31 **Abstract**

32 Groundwater discharge in coastal karst aquifers worldwide represents a substantial
33 part of the water budget and is a main pathway for nutrient transport to the sea.
34 Groundwater discharge to the sea manifests under different forms, making its assessment
35 very challenging particularly in highly heterogeneous coastal systems karst systems. In this
36 study, we present a methodology approach to identify and quantify four forms of
37 groundwater discharge in a mixed lithology system in southern Spain (Maro-Cerro Gordo)
38 that includes an ecologically protected coastal area comprised of karstic marble. We found
39 that groundwater discharge to the sea occurs via: (1) groundwater-fed creeks, (2) coastal
40 springs, (3) diffuse groundwater seepage through seabed sediments, and (4) submarine
41 springs. We used a multi-method approach combining tracer techniques (salinity, ^{224}Ra ,
42 and ^{222}Rn) and direct measurements (seepage meters and flowmeters) to evaluate the
43 discharge. Groundwater discharge via submarine springs was the most difficult to assess
44 due to their depth (up to 15 m) and extensive development of the springs conduits. We

45 determined that the total groundwater discharge over the 16 km of shoreline of the study
46 area was at least $11 \pm 3 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ for the four types of discharge assessed. Groundwater-
47 derived nitrate (NO_3^-) fluxes to coastal waters over ~3km (or 20%) in a highly populated
48 and farmed section of Maro-Cerro Gordo was $641 \pm 166 \text{ mol d}^{-1}$, or ~75% of the total NO_3^-
49 loading in the study area. We demonstrate in this study that a multi-method approach must
50 be applied to assess all forms of SGD and derived nutrient fluxes to the sea in highly
51 heterogeneous karst aquifer systems.

54 method approach.

55

56 **1 Introduction**

57 Coastal karst aquifers are 46% of the Mediterranean coastline, and play a key role in
58 regional socioeconomic, providing residents with essential water resources (Fleury et al., 2007;
59 Bakalowicz, 2015; Arfib and Charlier, 2016; Trezzi et al., 2017). Groundwater is often the only
60 available source as Mediterranean precipitation is scarce and sporadic, and often limited runoff
61 due to efficient infiltration and percolation through the karst aquifers (McCormack et al., 2014).

62 Typically, karstified carbonate aquifers are comprised of a complex set of fractures,
63 conduits, and cavities generating high spatial and temporal heterogeneity in groundwater flow
64 (Worthington, 1999; Bakalowicz et al., 2005; Barberá and Andreo, 2015). This in turn results in
65 challenging water resources management and attempts to develop water budgets and numerical
66 models describing karst systems often fail or result in estimates with large uncertainties
67 (Butscher and Huggenberger, 2007; Martínez -Santos and Andreu, 2010; Rapaglia et al., 2015).

68 When a karst system is hydraulically connected to the sea, a significant part of
69 groundwater can flow directly to the sea in different forms (Stringfield and Legrand, 1971;
70 Pinault et al., 2004; Custodio, 2010). Groundwater discharge to the sea can occur via submarine
71 springs (Fleury et al., 2007; Bakalowicz et al., 2008; Dimova et al., 2011) or subaerial coastal
72 springs near the shoreline (Aunay et al., 2003; Mejías et al., 2008; García-Solsona et al., 2010)
73 depending on the geologic structure (Bonacci and Roje-Bonacci, 1997; Benac et al., 2003;
74 Stamatis et al., 2011). Conduits and fractures buried under seabed sediments near the shoreline
75 can also produce diffuse groundwater seepage (e.g. Tovar-Sánchez et al., 2014; Rodellas et al.,
76 2012). Conversely, impervious strata can create enough hydraulic pressure for inland springs
77 whose runoff flows to the sea as groundwater-fed creeks without experiencing infiltration (e.g.
78 Yobbi, 1992; Katz et al., 2009). In this work, we will use the widely accepted term submarine

79 groundwater discharge (SGD) for the submerged forms of groundwater discharge to the sea as
80 defined by Burnett et al. (2003) and Moore (2010).

81 Groundwater discharge of unconsolidated sedimentary coastal aquifers has been
82 considered an insignificant component in water and nutrient budgets, mostly due to its relatively
83 small (<10%) volumetric contribution compared to surface water (Burnett and Dulaiova, 2003;
84 Moore 2010). However, in karst systems with limited runoff, SGD is a major component of the
85 coastal aquifer water and nutrient budget. Where excess of nutrients are delivered in coastal
86 systems, these produce ecological perturbations such as harmful algae blooms (e.g. Hallegraeff,
87 1993; Smith and Swarzenski, 2012), and seagrass habitat modification (e.g. Valiela et al., 1992)
88 to mention a few.

89 Coastal karst SGD can have very different composition due to the wide range of
90 groundwater residence time and complex pathways of the discharging waters (Weinstein et al.,
91 2011; Tovar-Sánchez et al., 2014; Trezzi et al., 2016). It is therefore necessary to apply a multi-
92 method approach to adequately identify and assess all forms of groundwater discharge when they
93 coexist.

94 A number of techniques have been developed to identify and estimate groundwater
95 discharge to coastal areas under different climatic conditions and geologic settings. For instance,
96 naturally occurring radon and radium isotopes are effective groundwater tracers of SGD (e.g.
97 Cable et al., 1996; García-Solsona et al., 2010; Rodellas et al., 2015; Dimova et al., 2015) as they
98 are chemically conservative and are typically a few orders of magnitude higher concentrations in
99 groundwater than surface waters, allowing for easy detection in receiving coastal waters (Burnett
100 et al., 2003). Furthermore, mass balance determination of radium and radon excess in near-shore
101 surface quantifies the magnitude of groundwater fluxes (Cable et al., 1996; Wong et al., 2013;

102 Tovar-Sánchez et al., 2014). Specifically, ^{222}Rn ($t_{1/2} = 3.8$ d) and ^{224}Ra ($t_{1/2} = 3.6$ d) which have
103 relatively short half-lives, and in the time-scale range of typical coastal mixing processes can be
104 used in combination to assess SGD (Moore, 1996; Cable et al., 1996; Burnett and Dulaiova,
105 2003).

106 Alternatively, in areas of faster groundwater flow regimes (e.g. karst and volcanic
107 systems), salinity (e.g. Knee et al., 2010; Stieglitz et al., 2010; García -Solsona et al., 2010;
108 Dimova et al., 2011) and thermal anomalies along the shoreline at the points of discharge are
109 proven to be good indicators of SGD (e.g. Pluhowski, 1972; Johnson et al., 2008; Peterson et al.,
110 2009; Mejías et al., 2012; Tamborski et al., 2015). In areas where permeable sediments are
111 present, direct measurements of SGD using seepage meters are used in parallel with radiotracer
112 techniques (Lee, 1977; Burnett et al., 2006; Sadat-Noori et al., 2015).

113 The mixed lithology Maro-Cerro Gordo coastal area is an example where identifying and
114 quantifying all components of groundwater discharge are critical to building a comprehensive
115 water budget that addresses adequately the existing economic and ecological demands of the
116 adjacent coastal communities and ecosystems. Land use includes intensive agriculture with 1.3
117 km² of greenhouses and additional surface tropical crops, in combination with accelerating
118 tourism in the area during the past decades. These land uses are increasingly satisfied by
119 groundwater extractions, in this case from the Sierra Almirajara-Alberquillas Aquifer (Andreo and
120 Carrasco, 1993), a highly fissured and karstified marble formation within the study site.

