land cover information (see details
250 in the Results section and in Table 4). A 30 m resolution land cover map, produced by
251 Andrieu (2015), was available for part of the study area (see black rectangle with broken line
252 in Figure 1). It was derived from multiple Landsat images made in 2013 using an
253 unsupervised classification method (Andrieu, 2015) with the following nomenclature: 1=
254 uncovered soils, urban, roads, rocks; 2= early crops (spring vegetation growth); 3= late crops
255 (summer vegetation growth); 4= vineyards, bare soils, rocks; 5= grasslands; 6= broadleaf
256 forests; 7= mixed forests; 8= coniferous forests; 9= shrublands; 10= water bodies. The map

257 was reclassified to match the land cover classification used in our study by merging classes 2
258 and 3 to match our class 10 (cultivated grassland and crops); class 5 was assumed to be
259 permanent grassland (class 11); class 7 was merged with class 6 to match our class 20
260 (broadleaf forest) and class 9 was assumed to be our class 22 (lands/moors).

261 A vector geology map from BRGM was available at the 1/1000000 scale and the geology
262 layer was simplified according to the classes listed above (see Figure 1). This map was
263 converted to raster layer at the land cover map resolution and reclassified according to the
264 combinations proposed in Table 4 and the average $\log(Kf_s)$ of each combination was assigned
265 to the class for mapping.

266 This map was compared to the results obtained by Manus et al. (2009) and Vannier et al.
267 (2016) using the Rawls and Brackensieck (1985) pedotransfer functions (RB85) over the area.
268 For this mapping, these authors used a soil data base from the IGCS (Inventaire Gestion et
269 Conservation des Sols, <https://www.gissol.fr/tag/igcs>) program, associated with a vector map
270 of soil cartographic units at the 1/250000 scale (pedology map in the following discussion). It
271 was possible to derive maps of clay, sand and silt contents, and porosity from this information
272 (Manus et al., 2009), which were used to compute Kf_s from the RB85 formula (see details in
273 Manus et al. (2009) for the Languedoc-Roussillon region and Bonnet (2012) for the extension
274 to the whole Cévennes-Vivarais region). The values obtained at the infiltration measurement
275 locations were extracted and compared to the values derived from Table 4, to assess the
276 predictive power of the RB85 pedotransfer function.

277 **Results**

278 **General description of the data sets**

279 Table 1 shows the contingency tables of number of sampling for the various infiltration tests
280 (original data set) by infiltration method and geology and land cover. In both cases, the chi-
281 squared test had a p-value <0.0001, showing that the points distribution was far from being
282 homogeneous, in particular in terms of geology. Indeed, two geologies: alluviums and marls
283 were only sampled using DR and GP methods, whereas volcanic rocks were only sampled
284 using the SR and TI methods. Nevertheless, most of the samples were taken for the dominant
285 geology classes in the area: sedimentary, granite and schist. The sampling is somehow more
286 homogeneous for land cover, but TI data are much less abundant, given the longer time
287 required to perform this kind of infiltration tests. Three points with very low Kf_s values were
288 removed from the GP data set for subsequent analysis as they were outliers.

289 For the SR and TI data sets, soil texture was available, so it is possible to show the sampling
290 points in the USDA textural triangle (Figure 4). We can see that the data span over a large
291 range of clay and sand contents. Nevertheless, coarse soils (sand and loamy sands) are hardly
292 represented.

