Abstract

The lower terraces of the Dordogne River at Bergerac (south-west France) were studied in detail using cores, trenches, ground penetrating radar profiles, and ¹⁴C, optically stimulated luminescence and infrared stimulated luminescence dating. This study shows that the lowest terrace (Fx) is made up of two major lithostratigraphic units: (i) dominantly horizontal gravel strata interpreted as compound bar deposits in a braided river, which pre-date 18–17 ka, and (ii) thick lateral accretion gravel units (point bars) formed in an anabranching river during the Late Pleniglacial and Lateglacial. Most of the anabranching channels were abandoned at ca. 11–10 ka following shrinkage of the river bed into a single meandering channel and were partially filled by gyttjas during the Boreal chronozone. Finally, the channels were plugged by overbank fines until about 5 ka. Floods seldom reached the Fx terrace during the late Holocene and accretion became negligible. The main phase of bedrock incision spanned the Holocene, whereas the period of channel adjustment to change in river regime during late Marine Isotope Stage (MIS) 2 only led to a redistribution of the Pleniglacial gravels. The higher terrace (Fw3) formed before the Eemian and was covered by colluvial fans, mainly during MIS 2 and 3.

Keywords

Dordogne River; fluvial dynamics; Holocene; south-west France; Weichselian.

Introduction

The formation of alluvial terraces has generated many geomorphological studies over the past few decades and still remains a widely debated subject. Different models have been proposed to explain bedrock erosion, deposition and terracing in relation to tectonic, climatic and intrinsic (autogenic) factors (Vandenbergh, 2008; Bridgland and Westaway, 2008, 2012; Lewin and Gibbard, 2010; Murton and Belshaw, 2011, and additional references therein). One of the main difficulties in evaluating the validity of the various hypotheses usually resides in the limited range of available data concerning both the geometry and the chronology of the alluvial bodies preserved in the terraces. Although the recent development of quartz or feldspar luminescence dating methods has significantly increased the possibilities of obtaining age information from alluvial deposits and enabled refinement of the chronological frameworks, most studies are based on observations of distant sections or cores and fail to take account of the real

complexity of the terrace architecture. Therefore, establishing accurate links between river evolution and the various forcing factors remains difficult.

The development of rescue archaeology in France over the past few years has provided abundant, closely spaced observation windows in alluvial terraces, mainly around large towns currently undergoing rapid expansion. Bergerac in south-west France, located in the middle course of the Dordogne River, is one of these towns (Fig. 1). Over the past 5 years, all the geotechnical cores and archaeological trenches dug in the lower terraces near the town have been surveyed and various elements have been gathered for dating [archaeological remains, samples for radiocarbon and optically stimulated and infrared stimulated luminescence (OSL/IRSL)]. At two sites, these data have also been complemented by ground penetrating radar (GPR) profiles. Brought together, the data allow us to map in detail the alluvial deposits and to document their architecture and depositional history, thereby providing a high-resolution picture of river changes during the last glacial–interglacial transition.

Regional setting

The Dordogne is a large river flowing in south-west France westward to the Atlantic Ocean. In the study area, which is located in the middle course of the river, the valley is ca. 7km wide and bordered by outcrops of Eocene alluvial sands (e5, Platel, 1985), overlain by fluvial–deltaic clays, sands and marls (e6–7) (Fig. 1). The underlying Cretaceous limestones do not outcrop on the slopes but form the bedrock of the current channel. Two main terraces, labelled Fx and Fw3 on the 1:50 000 geological map (Platel, 1985), are preserved on either side of the current river floodplain (Fz) (Supporting information Fig. S1). Older terrace remnants are also visible on the slopes (Fw2 to Fu). Available core data show that they form a system of platforms cut into the substrate and covered by 5–7m of alluvial deposits, forming typical paired (although unequally developed) stepped units (Lewin and Gibbard, 2010). Abundant archaeological remains spanning the last two glacial– interglacial cycles have been found in this part of the valley and attest to recurrent human settlement since the Middle Palaeolithic. This article focuses on the two lower units.

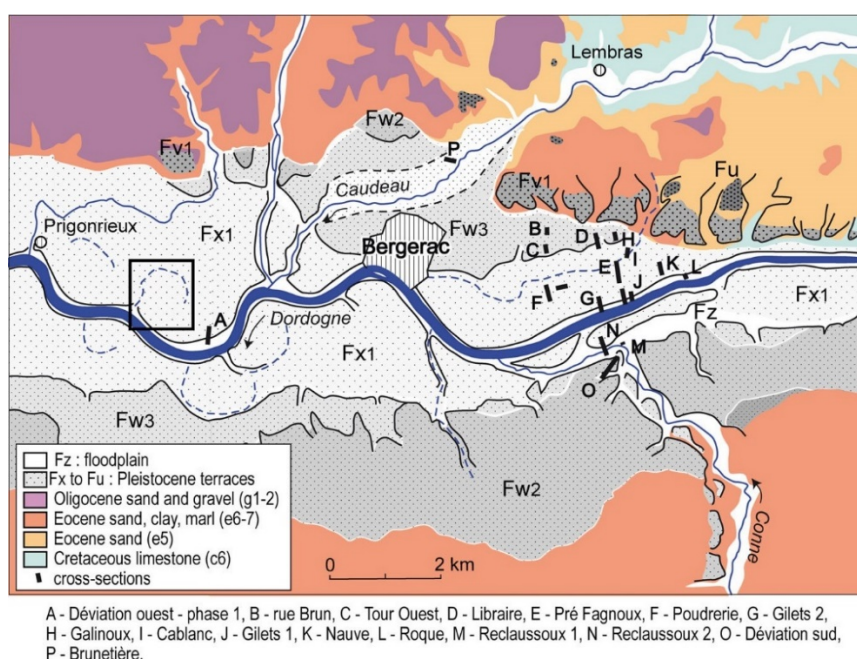

Figure 1. Geological map of the study area, simplified after Platel (1985), and location of the cross-sections. The rectangle indicates the location of Fig. 7. This figure is available in colour online at wileyonlinelibrary.com.