121 In order to assess the severity and impact of the increasing groundwater abstractions,
122 water managers require a comprehensive water budget for the area. The current water budget
123 based on a mass balance approach indicates total fresh water of $50 \times 10^6 \text{ m}^3 \text{ y}^{-1}$ for the Sierra
124 Almirajara-Alberquillas Aquifer (Castillo et al., 2001). This budget was suggested to be comprised

125 of: (1) inland springs and intermittent creeks ($32 \times 10^6 \text{ m}^3 \text{ y}^{-1}$), (2) extraction for irrigation and
126 consumption purposes ($12 \times 10^6 \text{ m}^3 \text{ y}^{-1}$), (3) water transfer to the Neogene-Quaternary coastal
127 formations, and the remaining part to (4) groundwater discharge to the sea ($6 \times 10^6 \text{ m}^3 \text{ y}^{-1}$). A
128 more recent water mass balance budget using the APLIS (A = altitude, P = slope, L = lithology, I
129 = infiltration landforms, S = soil type) method (Andreo et al., 2008) included an infiltration
130 coefficient of 40 - 45% and confirmed that the total budget of the Sierra Almirajara-Alberquillas
131 Aquifer is $50 \times 10^6 \text{ m}^3 \text{ y}^{-1}$ for 2003 – 2005, which were notably dry years (Pérez-Ramos and
132 Andreo, 2007). This assessment based on 2003-2005 data found a slightly higher natural
133 drainage through springs ($38 \times 10^6 \text{ m}^3 \text{ y}^{-1}$) and extraction ($15 \times 10^6 \text{ m}^3 \text{ y}^{-1}$) compared to the
134 estimate by Castillo et al. (2001), suggesting that groundwater discharge is negligible. However,
135 more recently SGD was found to be significant at $1 \times 10^6 \text{ m}^3 \text{ y}^{-1}$ in Maro-Cerro Gordo using a
136 combination of GIS-based approach, hydrometeorological methods, and preliminary ^{224}Ra
137 evaluations (Andreo et al., 2017).

138 In this study, we performed a comprehensive assessment of the total groundwater
139 discharge to the sea in the Maro-Cerro Gordo area through the application of a set of methods
140 selective to each form of discharge. We used a combination of radiotracers (^{222}Rn and ^{224}Ra) and
141 salinity mass balances, seepage meter measurements, and flowmeter measurements to: (1)
142 identify point discharges to the sea; and (2) quantify the total groundwater discharge from the
143 Sierra Almirajara-Alberquillas Aquifer to adjacent coastal waters. We further (3) estimated
144 groundwater-derived nitrate (NO_3^-) fluxes to the coastal waters of Maro-Cerro Gordo and
145 compared these NO_3^- fluxes in an ecologically protected area (with low anthropogenic activities)
146 to unprotected zones (with intense agriculture and overpopulation). The sampling campaigns
147 were conducted during base flow conditions to provide a conservative estimate of the total

148 groundwater discharge to the sea and nitrate fluxes of the Sierra Almijara-Alberquillas Aquifer
149 and Maro-Cerro Gordo coastal area. Finally, (4) we compared the applicability of each method to
150 assess the forms of groundwater discharge and made recommendations for applying this
151 approach to other karst aquifer systems worldwide.

152

153 **2 Study site and hydrogeological settings**

154 The study site, Maro-Cerro Gordo, is located along the coastal fringe between Nerja and
155 La Herradura in the easternmost section of the Malaga Province and part of the western Granada
156 Province (Southern Spain) along 16 km of shoreline (Fig. 1). Approximately 80% of the study
157 area is within the environmentally protected Maro-Cerro Gordo Natural Area, which comprises
158 3.58 km² and 14.31 km² of terrestrial and marine surface respectively. The area is characterized
159 by a typical Mediterranean climate with average annual precipitation of 500 mm y⁻¹ occurring
160 almost entirely during fall and winter (Andreo and Carrasco, 1993). We have divided the area in
161 three sections based on their predominant lithology and associated forms of discharge. From east
162 to west these are: (1) karst section, which includes the Cerro Gordo cape from Cañuelo Beach to
163 La Herradura; (2) schist section, confined between El Cañuelo Beach and Maro Beach; and (3)
164 conglomerate section, which comprises the area between Maro Beach and Nerja (city) (Fig. 1).

165

166 **Figure 1: Study site location and geological map showing water table contour lines (from**
167 **Pérez-Ramos and Andreo, 2007), groundwater flow direction, important wells and piezometers,**
168 **sampling points, and terrestrial springs. Groundwater discharge to the sea (TGD) is represented in**
169 **purple and is based on this study. Coastal springs are represented as CS, groundwater-fed creeks as**
170 **GC, diffuse groundwater seepage as GS, and submarine springs as SS. The study area is divided in**

171 **three sections: conglomerate section, schist section, and karst section. The distribution of seagrass**
172 **beds are based on Bañares-España et al. (2002), and Aranda and Otero (2014).**

173

174 **2.1 Alberquillas Aquifer Unit**

175 The main aquifer formation in the study area is the Alberquillas Aquifer Unit, a
176 telogenetic karst formation that underlines the southeast sector of the Sierra Almirajara Aquifer
177 unit and is comprised of highly fissured and karstified Triassic marble (Andreo and Carrasco,
178 1993). The lithology varies from dolomitic to calcitic marble over the 600 m maximum
179 thickness from basement to the surface (Andreo et al., 1993). In general, the primary porosity of
180 this unit is negligible and the degree of karstification is locally higher in the lower portion, with
181 the exception of Nerja Cave, which is a $3 \times 10^5 \text{ m}^3$ cavity located 158 m above sea level and 930
182 m from the shoreline (Durán, 1996; Andreo et al., 1993; Jordá et al., 2011).

183 The Alberquillas Aquifer Unit exhibits an elongated shape towards the southeast and a
184 total surface of 60 km^2 , and is directly in contact with the Mediterranean Sea only along the karst
185 section (Fig. 1). The two aquifer units (Alberquillas and Almirajara Aquifer units) are
186 hydraulically connected, constituting the Sierra Almirajara-Alberquillas Aquifer (142 km^2), which
187 recharges from local precipitation (Carrasco et al., 1998). Conceptual hydrogeological models
188 developed for the Sierra Almirajara-Alberquillas Aquifer suggest that groundwater generally flows
189 from north to south, and SGD occurs mainly in eastern Cerro Gordo (Andreo and Carrasco 1993;
190 Carrasco et al., 1998; Pérez-Ramos and Andreo, 2007).

191 The first attempt to locate SGD in Maro-Cerro Gordo was performed by Espejo et al.
192 (1988) via airborne infrared thermal (IRT) remote sensing. Two thermal anomalies were detected
193 during this survey, one in the Maro area (conglomerate section), and one in the vicinity of Cerro

194 Gordo and Cantarrijan (karst section); these were also confirmed by lower surface seawater
195 salinity (Espejo et al., 1988).

196 A cluster of three submarine caves with active springs (Cantarrijan Caves) were
197 identified at water depths of about 7 m near the Cantarrijan Beach (Fig. 1) during SCUBA diving
198 explorations in the karst section during this study. The vents of these springs are located at the
199 same depth and only 2 – 3 m away from each other. Thus, in our assessments the flux of these
200 three springs was treated as a single discharge point. We identified the vents of two additional
201 submarine springs at water depths of 12 m (Palomas Cave) and 15 m (Sifon Cave) in anchialine
202 caves with up to 10 m of horizontal development (Fig. 1). These caves, together with the three
203 small Cantarrijan Cave springs, represent the deep SGD of Sierra Almirajara-Alberquillas Aquifer
204 in the karst section. From SCUBA diving observations, we found that all three discharge points
205 are related to highly-developed karstic conduits at depth. We found during this study that they
206 were active even during droughts (Fig. 2), showing base flow conditions of Sierra Almirajara-
207 Alberquillas Aquifer water budget drainage.