293 **Results obtained when pooling all data sets**

294 Table 2 presents the average and standard deviation of the GP and DR data sets for different
295 combinations of geology and land cover information. Only the combinations with more than
296 two samples (bold figures in Table 2) were retained to build the relationship between the
297 values of $\log(Kf_s)$ in the two data sets. Two regressions were tested (Figure 5): one with equal
298 weights for all the points, one with non-equal weights (see documentation of the *lm* function
299 in R software : <http://127.0.0.1:28603/library/stats/html/lm.html>), w_i , inversely proportional to
300 the average variance of $\log(Kf_s)$ at each point computed as: $w_i = 1 / ((\text{var}(\log(Kf_{s_DRi})) +$
301 $\text{var}(\log(Kf_{s_GPi}))) / 2)$ where i refers to one combination of geology and land cover. The equal-

302 weight regression was chosen as it resulted in a higher determination coefficient ($R^2 = 0.665$,
303 $p=0.0045$) than when non-equal weights were used ($R^2 = 0.566$, $p=0.012$). The corresponding
304 equation was the following:

$$305 \log(Kf_{s_DR}) = (1.3148 \pm 0.32) * \log(Kf_{s_GP}) + (0.4712 \pm 0.46) \quad R^2 = 0.66 \quad p = 0.0045 \quad (2)$$

306 Although each point had a large standard deviation, the relationship was quite good, with an
307 R^2 value of 0.665. This determination coefficient is lower than that of Eq.(1) by Desprats et al.
308 (2010), but Eq. (2) was not established with exactly the same data set. In addition, fitting a
309 linear regression allows providing easily uncertainty bounds for the regression coefficients.
310 Eq.(2) shows that the uncertainty on the intercept is higher than that of the regression slope.
311 More importantly, Eq. (2) is more consistent with physical principles than Eq. (1), previously
312 established by Desprats et al. (2010) on Kf_s values instead of $\log(Kf_s)$. Indeed, in Eq. (1),
313 Kf_{s_DR} tends towards a constant value when Kf_{s_GP} tends towards zero, which was not very
314 satisfactory. This problem is avoided with Eq. (2).

315 Once this equation was established, for each sample point where a GP value was measured, an
316 equivalent DR Kf_{s_DR} value was computed using Eq. (2). Similarly for each sample point at
317 which a DR value was measured, an equivalent GP Kf_{s_GP} value was computed using the
318 regression between GP and DR values. These values were used to draw box plots of $\log(Kf_s)$
319 for three infiltration methods (GP, SR and TI) and (DR, SR and TI) (Figure 6a and Figure 6b,
320 respectively). The Kruskal-Wallis test showed that GP and SR, and GP and TI data were all
321 significantly different ($p < 0.0001$) and could not be analyzed together. On the other hand, DR
322 and TI data did not have significantly different distributions ($p=0.25$) and could be analyzed
323 together. The SR data were still significantly different from the other two data sets
324 ($p<0.0001$). Therefore, similarly to what was done for the DR and GP data sets, we tried to
325 establish a relationship between the SR and DR+TI data sets. For both data sets, geology and

326 land cover information was used to compute averages for each geology * land cover class, as
327 the Kruskal-Wallis test showed that the $\log(Kf_s)$ values were significantly different for
328 geology and land cover classes with p values < 0.0001 . Table 3 shows the averages and
329 standard deviations for both types of infiltration methods and Figure 7 shows the relationships
330 that were fitted using either equal weights (black line, $R^2=0.25$, $p=0.07$) or with weights
331 inversely proportional to the variance of each point (blue line, $R^2=0.32$, $p=0.05$). This second
332 equation, with the highest determination coefficient and the lowest p value, was retained for
333 further analysis and reads:

$$334 \log(Kf_{s_{DR+TI}}) = (0.33 \pm 0.14) * \log(Kf_{s_{SR}}) + (1.49 \pm 0.50) \quad R^2 = 0.32 \quad p = 0.05 \quad (3)$$

335 The determination coefficient is much lower than in Eq. (2) but still significant at the 5%
336 level. Table 3 shows that only two geologies could be used to establish this relationship:
337 granite and sedimentary. We must therefore assume that the relationship is also valid for all
338 the other combinations of geology and land cover information, which is a limitation of the
339 results as all available combinations were not used in establishing the relationship.