Materials and methods

The archaeological trenches are generally 1.5–3m deep and 20m long and allow for the detailed observation of the finegrained lithostratigraphic units overlying the gravel bodies. The latter have only occasionally been exposed by the trenches. Complementary information was obtained from geotechnical cores and auger or penetrometer data. In addition, GPR profiles were collected with a 200-MHz antenna and a Radar SIR System-3000 GSSI (Geophysical Survey systems, Inc., Salem, MA, USA). Data were collected at 16 bits per sample, 64 scan s⁻¹ over 120ns. The raw GPR data were processed using RADAN software, which included bandpass filtering (30–400MHz), gain adjustment and stacking (16). Direct measurement was used to estimate velocity (with a target at a known depth) on one of the investigated sites. Based on this estimation a velocity of 0.134mns⁻¹ was selected for data processing. Several profiles were made in this way. However, it was only possible to exploit the first radar campaign as the following profiles made 2 years later were strongly perturbed by noise of unknown origin.

The lithostratigraphic units were sampled for chemical analysis and for dating. Samples for chemical analysis were analysed by energy-dispersive X-ray-fluorescence analysis (ED-XRF) using a portable SPECTRO X-SORT device (40kV, 50mA), after separation into two fractions by wet sieving at 63mm and grinding the sand fraction. Measurements were made in air with an acquisition time of 60s and replicated three times. They displayed good reproducibility. Elements lighter than Si were not detected with this method. The chemical compositions were then compared with those stored in the PACEA geochemical database obtained from different geological formations in the same geographical sector. All data underwent a multivariate statistical analysis. Since the application of classic statistics to compositional data (e.g. data expressed as percentages) is not correct and can lead to partial or even erroneous interpretations (Buccianti, 2012), the approach introduced by Aitchison (1982) was followed. In this paper, the biplot for compositional data was chosen as a tool for multivariate analysis (Aitchison and Greenacre, 2002). Values below the detection threshold were treated in accordance with the method proposed by Martin-Fernandez et al. (2003) before analysis. Only elements for which more than 80% of the values were higher than the detection threshold were used in the analysis, made with the CoDaPack software (Thio-Henestrosa and Comas, 2011).

Thin sections were also prepared from undisturbed samples from the Rue Brun site, after vacuum impregnation with a polyester resin following the method proposed by Guillore' (1980), and observed with a petrographic microscope. Radiocarbon dating was carried out on charcoal or peat samples. OSL dating was applied to quartz grains and IRSL to feldspar. The dose accumulated by the grains was calculated using a single aliquot regenerative-dose protocol (SAR; Murray and Wintle, 2000). For feldspars, two distinct approaches were nonetheless applied. The IR-postIR_{225°C} protocol (Buylaert et al., 2009) was applied to samples from Tour Ouest and Nauve, whereas those from Poudrierie and Gilets 2 were analysed with IR_{50°C}. The ages reported in Table 1 take account of the corrections linked to the fading rate (Auclair et al., 2003; Thomsen et al., 2008) and to the residual signals specific to each approach, as well as dose rates measured in situ with a gamma spectrometer.

Lithostratigraphy

Terrace Fw3

Terrace Fw3 forms a vast surface dipping gently towards the Dordogne River. Such morphology may indicate the presence of a colluvial cover overlying fluvial sediments. The deposits were observed in trenches at several sites (Tour Ouest, Rue Brun, Libraire and Galinoux; Fig. 2). The depositional sequence shows, from bottom to top:

A gravel body about 5m thick, with a base at approximately 30–31m above sea level (a.s.l). This unit (T3a) has only been observed from geotechnical cores. It is interpreted as coarse-grained channel or bar deposits.

Massive dominantly sandy deposits, 3–6m thick (T3b, c). Near the slope, they include clast- to matrix-supported gravel beds (Dmc, Dmm; Miall, 1996). The distal part of this unit becomes siltier. The overall massive character suggests a gradual homogenization of the sediments during deposition (bioturbation, freeze–thaw cycles) or emplacement as mudflows. These deposits are interpreted as coalescent colluvial fans. Overbank sandy silt inputs from the Dordogne may also have contributed. This question is tackled using geochemistry. At Rue Brun, a complex palaeoluvisol makes up a major chronostratigraphic limit within the sands and allows us to divide these deposits into two subunits, T3b at the bottom and T3c at the top. Unit T3c yielded Upper Palaeolithic industries in different places (i.e. Aurignacian, Magdalenian, indeterminate Upper Palaeolithic: Prodeo et al., 2001; Grigoletto, 2010).

The various observation windows provide complementary information with regard to the geometry of the units. At Libraire, the core data indicate that the T3a and b units were cut by a gully perpendicular to the valley and filled afterwards by mainly sandy sediments. No evidence for the interglacial palaeoluvisol was observed in this cross-section. A major unconformity thus separates unit T3b from unit T3c. These are interpreted as two interlocking sedimentary lobes of a segmented colluvial fan, possibly because of base-level-induced distal trenching (Harvey, 1997).