208 **2.2 Schist formation**

209 Alberquillas Aquifer Unit is overlaying a concordant Paleozoic schist formation along
210 most of its extension and is tectonically in contact through a set of faults (Andreo et al., 1993).
211 Metamorphosed during the Alpine Orogeny it presents a maximum thickness of 500 m and very
212 low hydraulic conductivity (Andreo et al., 1993). Outcrops of the schist formation can be found
213 almost along the entire schist section (Fig. 1). The schist formation serves as a hydrogeological
214 barrier for SGD in this area (Andreo and Carrasco, 1993), and groundwater discharge to the sea
215 in this section manifests as four small-size creeks and one coastal spring. The four creeks
216 include: Tierras Nuevas Creek which emanates from a soil layer on the schist formation; the

217 Colmenarejos Creek which was dry over the sampling campaigns; Miel Creek which is of
218 particular interest as it is solely fed by permanently discharging springs located along the Sierra
219 Almirajara-Alberquillas Aquifer in the sea (Andreo and Carrasco, 1993). The Maro Stream was
220 observed to be produced by irrigation excess from abundant agriculture located nearby.

221 Lastly, the Alberquillas coastal spring, located 20 m from the shore at the Alberquillas
222 Beach at the contact between the highly permeable Alberquillas Aquifer Unit karstic marble and
223 impermeable schist, was found to have a perennial flow regime.

224 **2.3 Conglomerate, breccia, and travertine formations**

225 Pliocene conglomerate and breccia deposits with a maximum thickness of 60 m, form ~
226 90% of the conglomerate section of the study area, representing the second most important
227 permeable formation in the study site (Fourniguet, 1975; Andreo et al., 1993; Guerra-Merchán
228 and Serrano, 1993). This formation is comprised of marble fragments cemented by a red matrix,
229 showing signs of dissolution in the upper portion due to its calcite composition. Its hydraulic
230 conductivity permits limited groundwater flow mainly due to primary porosity and the slight
231 presence of fractures (Andreo and Carrasco, 1993). In the coastline comprised of this formation,
232 groundwater discharge can be identified visually as two coastal springs, the Doncellas and
233 Barranco Maro Spring and the groundwater-fed creek (Caleta Creek) which originates from a
234 spring located near the town of Maro (Fig. 1). On the easternmost sector of the conglomerate
235 section, south from the town of Maro, a 30 m thick highly porous and permeable quaternary
236 travertine is present in direct contact with the sea at Maro Cliff to the south (Jordá, 1988). The
237 two small coastal springs of Huerto Romero and Maro Beach are present in this formation along
238 with the intermittent groundwater-fed creek of Maro Creek. We have observed that excess water
239 from the Maro Spring located approximately 1 km to the north of Maro Cliff, flows as Maro

240 Creek and discharges to the sea from the travertine cliff as a waterfall that is intermittently active
241 depending on irrigation times. The Maro Sprig is well-known and it was included in the Sierra
242 Almirajara-Alberquillas Aquifer water budget, and it is utilized for drinking and irrigation
243 purposes (Liñán et al., 2000). The Sanguino Creek remained dry throughout this study.

244
245 **Figure 2: Average monthly precipitation and sea level change during 2010, 2015, and 2016. Error**
246 **bars show the monthly rainfall variability during this study. In December of 2015 slight**
247 **precipitation occurred only during the first week, however, abundant rainfall took place during**
248 **September-November. Sea level showed lower values during January-May and higher during**
249 **August-December. Sampling campaigns were conducted during May-July (dry periods) and**
250 **December (wet periods).**

251

252 **3 Methods**

253 Water fluxes to the sea from karstic submarine springs were quantified using (1) ^{224}Ra
254 and (2) salinity mass balances, groundwater seepage was quantified using both (3) a ^{222}Rn box
255 model mass balance and (4) seepage meter deployments in the locations where radon anomalies
256 were observed. Subaerial groundwater discharge from coastal springs and groundwater-fed
257 creeks was measured directly using a flowmeter (5).

258 **3.1 Tracer techniques**

259 **3.1.1 ^{224}Ra distribution and submarine springs discharge assessment**

260 A total of 38 discrete ^{224}Ra samples of 60 L each were collected in September of 2006
261 and 2010 to survey the schist and karst sections (Fig. 1). All seawater samples were collected at a
262 depth of 0.3 m, with the exception of SW- 7 and SW-21 that were collected at the submarine
263 springs at 8 m and 15 m respectively. Seawater (n = 30) and groundwater (n = 8) samples were

264 obtained using a submersible pump, and were later passed through a PVC column filled with
 265 about 25 g of MnO₂-coated-fibers (Mn-fibers) at a flow rate of approximately 1 L min⁻¹ to allow
 266 for a quantitative absorption of ²²⁴Ra (Moore, 1976; 2008). Mn-fibers were then transferred to
 267 the lab, rinsed with Ra-free water, and partially dried (Sun and Torgersen, 1998). Activities
 268 of ²²⁴Ra were measured using a Radium Delayed Coincidence Counter (RaDeCC) system
 269 (Moore and Arnold, 1996; García-Solsona et al., 2008). The Mn-fibers were counted twice, with
 270 the first time immediately after collection to assess the total ²²⁴Ra in the water, and a second time
 271 after a month to evaluate the supported ²²⁴Ra in equilibrium with ²²⁸Th. The excess of ²²⁴Ra was
 272 used to construct a ²²⁴Ra mass balance following Charette et al. (2001), which assumes that
 273 the ²²⁴Ra excess in coastal waters is the result of groundwater inputs (Eq. 1). This approach was
 274 applied to assess water fluxes (F_{SGD} , m³ d⁻¹) originated from the three submarine springs present
 275 in the karst section of the study site (Fig 1):

$$276 \quad F_{SGD} = \frac{(Ra_{sw} - Ra_{ow}) \times V}{t} + Ra_{sw} \times V \times \lambda \quad (1)$$

277 where Ra_{sw} is the ²²⁴Ra activity in coastal waters, i.e. the surface water end-member (dpm m⁻³);
 278 Ra_{ow} is the offshore ²²⁴Ra activity in open waters (dpm m⁻³); Ra_{SGD} is the activity of the
 279 groundwater end-member (dpm m⁻³); t is the coastal water residence time (d); V is the volume
 280 (m³) of coastal water affected by each submarine spring (SGD plume; and λ is the ²²⁴Ra decay
 281 constant (0.1894 d⁻¹).

282 Because this area is greatly exposed to prevailing west winds, large waves, and intensive
 283 mixing, we assumed that the residence time (t) of the water in this high energy coastline must be
 284 no more than one day. Thus, we used the one-day value in our mass balance model. The volume
 285 affected by SGD (V) was constrained using the surface area of the salinity anomaly created by
 286 the spring plume and corresponding water depths, obtained from the Andalusia Council of

287 Environment bathymetry database: <http://www.juntadeandalucia.es/medioambiente/site/rediam>.
288 To obtain the ^{224}Ra activity (Ra_{sw}) surface water end-member representative of the whole water
289 column, average values of water samples collected from the surface and at the depth of the
290 spring discharge were used.