340 The Kf_s values of the SR data sets were converted to an equivalent DR+TI value using Eq. (3).
341 This pooled equivalent set of values is the one used subsequently for mapping $\log(Kf_s)$. Once
342 again, the Kruskal-Wallis test showed that geology and land cover were discriminating factors
343 in the distribution of $\log(Kf_s)$ and averages and standard deviations were computed for the
344 different combinations of geology and land cover information (Table 4 and Figure 8). In the
345 next section the average values per geology and land cover classes are proposed for mapping
346 $\log(Kf_s)$ at the regional scale.

347 ***Mapping topsoil field-saturated hydraulic conductivity***

348 The average $\log(Kf_s)$ values provided in Table 4 for each combination of geology (Fig. 1) and
349 land cover allowed the $\log(Kf_s)$ to be mapped for the three main catchments in the area

350 (Ardèche, Céze and Gardons, see rectangle in Figure 1). In the resulting map, no value was
351 assigned to pixels that had a geology and land cover combination not present in Table 4
352 (mainly land cover 1 (rocks and urban areas), but also some land cover for volcanic rocks).
353 The results are shown in Figure 9a and the corresponding map obtained using the RB85
354 pedotransfer function is shown in Figure 9b. Note that there are differences in orders of
355 magnitude between the two maps, which is expressed as lighter blue colors for the RB85 map.
356 The $\log(Kf_s)$ range of the RB85 map is -1.08 to 1.97 corresponding to a Kf_s range of 0.083 to
357 95.5 mm h^{-1} , whereas the map derived from geology and land cover (Table 4) leads to a range
358 of 1.58 to 3.00, corresponding to Kf_s values ranging from 38.0 to 996.6 mm h^{-1} . If other
359 pedotransfer function models such as those using only textural information (e.g; Cosby et al.,
360 1984) had been used, a smaller range would have been obtained as Manus et al. (2009)
361 showed that RB85 was the pedotransfer function leading to the largest range of Kf_s as
362 compared to the other methods they tested in this area. The patterns of Kf_s are also different in
363 the two maps. Figure 9b reflects the pedology map and soil cartographic units, whereas Figure
364 9a is mainly shaped by the geology map, modulated by the land cover map, which has a much
365 higher resolution. Figure 10 shows the comparison of the values of the two maps at the
366 infiltration tests sampling locations. It demonstrates that RB85 $\log(Kf_s)$ values are much lower
367 than the values obtained in the present study. The data points are not correlated at all, showing
368 that pedotransfer functions not taking into account land cover information is not a good
369 predictor of the spatial variability of Kf_s in the area.

370 **Discussion**

371 In this paper, we propose a simple method, based on statistical tests analyzing differences in
372 distributions and simple regressions to pool together values of topsoil field-saturated
373 hydraulic conductivity, Kf_s , obtained using different infiltration methods, mainly tension

374 infiltrometers (TI) and methods based on positive heads (Guelph permeameter (GP), double
375 ring (DR) infiltrometer, single ring – *Beerkan* (SR) infiltrometer). Our results are consistent
376 with previous studies that indicate that different methods may lead to differences of several
377 orders of magnitude in the estimated Kf_s . Thus, much lower values were obtained with GP
378 than with the other methods which could be expected as the GP measurements were
379 performed between 15 and 20 cm depth, whereas the depth was of less than 10 cm for the
380 other methods. We might expect larger Kf_s values with positive head infiltration methods than
381 with TI, since the extrapolation procedure for the latter may give underestimated values.
382 However, Bagarello et al. (2014) have reported, for some sampling points, lower Kf_s values
383 when a positive head is maintained during the measurements than when a falling head or even
384 tension infiltrometers are used. With a positive pressure head, soil particles may be disturbed
385 and clog the soil surface and top soil. For the SR data set, we only experienced clogging at a
386 few sampling points. In addition, the infiltration measurements were mainly performed on
387 vegetated surfaces and although vegetation was cut before the infiltration test, the root
388 network was still present, which should limit the clogging problem. The sampling surface is
389 also generally lower with TI than with the other methods. In our data set, TI leads to values of
390 the same order of magnitude as the DR method. Nevertheless, the number of sampling points
391 with TI was much lower (Table 1) than with the three other methods. This could reduce the
392 impact of TI data on the final results.