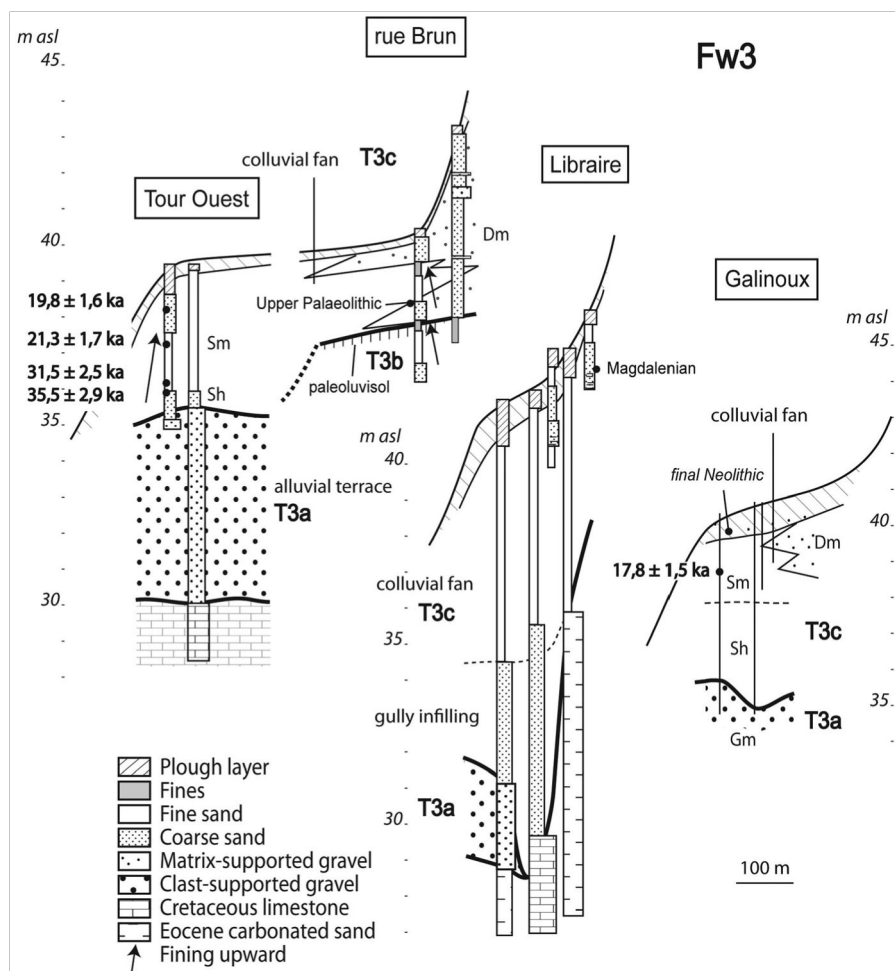

Figure 2. Cross-sections of terrace Fw3.

Terrace Fx

Terrace Fx makes up a wide berm bordered by levees (Fig. 3). Downstream from Bergerac where the terrace widens, oxbow depressions make it possible to identify former abandoned channels (Fig. 1). Numerous observation windows are available in this terrace (Cablanç, Gilets 1 and 2, Nauve, Poudrierie, Pre' Fagnoux, Roque). In addition to a probable isolated remnant of Fw3 in the Pre' Fagnoux site, the following units were observed (Fig. 4):

A gravel body about 5m thick overlying the limestone bedrock. The base is located at a relatively constant altitude in the study area, at about 27–28m a.s.l. The GPR profiles indicate that this unit is not homogeneous. Two types of architectural elements are identified:

Unit T2a comprises dominantly horizontal strata and subordinate oblique sets of strata typically 0.3–0.6m thick, interpreted as compound bar deposits, and concave-upward strata corresponding to scour fills (Vandenberghe and van Overmeeren, 1999; Lunt and Bridge, 2004; Sambrook et al., 2006) (Fig. 5). This unit indicates primarily vertical accretion of the deposits, presumably associated with a braided fluvial style.

Unit T2b is composed of low-angle oblique strata, interpreted as lateral accretion features of wide meandering channels (point bars) (Figs. 5 and 6). This unit cuts into and drapes unit T2a. The strata are subhorizontal and regular on the GPR profiles parallel to the channels.

Finer-textured units, corresponding to channel or depression fills. Two main types were observed: Filling of small depressions forming sub-parallel furrows at the top of unit T2b (supporting Fig. S2). These furrows and associated gravel ridges are interpreted as scroll bars (Leclerc and Hickin, 1997). Similar scroll bars are visible on aerial photos in the convexity of an abandoned meander downstream of Bergerac (Fig. 7). The fill (maximum thickness

of 1–2m) was mainly observed at Cablanc and Pre' Fagnoux. From bottom to top, it generally exhibits cross-bedded sands (St, Sr; Miall, 1996), horizontally bedded sands (Sh) and, lastly, laminated to massive sands, silts and sometimes clays (fl, Fm). Polygonal networks of cracks 1m in length cut into these deposits in places. These cracks are thought to result from (cryo-) desiccation of the deposits in a deep seasonal frost context (Van Vliet-Lanoe", 1985; Bertran et al., 2013).

Wide channel fills, visible both in cross-section and on the maps of gravel isobaths (T2c) (Fig. 3; supporting Fig. S3). This filling comprises generally massive sand units (Sm) then a fine-grained plug (Fm: silts and sands, gyttjas), often with a thickness of over 1m. On the Gilets 2 site, the basal sand unit, which forms a body dipping gently towards the channel (point bar), has yielded several prehistoric occupation levels attributed to the Mesolithic.

A general cover by a sandy silt unit which thickens to form a levee on the terrace margin. This unit corresponds to overbank deposits. Recent Neolithic remains were found in the subsurface at several points and show that Fx was seldom reached by floods from the Subboreal onwards. Protohistoric, antique and medieval remains are reworked in the ploughed layer.

The architecture of the Fx terrace is thus complex. It shows (1) a residual gravel unit, which appears to correspond to Fw3 remnants, (2) a thick gravel unit deposited in a braided river (T2a), (3) gravel point bar deposits and associated scroll bars (T2b), and (4) a final fill by fine-grained, sometimes organic deposits (T2c). Scattered depressions with sharp limits are also visible on the maps of gravel isobaths and in trenches (Figs. 3 and 6). They cut into the previous units and correspond to dolines formed along certain channels. Gyttja deposits are trapped at the bottom of these dolines.