291 **3.1.2 Salinity anomalies and submarine spring discharge evaluation**

292 To identify and quantify submarine springs discharge following the 1-meter isobath
293 parallel to the shoreline, three salinity boat surveys were performed in May, July, and December
294 of 2015 along the entire stretch of the studied coastline. Electrical conductivity (EC) and
295 temperature (T , °C) were measured continuously at a constant depth of 0.3 m with accuracies of
296 $\pm 20 \mu\text{S cm}^{-1}$ and $\pm 0.1^\circ\text{C}$ by towing a conductivity-temperature-depth sensor (CTD, Solinst[®])
297 from boat at a speed of about 2 km h^{-1} . Seawater salinity values were obtained from EC using the
298 conversion method 2520B (Standard Methods for the Examination of Water and Wastewater,
299 APHA, 1999). Data were recorded in 2 min intervals concurrently with precise GPS boat
300 positioning recorded in 30-sec intervals (Garmin Etrex[®] 20x) with an accuracy of $\pm 3 \text{ m}$.
301 Electrical conductivity and temperature of groundwater samples were measured using a Pro2030
302 (YSI Inc.) handheld instrument with accuracies of $\pm 1 \mu\text{S cm}^{-1}$, and $\pm 0.3^\circ\text{C}$. Before sampling,
303 the CTD sensor and handheld instrument (YSI) were calibrated using two conductivity solutions
304 (Oakton[®]): $1413 \mu\text{S cm}^{-1}$ and $12,880 \mu\text{S cm}^{-1}$, measured at 25°C . Temperature correction for EC
305 was automatically performed using linear compensations of $2\% \text{ }^\circ\text{C}^{-1}$ and $1.91\% \text{ }^\circ\text{C}^{-1}$ for the CTD
306 sensor and the handheld instrument respectively.

307 To compare data points from all surveys and identify consistent spatial salinity variations
308 (i.e. permanent groundwater fluxes) independent of seasonal fluctuations, salinity values from
309 each survey were normalized based on their total average. Salinity anomalies were defined as

310 positive when salinity is higher than average and negative when it is lower than the average
311 value.

312 A salinity mass balance based on the salinity anomalies generated by submarine springs
313 inputs was constructed to determine groundwater fluxes (F_{SGD} , $m^3 d^{-1}$) in the karst section using
314 Eq. 2 and following Crusius et al. (2005) and Knee et al. (2010). To calculate the fresh water
315 fraction of the spring discharge, we used the approach described in Knee et al. (2010), which
316 indirectly defines the groundwater salinity end-member (Sal_{SGD}) to be zero (Eq. 2):

$$317 \quad F_{SGD} = \frac{(Sal_{ow} - Sal_{sw}) \times V}{t \cdot Sal_{ow}} \quad (2)$$

318 where, Sal_{ow} and Sal_{sw} represent salinity values of open water and coastal surface waters. As in
319 Eq. 1, V is the volume of coastal water affected by SGD (m^3); and t is the coastal water residence
320 time (d). We used the same end-member values as in the ^{224}Ra mass balance. Note that this mass
321 balance assumes a groundwater salinity end-member (Sal_{SGD}) of zero in order to quantify only
322 the fresh component of SGD (Knee et al., 2010).

323 **3.1.3 ^{222}Rn surveys and groundwater seepage assessment**

324 Seawater ^{222}Rn concentrations were measured in surface coastal waters (at about 0.3 m
325 depth) in July, December of 2015, and July of 2016 along all sections using a RAD AQUA set
326 up (Durrige Co., Inc.) as described in Dulaiova et al. (2005) and further improved by Dimova et
327 al. (2009). To obtain radon-in-water concentrations, the measured radon-in-air was corrected
328 using the temperature-dependent Ostwald's solubility coefficient (Macintyre et al., 1995) (Eq. 3):

$$329 \quad \alpha = 0.105 + 0.405e^{(-0.05027 \times T)} \quad (3)$$

330 where T ($^{\circ}C$) is the water temperature, measured in 2 min intervals using a temperature data
331 logger (HOBO[®], Onset[®] Inc.). Analytical uncertainties of ^{222}Rn in water were most of the time
332 lower to 10%. The RAD AQUA system was run stationary for at least 20 min at the beginning of

333 all surveys to achieve water/air and radioactive equilibrium (Dimova et al., 2009), and set up to
334 measure in 10 min intervals while moving at boat speed of 2 km h⁻¹ to allow for detection of
335 rapid ²²²Rn changes. These data were coupled with GPS coordinates to be mapped later.

336 Diffuse groundwater seepage was quantified using a ²²²Rn mass balance (box model) as
337 described in Burnett and Dulaiova (2003) during July of 2015 and 2016, and December of 2016.
338 To evaluate diffuse groundwater seepage using a ²²²Rn mass balance (Eq. 4), ²²²Rn time-series (1
339 - 2 days long) were conducted in the Maro Cliff and Cantarrijan Beach seepage area. For this
340 study, this mass balance was modified to account for radon inputs to the sea from a small
341 groundwater-fed waterfall (Maro Creek) (Fig. 1). Radon fluxes (F_{GW}) (dpm m⁻² h⁻¹) from
342 groundwater discharge were determined using mass balance equation where total ²²²Rn inputs to
343 the water column are balanced by radon:

$$344 \quad F_{GW} = F_{Atm} + F_{Mix} - F_{Waterfall} - C_{Ra} - F_{Diff} \quad (4)$$

345 where F_{Atm} is the ²²²Rn atmospheric evasion fluxes through the water/air interphase; F_{Mix} are
346 mixing losses due to tidal variations and horizontal mixing; $F_{waterfall}$ are fluxes of ²²²Rn into the
347 system from a groundwater-fed waterfall present in Maro Cliff; C_{Ra} is the production of ²²²Rn
348 from ²²⁶Ra decay within the water column; and F_{Diff} is ²²²Rn diffusion flux from seabed
349 sediments.

350 To assess the contribution of ²²²Rn from Maro Creek the radon flux from the creek
351 ($F_{waterfall}$) was calculated by multiplying the average creek radon concentration by the water flux
352 which was based of flowmeter measurements and specific area of discharge. This correction was
353 only done during Creek flow regime. Corrections for the production of ²²²Rn from
354 dissolved ²²⁶Ra (i.e. supported radon) in coastal waters (C_{Ra}) were done utilizing the Mn-fiber
355 collected in September of 2006 (one sample) and in July of 2016 (two samples) in Maro Cliff

356 and Cantarrijan Beach at the time series stations. The average concentration (September 2006
 357 and July 2016) was applied in the ^{222}Rn mass balance. The procedure follows the technique
 358 described in details in (Charette et al., 2001). The ^{226}Ra equilibrated samples were counted via
 359 gamma spectrometry (HPGe well detector, Canberra GCW3522) using the ^{214}Pb peak at 352
 360 keV. Atmospheric evasion of ^{222}Rn (F_{Am}) was calculated based on the water/air interphase ^{222}Rn
 361 concentration gradient (dpm m^{-3}), ^{222}Rn Ostwald solubility coefficient, and ^{222}Rn gas transfer
 362 velocity (k , m h^{-1}). The gas transfer velocity (m h^{-1}) was calculated using Eq. 5 as described in
 363 Macintyre et al. (1995):

$$364 \quad k(600) = 0.45 \times u_{10}^{1.6} \left(\frac{S_c}{600} \right)^{-b} \quad (5)$$

365 where u_{10} is wind velocity at 10 m above sea level (m s^{-1}) acquired from an internet web service
 366 (<http://www.wunderground.com/>), S_c is the Schmidt number, and b is a factor that ranges from $\frac{1}{2}$
 367 ($u_{10} < 3.6 \text{ m s}^{-1}$) to $\frac{2}{3}$ ($u_{10} > 3.6 \text{ m s}^{-1}$).