393 The standard deviations of the regression coefficients in Eq.(2) and Eq. (3) are quite large,
394 showing that the fitted regressions have a large uncertainty that is propagated to the final map
395 of Fig.9a. In addition, only two geologies could be used in establishing Eq. (3): granite and
396 sedimentary. We had to assume that the relationship was also valid for all the other
397 combinations of geology and land covers, which was a limitation of the study. All those

398 uncertainties should be kept in mind when considering using the final map in hydrological
399 models for instance.

400

401 It was not possible to include soil texture, organic carbon and dry bulk density in our analysis
402 because they were only available for the SR and TI data sets. It would have been interesting to
403 perform the kind of analyses proposed by Jarvis et al. (2013) and Jorda et al. (2015) on those
404 data, but the sample size was too small. Nevertheless, similarly to these studies, our analysis
405 points out the main impact of land cover on Kf_s , calling for an inclusion of land cover in soil
406 surface Kf_s mapping methods. In addition, near saturated hydraulic conductivity at -20 mm
407 applied water potential ($K(-20mm)$) was also acquired using mini-disk infiltrometers
408 (Decagon Devices Inc., Pullman, WA, diameters 4.5 and 8 cm) at the locations of the SR data
409 sets (Gonzalez-Sosa et al., 2010; Braud and Vandervaere, 2015). The results showed the Kf_s
410 / $K(-20 mm)$ ratio ranging between 21 and 570, which highlights the influence of macropores
411 close to saturation. This change in hydraulic conductivity is generally not taken into account
412 in hydrological models, but it would be preferable to do so. The adaptation of classical
413 hydraulic conductivity functions such as those proposed by Jarvis (2008) or Gonzalez-Sosa et
414 al. (2010) could be used. On the other hand, for deeper horizons (< 10-30 cm) where land
415 cover is supposed to be less influential (Jarvis et al., 2013), a map such as the one proposed in
416 Figure 9b, computed pedotransfer functions for the deeper horizons could be relevant.
417 Infiltration data of deeper horizons are much less abundant as most methods require
418 pedological pits to be dug, and using pedotransfer functions is thus the easiest available
419 method. In this context, the GP method is practical since measurements can easily be made at
420 deeper horizons in replicated auger made by drilling.

421

422 The mapping method proposed in the present paper is quite simple and only relies on two
423 easily accessible maps: geology and land cover. Ferrer et al. (2004) proposed a map of soil
424 saturated hydraulic conductivity for Spain, based on interpolation of point data. They showed
425 that the final map was consistent with the geology map, indirectly pointing out the relevance
426 of this factor for Kf_s mapping. In the Mercier catchment (6.7 km²), where geology was
427 homogeneous (gneiss), Gonzalez-Sosa et al. (2010) proposed land use as a main factor for
428 mapping Kf_s , based on a high resolution field scale land cover map. The advantage of the
429 method we propose is that land cover maps at various resolutions are easily available and the
430 method can be adapted to the resolution of available data, or aggregated at the model mesh
431 scale. It would be interesting to have also a higher resolution of the geology map to improve
432 the Kf_s map for smaller catchments. The mapping method could also be improved by
433 introducing spatial variability in each geology * land cover combination, by assigning to each
434 pixel a Kf_s value taken from a lognormal distribution as defined in Table 4. It is far beyond the
435 scope of this paper to investigate which of the two maps in Figure 9 would lead to the best
436 predictions in terms of hydrological modeling, but it would be worth investigating this
437 question further, in order to determine the proper applicability of the proposed mapping
438 methods. Nevertheless, Figure 10 and the results obtained in this study showed that for topsoil
439 horizons, the RB85 pedotransfer function method gives lower Kf_s than Kf_s from the pooled
440 procedure in our study and that additional information such as land cover and geology should
441 be taken into account when mapping topsoil hydraulic properties.