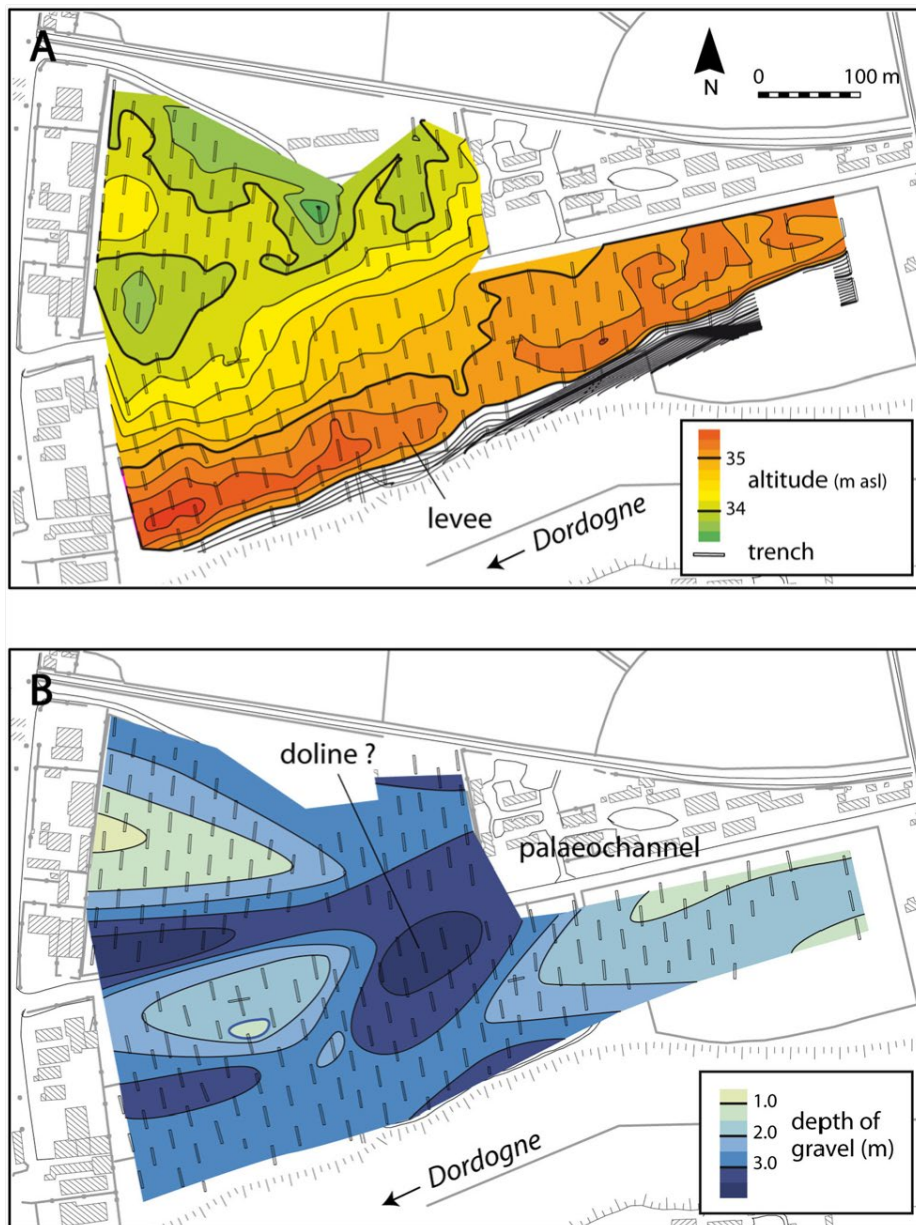

Figure 3. (A) Topography of terrace Fx at the Nauve site; (B) isobath map of the gravels.

Fz floodplain

The Fz floodplain forms a narrow corridor about 6m below Fx and was surveyed at two sites, Roque, which is located slightly upstream from the study area, and Déviation Ouest downstream from Bergerac. The first site only yielded 2m of organic sands lying on the limestone bedrock, associated with medieval archaeological remains. The second site shows a channel cut into the Eocene formations and filled by about 4m of gravels and sands (Supporting Fig. S4).

Geochemistry

A geochemical analysis of the sediments from the various formations outcropping in the valley and from other regional sedimentary contexts was undertaken to understand in detail the origin of unit T3c. This analysis brings to light several points. For the sand fraction (>63mm), the biplot shows that (Fig. 8):

The Late Pleistocene deposits of the Dordogne and Garonne Rivers plot close to the calcic pole. In so far as these sediments are decalcified, Ca comes mainly from plagioclases, but also from ferromagnesian silicates (amphiboles, pyroxenes, epidote). Because calcic minerals are very sensitive to alteration and Ca is highly mobile in soils, this pole corresponds to relatively unaltered materials.

The Oligocene plateau alluvium and Eocene molasses (e6–7) are differentiated on the basis of their potassium content (plus Rb and to a lesser extent Sr, which generally substitute K in silicates), mainly associated with K-feldspars and muscovite (Salminen, 2005).

The residual clays derived from weathering of the Cretaceous limestone are characterized by their high Ti, Zr, Fe and Mn content as oxides and, for Fe, as silicates resistant to alteration (tourmaline, staurolite, garnet).

The coversands are dominated by quartz (pole Si), whereas the aeolian silts also contain a certain percentage of iron oxides. Zn, Ni, Cr and Y, which plot between Fe and Si, are probably associated with resistant silicates, such as garnet (Salminen, 2005). Eocene sands (e5) and the Lower Pleistocene alluvial deposits of the Dordogne River (Fv) are of similar composition as the aeolian deposits.