368 During high wind conditions (July of 2015), we used Eq. 6 (all terms are defined in Eq.
 369 5) designed in Kremer et al. (2003) for shallow waters and a wide range of wind speeds
 370 (Cockenpot et al., 2015):

$$371 \quad k(600) = 1.65 \times e^{(u_{10})} \left(\frac{S_c}{600} \right)^{-b} \quad (6)$$

372 Molecular diffusion flux of ^{222}Rn from seabed sediments (F_{Diff}) was determined using the
 373 approach described in Martens et al. (1980).

374 After all corrections were made, negative fluxes were considered mixing losses (F_{Mix}).
 375 The pore water ^{222}Rn concentration and porosity of sediments were determined based on the
 376 procedure reported in Corbett et al. (1998). Groundwater seepage velocity (SGD , cm d^{-1}) was
 377 then calculated (Eq. 7) by dividing SGD -derived ^{222}Rn fluxes by the representative
 378 groundwater ^{222}Rn concentration end-member (Rn_{SGD} , dpm m^{-3}) (Burnett and Dulaiova, 2003).

379 The groundwater end-member (Rn_{SGD}) was assessed in groundwater collected from a
380 small cavity in the travertine cliff located 1 m a.s.l. in Maro Cliff, and GW-Well in Cantarrijan
381 Beach (Fig.1). Groundwater ^{222}Rn concentrations were analyzed with a RAD7 using a RAD H₂O
382 set up in duplicate 250 mL samples.

$$383 \quad \text{SGD} = \frac{F_{\text{GW}}}{Rn_{\text{SGD}}} \quad (7)$$

384 In order to calculate groundwater fluxes (F_{SGD} , m³ d⁻¹), the obtained seepage velocities
385 were multiplied by the total area through which SGD occurs using Eq. 8:

$$386 \quad F_{\text{SGD}} = \text{SGD} \times A \quad (8)$$

387 where SGD represents seepage velocity (cm d⁻¹), and A is the seepage area (m²). To constrain the
388 seepage area (A) at the beach face, we conducted a high-resolution ^{222}Rn survey by manually
389 moving a small boat at a speed of 15 m h⁻¹. For more precise results, during this survey, the RAD
390 AQUA system was let to equilibrate for 20 min every 2 - 10 m of shoreline. The high-
391 resolution ^{222}Rn survey data was mapped using a linear ordinary kriging interpolation method
392 (ArcGIS 10), each concentration interval was then contoured (using the ArcGIS 10 contour
393 spatial analyst) to obtain ^{222}Rn concentration isolines. The seepage area (A) was delineated by
394 creating a polygon that followed the 35×10^3 dpm m⁻³ isoline as a threshold in Maro Cliff and 6
395 $\times 10^3$ dpm m⁻³ in Cantarrijan Beach. The seepage area (m²) was obtained by calculating the
396 polygon geometry based on the ETRS 1989 UTM Zone 30N projected coordinate system.

397 **3.1.4 Fresh SGD assessment in diffuse seepage**

398 As defined by Taniguchi et al. (2002), diffuse groundwater seepage is comprised of two
399 components: (1) a fresh (meteoric) groundwater component and (2) a recirculated seawater
400 component. To calculate the fresh water component in seepage areas of the study site (e.g. in
401 Cantarrijan Beach), we applied a salinity mixing model (Eqs. 9 and 10) as described in

402 Taniguchi et al., (2005) and used by many others (e.g. Charette et al., 2007; Taniguchi et al.,
403 2008; Santos et al., 2009). The approach relies on two basic equations:

$$404 \quad f_{\text{FSGD}} + f_{\text{RSGD}} = 1 \quad (9)$$

$$405 \quad \text{Sal}_{\text{FSGD}} \times f_{\text{FSGD}} + \text{Sal}_{\text{RSGD}} \times f_{\text{RSGD}} = \text{Sal}_{\text{SGD}} \times f_{\text{SGD}} \quad (10)$$

406 where f_{FSGD} and f_{RSGD} represent the fresh and recirculated fractions of SGD, and Sal_{FSGD} and
407 Sal_{RSGD} are the salinity values measured in fresh groundwater (GW-Well) and maximum
408 recirculated salinity (GW-PZ-4).

409 **3.2 Direct groundwater flow measurements**

410 **3.2.1 Flowmeter measurements of coastal springs and creeks**

411 The location of coastal springs and inland springs feeding groundwater-fed creeks were
412 identified via field observations. The discharge from the identified coastal springs (Doncellas,
413 Barranco Maro, Huerto Romero, Maro Beach, and Alberquillas) and groundwater-fed creeks
414 (Caleta Creek, Tierras Nuevas Creek, and Miel Creek) entering the sea, were measured using a
415 flowmeter (OTT C2, OTT Hydromet GmbH) with an accuracy of $\pm 10\%$. Channel widths were
416 between 10 cm and 140 cm and depths were below 30 cm in all springs and creeks. Flow
417 velocity measurements at the average water depths were recorded in 10 cm intervals across the
418 stream cross section right before discharge into the sea. Water fluxes were calculated for each
419 interval multiplying width (10 cm) and depth by flow velocity. Total water flux ($\text{m}^3 \text{d}^{-1}$) was then
420 calculated by adding water fluxes in all intervals. To observe differences between dry and wet
421 periods measurements were conducted during July and December of 2016.

422 **3.2.2 Seepage meter measurements of diffuse seepage**

423 To verify ^{222}Rn -based SGD estimates, we deployed multiple seepage meters in July of
424 2016. Lee-type seepage meters, built following the procedure described in Lee (1977) were

425 deployed near the ^{222}Rn time series station in areas of active groundwater seepage (Maro Cliff
426 and Cantarrijan Beach) during July of 2016. Four seepage meters were deployed in Maro Cliff
427 and nine in Cantarrijan Beach to obtain a representative evaluation of the seepage area. These
428 were made of a bottomless 60 L plastic drum with an area of 0.12 m^2 with a plastic bag attached
429 to a two-way valve (Isiorho and Meyer, 1999; Schincariol and McNeil, 2002; Rosenberry, 2008).
430 The seepage meters were submerged and slowly inserted in the sediments leaving 2 cm of space
431 between the sediments and the drum interior top. The seepage meter was positioned inclined in
432 order to leave the valve side slightly higher allowing any gas to escape before plastic bag
433 attachment; the water volume entering the plastic bag and time elapsed were then recorded (Lee,
434 1977). Seepage velocities (SGD , cm d^{-1}) were calculated using Eq. 11 modified from Lee (1977):

$$435 \quad \text{SGD} = \frac{68.79 \times V}{t} \quad (11)$$

436 where V is volume of water entering the plastic bag (mL); t is the time elapsed (s), and 68.79 is a
437 unit conversion factor specific to the 0.12 m^2 flow area to obtain seepage velocity in cm d^{-1} .
438 Groundwater discharge ($\text{m}^3\text{ d}^{-1}$) was calculated using Eq. 8.

439 **3.3 Groundwater chemistry, stable isotopic composition, and NO_3^- fluxes**

440 During July and December of 2015, and in July of 2016 water stable isotopes ($\delta^2\text{H}$ and
441 $\delta^{18}\text{O}$), NO_3^- and SO_4^{2-} were measured in all points of groundwater discharge to the sea, Maro
442 Spring, and a well located in the conglomerate section (Nerja Cave) (Fig. 1). A total of 23
443 samples were collected in Maro Cliff and Cantarrijan Beach (GW-Well) ($n = 4$), all subaerial
444 coastal springs (Doncellas, Barranco Maro, Huerto Romero, Maro Beach, and Alberquillas, $n =$
445 14), and groundwater-fed creeks (Maro Creek and Miel Creek, $n = 5$) during all sampling
446 campaigns.