442 To our knowledge, no study tried to pool data obtained from infiltrometers and different types
443 of positive head infiltration tests. Our study shows that simple relationships can be obtained
444 allowing for pooling initially heterogeneous data sets, and obtaining larger homogeneous data
445 sets for further analysis.

446 An interesting perspective of this work would be the use of both Kf_s maps in uncalibrated
447 distributed hydrological models (see Vannier et al., 2016) to see if discharge simulation is
448 improved at the regional scale.

449

450 **Conclusions**

451 This paper reports on the significant efforts deployed to gather data obtained from infiltration
452 measurements in the Cévennes-Vivarais region. The main challenge of this data set was the
453 diversity of methods used to perform those measurements, which resulted in Kf_s values
454 varying with several orders of magnitude, and the very small number of factors available at all
455 studied sites (geology and land cover only). A method was proposed for pooling all the data
456 sets and deriving an “equivalent” double ring + tension infiltrometer (DR+TI) field-saturated
457 hydraulic conductivity. As geology and land cover were found to be significant discriminating
458 factors on Kf_s values, they were used to propose a method for mapping topsoil Kf_s in the
459 region. This map was compared to a map based on the RB85 pedotransfer function method.
460 Very different output pattern between the two maps was observed. RB85 values did not fit
461 observed values with our method at each measurement location, highlighting that soil texture
462 alone may not be a good predictor of Kf_s . An interesting perspective of the work is to compare
463 the impact of different Kf_s mapping method on the results of distributed hydrological models.

464

465 **Acknowledgements**

466 The FloodScale project was funded by the French National Research Agency (ANR) under
467 contract no. ANR2011 BS56 027, which contributes to the HyMeX program. It also benefited
468 from funding by the MISTRALS/HyMeX program (<http://www.mistrals-home.org>). The

469 authors thank Stanislas Bonnet, Flora Branger, Louise Jeandet, Mickaël Lagouy, Olivier
470 Vannier for their participation in the field infiltration tests in the Claduègne catchment; Pascal
471 Brunet, Olivier Le Bourgeois and students from Ecole des Mines d'Alès for their help in
472 deploying infiltrometers in the Gardons and Vidourle catchments. BRGM thanks the SCHAPI
473 for its support of the infiltration campaigns conducted in the Gardons and Avène catchments.
474 The Cévennes soil data base was built from the Languedoc-Roussillon and Ardèche data base
475 provided by the Chambre d'Agriculture of both areas in the framework of the IGCS program
476 (<https://www.gissol.fr/tag/igcs>). Julien Andrieu provided the land cover map used in this
477 study. We thank the editor M. Iovino and two anonymous reviewers for their help in
478 improving the quality of the paper, and Charles La Via for helping us improve our English.
479 The data set is available upon request to any interested researcher. The request can be sent to
480 the corresponding author.

631 **List of figures**

632 Figure 1: Location of the study areas in France and simplified geology map of the Cévennes-
633 Vivarais region. The blue rectangle shows the location of the Yzeron catchment in France.
634 The location of the infiltration measurements in the Yzeron catchment (blue rectangle) is not
635 provided here and can be found in Gonzalez-Sosa et al. (2010). The dotted black rectangle
636 corresponds to the location of the land cover map used in the study. The infiltration methods
637 are Guelph Permeameter (GP), Double Ring (DR), Single Ring (SR) and Tension
638 Infiltrometer (TI).

639 Figure 2: Photos of the various infiltration methods (a) Guelph permeameter; (b) double ring
640 infiltrometer; (c) *Beerkan* (single ring) infiltrometer; (d) Tension infiltrometer where the disk
641 has been removed from the tower (SDEC, SW 080 B); (e) Home-made tension infiltrometer
642 from LTHE.