The T3c colluvium shows a strong variability, ranging between the terraces Fx and Fv and the Eocene (e5) sands. For the fraction finer than 63mm, the pattern is somewhat different. The Ca pole, which aggregates relatively unaltered deposits, remains unchanged. In contrast, Si, Ti and Zr are grouped in the same pole, which corresponds to assemblages dominated by quartz and minerals resistant to alteration. Fe and iron substitution elements, such as Cr, Ni and Zn, form another pole corresponding to oxides in association with kaolinite. It is opposed to K, coming from clays from the illite group. The distribution of the sedimentary formations indicates that (Fig. 9):

1. The aeolian silts plot near the quartz pole and extend towards the illite pole.
2. The Eocene (e5) and the Lower Pleistocene alluvial (Fv) units are close to the oxides and kaolinite pole.
3. The T3c unit plots between Late Pleistocene alluvial deposits and aeolian silts. Note that there is marked similarity in the composition of the silty sand distal lithofacies of the colluvium and the plateau aeolian cover.

The chemical composition of unit T3c thus indicates that the sand fraction corresponds to a mixture of Eocene and Pleistocene alluvial formations outcropping on the slope. The molasses do not appear to have contributed much to their formation. By contrast, the fine-grained fraction shows that contribution of Fx overbank material is unlikely but points towards a more or less distant silty aeolian contribution, similar to that forming the plateau cover.

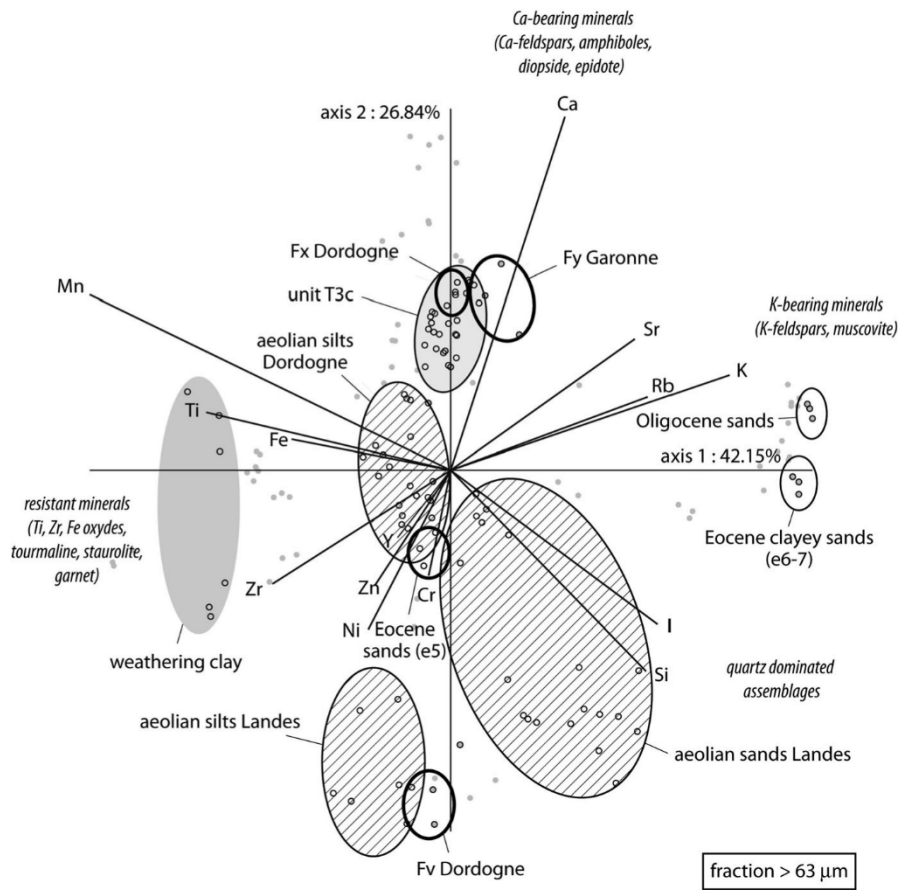

Figure 8. Biplot of the geochemical composition of various geological formations from Aquitaine, fraction >63mm. The shaded points correspond to the lithological units used in the analysis but not detailed in the text.

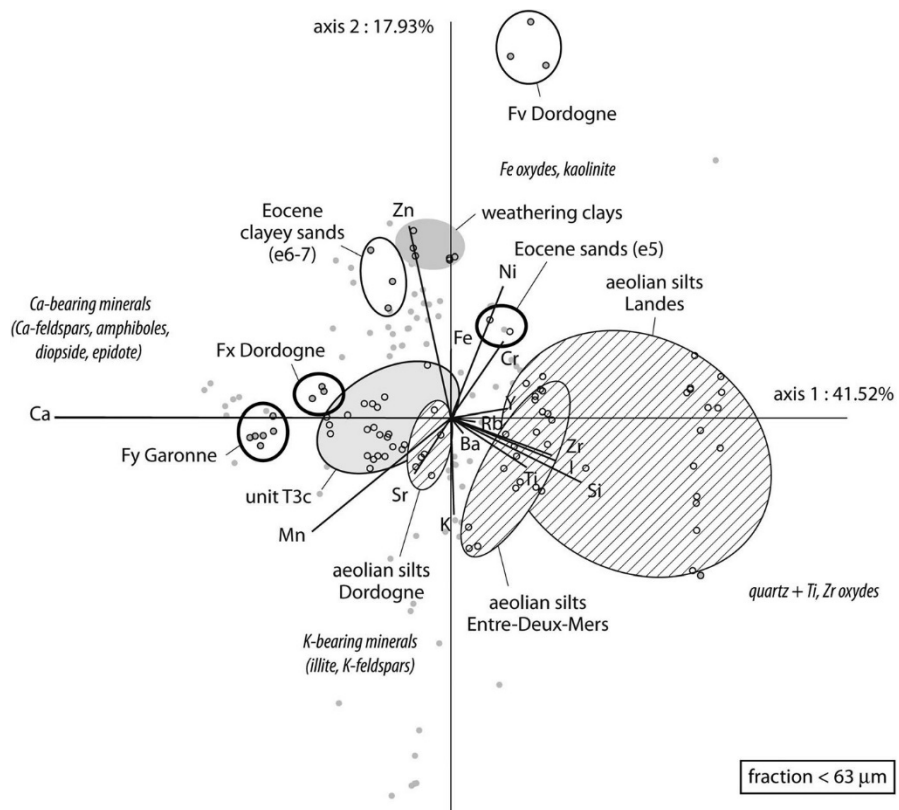

Figure 9. Biplot of the geochemical composition of various geological formations from Aquitaine, fraction <63mm.