447 Water samples were collected for analysis in 150 mL bottles and stored at 4°C until
448 measurement, diluted to 1 mS cm⁻¹, and filtered before analysis. NO₃⁻ and SO₄²⁻ concentrations
449 were analyzed at the CEHIUMA (Center of Hydrogeology of the University of Malaga)
450 laboratory via ionic chromatography (Metrohm 881 Compact IC Pro) with an accuracy of ± 2%.
451 Water stable isotopes (δ²H and δ¹⁸O) were also analyzed at the CEHIUMA using a Laser Cavity
452 Ring-Down Spectrometer (Picarro CRDS L2120-i) with accuracies of ± 1‰ and ± 0.1‰ for δ²H
453 and δ¹⁸O respectively. Isotopic ratios were calculated using the Vienna Standard Mean Ocean
454 Water (VSMOW, in ‰). Nitrate fluxes ($F_{NO_3^-}$, mmol d⁻¹) to the sea were calculated by
455 multiplying NO₃⁻ concentrations at each point of discharge during each sampling campaign by
456 corresponding measured groundwater flux (Eq. 12):

$$457 \quad F_{NO_3^-} = F_{SGD} \times [NO_3^-] \quad (12)$$

458 where $[NO_3^-]$ represents nitrate concentrations (mmol m⁻³), and F_{SGD} is the groundwater flux
459 (m³ d⁻¹)

460

461 **4 Results**

462 **4.1 Detecting submarine spring discharge using ²²⁴Ra and salinity**

463 **4.1.1 ²²⁴Ra activities in seawater and groundwater**

464 During the ²²⁴Ra sampling campaign in September of 2010, the average ²²⁴Ra
465 concentrations in surface waters along the study area was 17 ± 2 dpm m⁻³ (n=30) ranging from
466 56 ± 4 dpm m⁻³ to 8 ± 1 dpm m⁻³ (Fig. 3; Supplementary material Table A.1). In general, ²²⁴Ra
467 values along the schist and karst sections of the study area were lower compared to other
468 Mediterranean regions (e.g. Moore, 2006; García-Solsona et al., 2010; Rodellas et al., 2014).
469 However, two distinctive ²²⁴Ra-high anomalies in coastal surface waters were identified during

470 this survey; these were associated with water inputs with average salinity of 0.8 from the
471 groundwater-fed Miel Creek (56 ± 4 dpm m^{-3}), and the three clustered submarine springs
472 discharging from Cantarrijan Caves (51 ± 4 dpm m^{-3}) located in the Cantarrijan area (Fig. 3).
473 Miel Creek (average salinity anomaly = 0.3), which flows through the marble formation of
474 Alberquillas Aquifer Unit for a total length of approximately 5 km, has a perennial flow, a firm
475 indication that it is fed by groundwater (Fig. 3). Indeed, a set of springs located predominantly in
476 the southernmost section of the Creek at the marble-schist contact have been observed to
477 maintain the constant creek flow regime all year long. The second peak of ^{224}Ra was located
478 right above the three submarine springs (Cantarrijan Caves) near Cantarrijan Beach.
479 Average ^{224}Ra values significantly higher (20 ± 7 dpm m^{-3}) than offshore background activity (8
480 ± 1 dpm m^{-3}) were detected also along the karst section from Cantarrijan to Cerro Gordo, where
481 Alberquillas Aquifer Unit is directly in contact with the sea (Fig. 3).

482

483 **Figure 3: Interpolated ^{224}Ra activity concentrations in September of 2010 along the schist and karst**
484 **sections. Two areas of high ^{224}Ra in coastal waters were identified in the schist section near**
485 **groundwater-fed Miel Creek (56 ± 4 dpm m^{-3}), and the three clustered submarine springs**
486 **discharging from Cantarrijan Caves (51 ± 4 dpm m^{-3}) located in the Cantarrijan area (karst**
487 **section).**

488

489 Radium-224 in groundwater in Cantarrijan Beach varied from 660 ± 30 dpm m^{-3} (salinity
490 anomaly = 1.6) in a shallow well (GW-Well, Supplementary material Table A.1) to 5500 ± 430
491 dpm m^{-3} (salinity = 31.1) in five piezometers installed on the shore (GW-Pz-1-5, Supplementary
492 material Table A.1). Activity of ^{224}Ra in groundwater collected from two wells in the karstic
493 marble (GW-CG-1 and GW-CG-2, Supplementary material Table A.1) showed similar activities,

494 $1260 \pm 90 \text{ dpm m}^{-3}$ and $1020 \pm 80 \text{ dpm m}^{-3}$ with salinities of 2.2 and 0.6 respectively. The
495 variation of ^{224}Ra concentrations in GW-Well and Pz-1-5 (Fig 5c) can be explained by the
496 seawater recirculation in the beach sediments. Radium concentration in fresh waters is very low
497 due to adsorption onto particles. However, in pore water with higher ionic strength (i.e. brackish
498 and salt water) radium desorbs due to cation exchange. This process increases dissolved ^{224}Ra
499 concentration (Webster et al., 1995).

500 **4.1.2 Salinity anomalies**

501 The average salinity in coastal waters of the study site during continuous measurements
502 in September of 2010 was 36.4 ± 0.2 , during May of 2015 was 36.6 ± 4.0 , in July 2015 was 37.2
503 ± 1.2 , and in December of 2015 was 34.5 ± 1.7 . A negative salinity anomaly of -1.2 to -1.7 was
504 observed during all sampling campaigns in the conglomerate section in the vicinity of multiple
505 coastal springs (Doncellas, Barranco Maro, Huerto Romero, and Maro Beach) and two
506 groundwater-fed creeks (Caleta Creek, and Tierras Nuevas Creek) (Fig. 4). However, in the
507 schist section where Alberquillas coastal spring enters the sea, salinity was generally similar to
508 the average throughout the coastline with a value of 36.3 in September of 2010, 37.1 in May of
509 2015, 37.1 in July of 2015, and 34.4 in December of 2015. Similarly, small salinity variation
510 (Fig. 4) associated with high ^{224}Ra (Fig. 3) was observed near the outlet of the groundwater-fed
511 Miel Creek.

512

513 **Figure 4: Salinity anomaly map showing combined results from May, July, and December of 2015.**
514 **Two areas of negative salinity anomalies were found in the conglomerate (salinity anomaly = -1.2 to**
515 **-1.7) and karst (salinity anomaly = -0.3 to -1.0) sections almost perfectly aligned with their**
516 **delineated extent.**

517

518 In the karst section (Fig. 1), where the karstic marble formation is in contact with the sea,
519 negative salinity anomalies (-0.3 to -1.0) coincided with previously observed high ^{224}Ra
520 concentrations in coastal waters near the Palomas and Sifon Caves submarine springs. The
521 largest salinity anomaly (-1.0) in the karst section was found in Cantarrijan Beach, which could
522 be related to Cantarrijan Caves springs. However, the lowest values are distributed along the
523 beach area, slightly deviated to the East off Cantarrijan Caves, where groundwater seepage
524 through marine sediments can, therefore, also be occurring.