643 Figure 3: Box plot of the original data set of field-saturated hydraulic conductivity Kf_s (mm h⁻¹)
644 (log scale) for the different infiltration methods. In the box plots, the box boundaries
645 indicate the 25th and 75th percentiles, the bold line indicates the median, and the top and
646 bottom whiskers indicate the 10th and 90th percentiles. The open circles are the outliers.

647 Figure 4: Location of the Single Ring (SR) and Tension Infiltrometer (TI) data sets in the
648 USDA textural triangle. The numbers in parenthesis are the land cover class numbers.

649 Figure 5: Regression between $\log(Kf_s)$ (mm h⁻¹) for Guelph permeameter (GP) and Double
650 Ring (DR) infiltration methods. The points are mean values per geology * land cover classes
651 and the vertical and horizontal lines correspond to one standard deviation. Two regressions
652 are shown: the first one with equal weights for all points (black), the second with weights
653 inversely proportional to the variance of each point (blue).

654 Figure 6: Box plots of all $\log(Kf_s)$ values when (a) DR values of the BRGM data set are
655 converted to GP values using Eq. (2) and (b) GP values of the BRGM data are converted to
656 DR values using the regression between GP and DR values.

657 Figure 7: Regression between $\log(Kf_s)$ (mm h^{-1}) for Single Ring (SR) and Double Ring +
658 Tension disk Infiltrometer (DR+TI) infiltration methods. The points are mean values per
659 geology * land cover classes and the vertical and horizontal lines correspond to one standard
660 deviation. Two regressions are shown: the first one with equal weights for all points (black),
661 the second with weights inversely proportional to the variance of each point (blue).

662 Figure 8: Bar plot of average $\log(Kf_s)$ (mm h^{-1}) plus one standard deviation for the different
663 combinations of geology and land cover derived from the final homogenized data set.

664 Figure 9: Maps of $\log(Kf_s)$ for part of the Cévennes-Vivarais region using (a) the geology and
665 land cover maps and the results of Table 4 and; (b) the pedology map and Rawls and
666 Brackensieck pedotransfer function RB85.

667 Figure 10: Comparison of $\log(Kf_s)$ obtained at the infiltration sampling points from the map
668 obtained using the RB85 pedotransfer function (Figure 9b) and the geology and land cover
669 map based on Table 4 (Figure 9a).

700 Table 1 : Contingency tables of the original values of $\log(Kf_s)$ (mm h^{-1}) by infiltration method
 701 and geology/land cover. The chi-squared test has a p-value lower than 0.0001 in both cases.
 702 The class numbers for land cover are cultivated grassland and crops (10), permanent grassland
 703 (11), broadleaf forest (20), coniferous forest (21), lands and moors (22), vineyards and
 704 orchards (30). The infiltration methods are Guelph Permeameter (GP), Double Ring (DR),
 705 Single Ring (SR) and Tension Infiltrometer (TI)

Infiltration type	Geology						
	Alluviums	Sedimentary	Granite	Marls	Schist	Volcanic	Total
DR	21	67	29	22	24	0	163
GP	46	28	18	35	16	0	143

708 Table 2: Mean, standard deviation of $\log(Kf_s)$ and number of samples for Guelph
 709 Permeameter (GP) and Double Ring (DR) data sets for different combinations of geology and
 710 land cover (only combinations common to both infiltration methods are shown, which
 711 explains why the total number of points is lower than in Table 1). The class numbers for land
 712 cover are cultivated grassland and crops (10), permanent grassland (11), broadleaf forest (20),
 713 coniferous forest (21), lands and moors (22), vineyards and orchards (30)

Geology * land cover	DR mean $\log(Kf_s)$ (mm h ⁻¹)	DR standard deviation $\log(Kf_s)$ (mm h ⁻¹)	Number of samples DR	GP mean $\log(Kf_s)$ (mm h ⁻¹)	GP standard deviation $\log(Kf_s)$ (mm h ⁻¹)	Number of samples GP