Palaeosols

A pedocomplex typified by two superposed illuvial horizons was observed at Rue Brun at a depth of 2.2m in between the colluvial units T3b and c (supporting Fig. S5). The upper horizon (IIBthg) has a sandy silt texture and shows scattered black Fe–Mn coatings and concretions. In thin sections, clayey silt coatings stained brown by organic matter fill a porosity of biological origin (root and animal burrows) (Fig. 10). This palaeosol is interpreted as a greyzem (FAO-WRB, 2006), which suggests a boreal forest or forest-steppe context (Bronger, 1978; Miedema et al., 1999). The underlying IIIBtg horizon displays abundant Fe–Mn concretions and bleached degradation tongues. Under the microscope, it corresponds to a polyphased argillic horizon (Fig. 11). A first generation of thick, hydromorphic, light brown clay coatings is visible in the lower part of the horizon. The coatings are fragmented by frost and are covered by humic illuvial clay. This palaeosol has an interglacial rank and is similar to the Eemian–Early Glacial luvisol described elsewhere in France (Fe´doroff and Goldberg, 1982; Antoine, 2002; Loch et al., 2003).

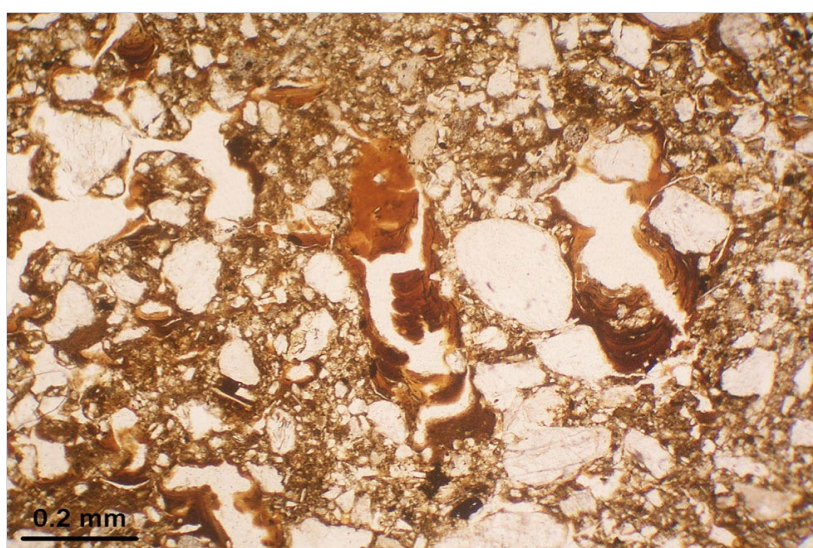

Figure 10. Humic clay coatings, horizon IIBth, thin section 1.

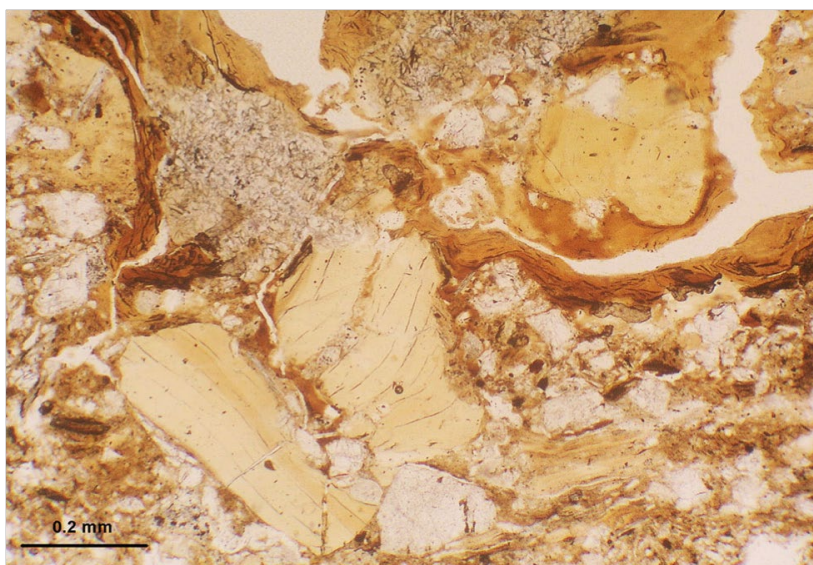

Figure 11. Light brown, microlaminated clay coatings fragmented by frost and overlain by humic clay coatings, horizon IIIBt, thin section 3.