525 **4.2 Evaluating submarine spring discharge using ^{224}Ra and salinity**

526 **4.2.1 ^{224}Ra mass balance**

527 To assess groundwater discharge in the areas of high ^{224}Ra ($12 - 51 \text{ dpm m}^{-3}$) and
528 negative salinity anomalies (-0.3 to -1.0), i.e. the areas of Cantarrijan Caves, Palomas Cave, and
529 Sifon Cave submarine springs (Figs. 2 and 3), we used a ^{224}Ra mass balance following Moore
530 (1996) and Charette et al. (2001; Eq.1). The main assumption in this approach is that the ^{224}Ra
531 excess in the karst section is considered to be originated solely by submarine springs.

532 SGD through Cantarrijan Caves was quantified using the ^{224}Ra coastal water end-member
533 measured in SW-6, SW-7, SW-13 and SW-24 ($Ra_{sw} = 25 \pm 2 \text{ dpm m}^{-3}$, $n = 4$), where SW-7 was
534 collected at the depth of discharge (8 m). Average offshore background activity ($8 \pm 1 \text{ dpm m}^{-3}$)
535 measured in SW-23, SW-27, SW-29, and SW-30 was used as the open water end-member (Ra_{ow})
536 (Supplementary material Table A.1). Groundwater samples collected from well GW-CG-1
537 (Fig.1), which is the closest well to the submarine springs and is representative of the marble
538 aquifer formation, was used as the groundwater end-member ($1260 \pm 90 \text{ dpm m}^{-3}$, salinity = 2.2).
539 Following the same approach, SGD was also evaluated in the area of Palomas Cave using SW-
540 SW-20, SW-21, and SW-25 ($Ra_{sw} = 18 \pm 2 \text{ dpm m}^{-3}$, $n = 3$), where SW-21 was collected at 15 m

541 depth of discharge. In Sifon Cave samples SW-14, SW-22, and SW-26 were used as the coastal
542 water end-member. The same open water (Ra_{ow}) and groundwater (Ra_{SGD}) end-members were
543 used: 1260 ± 90 dpm m^{-3} and 8 ± 1 dpm m^{-3} respectively (Fig. 3; Table 1).

544 The estimated groundwater fluxes (F_{SGD}) through Cantarrijan Caves was $4.7 \pm 0.5 \times$
545 10^3 m^3 d^{-1} , at Palomas cave was $4.3 \pm 0.5 \times 10^3$ m^3 d^{-1} , and for Sifon Cave was $3.7 \pm 0.4 \times 10^3$ m^3
546 d^{-1} . This represents a total flux of $12.8 \pm 1.4 \times 10^3$ m^3 d^{-1} via submarine springs, where reported
547 errors are based on analytical uncertainties of ^{224}Ra measurements.

548 **4.2.2 Salinity mass balance**

549 The salinity anomaly created by the Cantarrijan, Palomas, and Sifon Caves in the karst
550 section (Fig. 4, Table 1) allowed us to construct individual mas-balances at each location and
551 calculate SGD independently of the ^{224}Ra approach. Considering that the salinity of groundwater
552 discharge of these springs is the same value of the endmember used for the ^{224}Ra method (Table
553 1), and applying Eq. 2 we calculated a total groundwater flux of $0.8 \pm 0.1 \times 10^3$ m^3 d^{-1} in
554 Cantarrijan Caves, $0.9 \pm 0.1 \times 10^3$ m^3 d^{-1} in Palomas Cave, and $0.5 \pm 0.1 \times 10^3$ m^3 d^{-1} through
555 Sifon Cave; representing a total of $2.3 \pm 0.2 \times 10^3$ m^3 d^{-1} .

556 **4.3 Assessing diffuse groundwater seepage using a ^{222}Rn mass balance and seepage** 557 **meter measurements**

558 **4.3.1 ^{222}Rn distribution in seawater**

559 High ^{222}Rn concentrations were measured in two distinct areas in the Maro Cliff area
560 (conglomerate section) and Cantarrijan Beach (karst section) with maximum concentrations of
561 $44 \pm 3 \times 10^3$ dpm m^{-3} and $30 \pm 2 \times 10^3$ dpm m^{-3} respectively (Fig. 5). In general, along the
562 conglomerate section, ^{222}Rn activities were within background levels ($1.9 \pm 0.6 \times 10^3$ dpm m^{-3})
563 with the mentioned exception of a cove in the Maro Cliff area where the travertine formation is

564 in contact with the sea. In this location, a 15-m travertine cliff ends in coarse seabed sand
565 through which groundwater seepage was identified underlying a 1.5-m water column. In the
566 karst section, high ^{222}Rn was detected only along the Cantarrijan Beach where a steep ravine,
567 formed in the marble formation, ends in a big opening comprised of coarse sand, pebbles,
568 cobbles, and even boulders suggesting flash flooding events in the ravine after significant
569 precipitations.

570

571 **Figure 5: Radon-222 distribution map based on surveys during July and December of 2015, and**
572 **July of 2016. Two radon peaks were in found in Maro Cliff (conglomerate section) and Cantarrijan**
573 **Beach (karst section) with maximum concentrations of $44 \pm 3 \times 10^3 \text{ dpm m}^{-3}$ and $30 \pm 2 \times 10^3 \text{ dpm}$**
574 **m^{-3} respectively.**

575

576 **4.3.2 Groundwater discharge assessments in the conglomerate section (Maro** 577 **Cliff)**

578 Diffuse groundwater seepage was identified in this area during all ^{222}Rn surveys (July
579 and December of 2015, and July of 2016) suggesting the seepage is maintained by base
580 groundwater flow (Fig. 6a). We calculated that ^{222}Rn contribution from the waterfall (i.e.,
581 $F_{\text{Waterfall}}$) was on average $16 \pm 6 \text{ dpm m}^{-2} \text{ d}^{-1}$ (Table 2). To account for the production of ^{222}Rn
582 from ^{226}Ra dissolved in coastal waters (C_{Ra}), we used the averaged concentration ($280 \pm 50 \text{ dpm}$
583 m^{-3} , $n = 3$) measured in September of 2006 ($306 \pm 40 \text{ dpm m}^{-3}$, $n = 1$) and July of 2016 (260 ± 50
584 dpm m^{-3} , $n = 2$) at the time series station (Table 2, Fig. 6b). Atmospheric evasion (F_{Atm}) was
585 calculated using Eq 8 except in July of 2015, when wind speed was much higher (8 m s^{-1}) and we
586 used Eq. 6 instead. Diffusive flux of ^{222}Rn from seabed sediments (F_{Diff}) was $619 \pm 57 \text{ dpm m}^{-2}$
587 d^{-1} accounting for only 0.2 – 0.5% of total ^{222}Rn fluxes (Fig. 7). As one would expect in coastal

588 waters with little protection against wind and waves, mixing losses in this study represent the
589 main ^{222}Rn loss in the model (Fig. 7).

590
591 **Figure 6: (a) Groundwater seepage velocity averaging results from radon mass balance and seepage**
592 **meters in areas of diffuse seepage (Maro Cliff and Cantarrijan Beach). Radon distribution in (b)**
593 **Maro Cliff (conglomerate section) and (c) Cantarrijan Beach (karst section) where cylinder**
594 **symbols represent seepage meter locations and the star radon time series stations.**

595
596 The ^{222}Rn concentrations in groundwater end-members (Rn_{SGD}) were $350 \pm 50 \times 10^3$ dpm
597 m^{-3} , $440 \pm 60 \times 10^3$ dpm m^{-3} , and $320 \pm 30 \times 10^3$ dpm m^{-3} during July, December of 2015, and
598 July of 2016 respectively, with an average value of $370 \pm 50 \times 10^3$ dpm m^{-3} . Based on these
599 estimates (Table 2) and applying Eq. 4, we obtained average seepage velocities of 39 ± 10 cm d^{-1}
600 ($n = 43$) in July 2015, 40 ± 11 cm d^{-1} ($n = 78$) in December of 2015, and 38 ± 10 cm d^{-1} ($n = 90$)
601 during July of 2016. Reported SGD uncertainties are calculated based on ^{222}Rn variations from
602 all samples collected in the area to obtain the groundwater end-members (Rn_{SGD}) (Burnett et al.,
603 2007); which ranged from $320 \pm 30 \times 10^3$ dpm m^{-3} to $690 \pm 50 \times 10^3$ dpm m^{-3} ($n = 8$) during this
604 study.