Chronology

Twenty-six radiocarbon, OSL and IRSL age estimations were obtained during the archaeological surveys (Table 1). The main chronological information is as follows (Fig. 12):

1. The T3c colluvial fans yielded OSL/IRSL ages ranging between 38.8 (lower boundary at 68% probability) and 16.3 ka (upper boundary at 68% probability). Discoveries of Aurignacian (40–31 cal ka BP, Higham et al., 2011; Bradtmöller et al., 2012) and Magdalenian remains (20–14 cal ka BP, Langlais et al., 2012; Ducasse, 2012) are consistent with this age range. Fan sedimentation thus extended over Marine Isotopic Stage (MIS) 2 and late MIS 3 and is thought to reflect an increase in slope dynamics due to the installation of periglacial conditions in the region. The silt component of the deposits appears to come from distant aeolian inputs, connected with the development of coversands and associated peripheral loess during the Late Pleniglacial in the nearby Landes region (Bertran et al., 2011). Unit T3c is separated by a major unconformity from the underlying units, which remains undated. However, the interglacial ranking palaeoluvisol at the top of T3b, presumed to be Eemian – Early Glacial (MIS 5) in age, suggests that the units T3a and b belong to the Saalian (MIS 6).
2. The lateral accretion gravel unit and the associated sand deposits (T2b) yield IRSL ages contemporaneous with the Late Pleniglacial (MIS 2) and the Lateglacial (18.7–10.1 ka, 68%). For an unknown reason, the two IR-postIR dates on sand strata intercalated within gravels gave an age close to 8 ka at the Nauve site. In so far as the dated levels are unambiguously older than the gyttjas, these ages are considered unreliable (even when considering the 2s interval). At Gilets 2, the sandy point bar unit at the bottom of a T2c channel fill is dated between 12.2 and 10.6 ka (68%) and show that the channel was still active during the Preboreal chronozone, although flow power reduced significantly.
3. The radiocarbon ages obtained from the gyttjas are close to each other and contemporary with the Preboreal and Boreal chronozones (11.6–9.6 cal ka BP, 95% probability). It remains difficult to decide whether the age scatter for the samples taken at the bottom of the gyttjas reflect uncertainties due to sampling or actual differences in the beginning of organic sedimentation. As the samples were retrieved from distant sites, which obviously correspond to distinct fills (see location of Pre' Fagnoux, Gilets 1–2 and Reclausoux 1 in Fig. 1), these ages suggest that multiple coexisting channels were abandoned virtually simultaneously at the beginning of the Holocene. The channels were also affected by the formation of dolines presumably because of organic matter accumulation and consecutive acidification of the pools. These data indicate that the Lateglacial and the very early Holocene were typified by an anabranching fluvial style (Eaton et al., 2010), then that the river bed reduced to a single active channel during the course of the Preboreal period. Sandy silt overbank deposits plugged the abandoned channels and formed levees until about 5 cal ka BP. Then, vertical accretion of the floodplain became negligible during the rest of the Holocene.
4. The filling of a unique channel located on the northern edge of the Fx terrace yielded relatively recent ages, ranging between 2.8 and 0.7 cal ka BP (95%). This channel was taken by a small tributary of the Dordogne River and clearly recorded a complex history during the Holocene.

(2013); (D) inferred fluvial dynamics.

Discussion

The abundant data collected in a restricted area of the Dordogne valley near Bergerac bring to light the complexity of the internal architecture of the lower terraces and allow us to establish a detailed chronological framework of the fluvial evolution during the last glacial–interglacial transition period. The chronological data are more limited before MIS 2; nonetheless they enable us to address general issues and to evaluate the relevance of the available conceptual models for river terrace formation in the study area.

The Weichselian Late Pleniglacial was marked by a major change in fluvial drainage pattern, which shifted from a braided to an anabranching one. This change pre-dates the Pleniglacial–Bølling transition (i.e. 14.6 ka) by 2–3 millennia, supposedly in response to the development of vegetation and consecutive stabilization of the river banks (Huisink et al., 2002; Vandenberghe, 2003; Horn et al., 2012; Turner et al., 2013). A similar shift from braiding to meandering or anabranching has already been described for many other rivers from northern Europe (Antoine et al., 2003; Kasse et al., 2005; Erkens et al., 2011; Janssens et al., 2012), where it appears to have occurred significantly later and is thought to have coincided more tightly with the onset of the Bølling warming. This may

have resulted from the latitudinal difference between the areas under investigation and from the delayed development of vegetation in northern Europe following deglaciation.

The Late Pleniglacial and Lateglacial globally appear to have been characterized by multiple anabranches moving laterally on the alluvial plain. Increase in the cross-sectional area of the channels was not accompanied by any significant incision of the underlying limestone bedrock. The erosion of the Pleniglacial gravels primarily reflects adjustment of channel size to increase in mean discharge. Accordingly, data from speleothems (Genty et al., 2005) as well as pollen (Jost et al., 2005) show that mean annual precipitation was close to 300mm in south-west France during the Last Glacial Maximum i.e. about one-third of the current one, and raised stepwise to the present level during the Lateglacial and the early Holocene. Point bar accretion occurred following meander shifting and was accompanied by the formation of scroll bars. No evidence for channel abandonment and oxbow lake formation with clay or peat infilling has been found in the Fx terrace (possibly because of subsequent erosion), in contrast to the nearby Caudeau River, a small tributary of the Dordogne. The Brunetie`re site (Fig. 1), ca. 3km north-west from the study area, yielded a sequence of bedded clay and gyttja extending over the entire Bølling (Bertran et al., 2009), which may have formed in the context of a small lake due to meander cutoff or channel avulsion.

River shrinkage and abandonment of most of the channels occurred within the course of the Preboreal chronozone (sandy point bar formed until 10.6 ka) and organic sedimentation took place during the Boreal. As no coarsegrained channel deposits post-dating this period have been found in the Fx terrace, we presume that channel incision took place at this time. Since medieval archaeological finds in the Fz floodplain units obviously indicate that these were deposited very recently, it is assumed that bedrock erosion continued throughout the whole Holocene and entailed vertical deepening of the active channel bed into the Cretaceous limestone by 3–4m. Incision appears to be disconnected from the periods of change in drainage pattern but corresponds to a long phase of stability of the hydrological regime. The previous phase of significant bedrock incision separates the terraces Fx and Fw3 and remains poorly dated. The presence of an interglacial palaeoluvisol on unit T3b strongly suggests that the gravel unit T3a was deposited during MIS 6, in agreement with earlier proposals (e.g. Texier and Raynal, 1984). We therefore suppose that the incision between the terraces Fw3 and Fx, which is of similar amplitude to the Holocene one, took place during the Eemian interglacial *sensu lato* (MIS 5). Poor chronological resolution, however, does not allow rejection of alternative hypotheses, such as erosion at the beginning of the last glacial.

These data from the middle course of the Dordogne River only partially fit with the most acknowledged conceptual model proposed for terrace formation (see Vandenberghe, 2003, 2008, and Bridgland and Westaway, 2008 for discussion), which suggests that channel incision occurred essentially during short transitional climatic phases (cold towards temperate or inversely), whereas periods of stability were rather typified by vertical aggradation of the bed. Although channel deepening associated with a change in drainage pattern occurred in connection with the cold–warm Late Pleniglacial transition, the most significant phase of bedrock incision has continued throughout the Holocene. The river obviously kept its capacity to erode the limestone substrate during the whole Holocene in association with forest development on the catchment, low sediment delivery from hillslopes and increased mean discharge. Limestone dissolution may have played a non-negligible role in bedrock incision. Unlike in the lower reaches of the Dordogne River and seemingly because of a higher uplift rate, erosion was sufficiently important for the Pleniglacial–Lateglacial terrace to be beyond the reach of floods and for aggradation by overbank deposits to become insignificant after 5 ka.

By contrast, the data obtained on terrace Fx corroborate the hypothesis of substratum planation and bed widening during cold periods, as discussed by Lewin and Gibbard (2010). The large lateral development of the terrace seems to be a legacy from unit T2a emplacement, which was typified by braiding. This unit has not yet been dated; however, deposition pre-dates 18–17 ka and is assumed to have occurred during late MIS 3 and early MIS 2 in the context of a periglacial environment. An OSL age of 272 ka was obtained on an equivalent gravel unit from the nearby Isle valley and is in accordance with this hypothesis (Brenet et al., 2013). Widening of the bed during the course of the Late Pleniglacial resulted in the erosion of previous Weichselian alluvial deposits; subsequently, no Early Glacial to Middle Pleniglacial units have yet been clearly identified. Murton and Belshaw (2011) suggested that planation was linked to the development of permafrost and associated brecciation of bedrock due to ice segregation. In such context, bed widening rather than downcutting was favoured by thermokarstic erosion of the banks. Available chronological data for Pleistocene permafrost in Aquitaine (Guhl et al., 2012; Lenoble et al., 2012; Bertran et al., 2013) show that such a hypothesis remains plausible for the Dordogne River, even though it is located at relatively low latitude (45°N). OSL ages obtained from the aeolian fill of wedge structures around Bordeaux indicate that episodes of permafrost development occurred in Aquitaine between 36 and 23 ka. These episodes probably lasted for no longer than a millennium (Bertran and Fabre, 2005) but may have had a major influence on fluvial dynamics. Aggradation of the gravel bed then continued in a periglacial context but probably without permafrost until about 17 ka, in connection with intense mass wasting and overland flow on the hillslopes as testified by the emplacement of thick colluvial deposits on higher terraces (T3c unit). Large volumes of glacial debris may also have been supplied by headwater sources (Veyret, 1986).

Overall, the gravel material deposited during the end of the Late Pleniglacial and the Lateglacial represents a significant part of the volume of Fx in the investigated area, and older sand and gravel deposits are only preserved as isolated bodies in the terrace. Global attribution of the gravel sheet to the Weichselian Pleniglacial, as often proposed, appears thus to be erroneous.

Conclusions

The lower Dordogne terraces at Bergerac, south-west France, were studied in detail using cores, trenches, GPR profiles, and ¹⁴C and OSL/IRSL dating. The main results of this study are as follows:

1. The Fx terrace comprises two main architectural elements: (i) a dominantly horizontally bedded gravel unit deposited in a braided river, and (ii) gravel point bars that reflect lateral shifting of large anabranching channels. The first unit is Middle to Late Pleniglacial in age while the second corresponds to the Late Pleniglacial and Lateglacial. In terms of volume, the contribution of both units to the formation of the Fx terrace is broadly equivalent.
2. The most recent phase of bedrock incision occurred throughout the Holocene. This long phase of incision took place in a meandering river within densely vegetated landscape and seems to be out of phase with the periods of rapid reorganization of the channel pattern following climate changes.
3. The presence of an interglacial (Eemian–Early Glacial) palaeoluvisol above the Fw3 gravels indicates that this terrace formed before MIS 5. The phase of incision that separates Fx and Fw3 is of similar amplitude to the Holocene one and is tentatively correlated with MIS 5.

4. The lateral development of Fx was associated with channel braiding in a periglacial context. Bedrock planation and bank undercutting were triggered by permafrost development during late MIS 3 and early MIS 2. Vertical gravel aggradation was then promoted by large inputs of hillslope-derived debris probably in a seasonal frost context. Thick colluvial fans formed subsequently on the higher terraces. Braidplain abandonment and transition to an anabranching river took place during the Late Pleniglacial, around 18–17 ka.
5. The Lateglacial does not correspond to disruption of the fluvial regime. The Late Pleniglacial anabranches persisted throughout the Lateglacial. The channels were all abandoned more or less simultaneously during the Preboreal.
6. Until about 5 ka, the channels were filled by gyttjas then by sandy silt overbank deposits. After this time, floodplain accretion becomes insignificant. Tectonic uplift may explain why, unlike for other rivers in Europe (Pastre et al., 2001; Antoine et al., 2003; Macklin et al., 2010; Morin et al., 2010; Erkens et al., 2011), increased suspension load during the Holocene due to anthropogenic activities in the catchment did not lead to significant floodplain accretion during the last five millennia.