605 Utilizing Eq. 8 we estimated total groundwater fluxes based on the ^{222}Rn box model to be
606 $3.0 \pm 0.8 \times 10^3$ $\text{m}^3 \text{d}^{-1}$ during July of 2015, $3.1 \pm 0.8 \times 10^3$ $\text{m}^3 \text{d}^{-1}$ in December of 2015, and $2.9 \pm$
607 0.7×10^3 $\text{m}^3 \text{d}^{-1}$ in July of 2016 (Table 2). Using Eq. 11 an average seepage velocity of 28 ± 6 cm
608 d^{-1} (Table 3) was calculated. This assessment is in good agreement with the average ^{222}Rn -based
609 value of 38 ± 10 cm d^{-1} . Using Eq. 8 and a seepage area of 7.7×10^3 m^2 based on the radon
610 concentration (Fig. 6b), we calculated a groundwater flux of $2.1 \pm 0.4 \times 10^3$ $\text{m}^3 \text{d}^{-1}$ in July of
611 2016 (Table 3).

4.3.3 Groundwater fluxes in the karst section (Cantarrijan Beach)

Multiple radon surveys in this area (July and December of 2015, and July of 2016) indicated a strong seasonality in seawater ^{222}Rn concentrations, with an average of $75 \pm 3 \times 10^3 \text{ dpm m}^{-3}$ in December and $11 \pm 2 \times 10^3 \text{ dpm m}^{-3}$ in July, suggesting higher SGD during the wet period. The average ^{226}Ra concentration (C_{Ra}) was $170 \pm 40 \text{ dpm m}^{-3}$ measured in September of 2006 ($169 \pm 30 \text{ dpm m}^{-3}$, $n = 1$) and July of 2016 ($170 \pm 40 \text{ dpm m}^{-3}$, $n = 2$) (Table 2). The variation of the groundwater ^{222}Rn end-member ($240 \pm 60 \times 10^3 \text{ dpm m}^{-3}$ to $350 \pm 40 \times 10^3 \text{ dpm m}^{-3}$, $n = 6$) was used to calculate the final groundwater discharge flux uncertainties. Seepage velocities in December and July were on average $52 \pm 8 \text{ cm d}^{-1}$ ($n = 61$) and $22 \pm 3 \text{ cm d}^{-1}$ ($n = 115$) respectively (Table 3).

We found that groundwater seepage occurs only in the westernmost sector at the end of the Cantarrijan Ravine (Fig. 6c). Seepage velocities, determined from all seepage meters deployed along the beach, show that groundwater seepage ceases exactly at the location where seepage meter SM-4 was deployed (Fig. 6c). We used this as a criterion to define the seepage face and decided to use the ^{222}Rn contour line of $6 \pm 1 \times 10^3 \text{ dpm m}^{-3}$ to calculate the seepage area, and averaged SM-1-4 to determine a seepage velocity of $23 \pm 7 \text{ cm d}^{-1}$. Using the ^{222}Rn method we found that the total diffuse groundwater seepage in the Cantarrijan Beach area ranged from $2.3 \pm 0.3 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ during the wet period to $0.9 \pm 0.1 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ during dry conditions; whereas seepage meter measurements resulted in $0.9 \pm 0.2 \times 10^3 \text{ m}^3 \text{ d}^{-1}$.

Figure 7: Radon fluxes result of each component of the mass balance box model during all sampling campaigns in Maro Cliff (conglomerate section) and Cantarrijan Beach (karst section). The largest tracer losses occurred via mixing due to the high exposure of both areas to waves and currents.

635 **Greater difference in SGD-²²²Rn fluxes was found between wet periods (December) and dry periods**
636 **(July) in Cantarrijan Beach compared to Maro Cliff.**

637
638 During all sampling campaigns, the groundwater sampled from the shallow well at Cantarrijan
639 Beach (GW-Well, Fig.1) always had salinity values of 1.6 – 3.2. During September of 2010,
640 salinities of 6.6 – 31.1 were also observed in pore water samples collected in all five piezometers
641 installed on the beach (GW-PZ-1-5, Fig 1). Based on the salinity mixing model (using Eqs. 9 and
642 10) we calculated that the fresh fraction of SGD at this site was 48% of the total groundwater
643 seepage. Therefore, when constructing the Sierra Almirajara-Alberquillas Aquifer freshwater water
644 budget for July of 2016, only $0.4 \pm 0.1 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ (representative of the 48% freshwater
645 component) should be taken into account.

646 **4.4 Groundwater contribution from coastal springs and groundwater-fed creeks**

647 Groundwater discharge to the sea during dry conditions calculated using flowmeter
648 measurements in July of 2016 from coastal spring Huerto Romero was $37 \pm 3 \text{ m}^3 \text{ d}^{-1}$, from Maro
649 Beach was $26 \pm 2 \text{ m}^3 \text{ d}^{-1}$, from Barranco Maro was $17 \pm 1 \text{ m}^3 \text{ d}^{-1}$, from Doncellas was 460 ± 40
650 $\text{m}^3 \text{ d}^{-1}$, and from Alberquillas was $1060 \pm 90 \text{ m}^3 \text{ d}^{-1}$ (Supplementary material Table A.2). The
651 discharge from groundwater-fed creek Miel Creek was $1230 \pm 110 \text{ m}^3 \text{ d}^{-1}$, from Caleta Creek 160
652 $\pm 10 \text{ m}^3 \text{ d}^{-1}$, and from Tierras Nuevas Creek was $110 \pm 10 \text{ m}^3 \text{ d}^{-1}$. The total discharge from all
653 creeks was $3100 \pm 280 \text{ m}^3 \text{ d}^{-1}$; which represents 33% of the total groundwater discharge in the
654 study area.

655 In December of 2016, during high flow conditions, discharge from coastal springs Huerto
656 Romero was $100 \pm 9 \text{ m}^3 \text{ d}^{-1}$, from Maro Beach was $43 \pm 4 \text{ m}^3 \text{ d}^{-1}$, from Barranco Maro was 69 ± 6
657 $\text{m}^3 \text{ d}^{-1}$, from Doncellas was $530 \pm 50 \text{ m}^3 \text{ d}^{-1}$, and from Alberquillas was $1590 \pm 140 \text{ m}^3 \text{ d}^{-1}$.
658 Discharge via groundwater-fed Miel Creek was $1820 \pm 160 \text{ m}^3 \text{ d}^{-1}$, from Caleta Creek was $220 \pm$

659 $20 \text{ m}^3 \text{ d}^{-1}$, and from Tierras Nuevas Creek was $190 \pm 20 \text{ m}^3 \text{ d}^{-1}$; which constitutes $4580 \pm 60 \text{ m}^3$
660 d^{-1} or 37% of the total discharge in the study area (Supplementary material Table A.2).

661
662 **4.5 Groundwater isotopic composition, water chemistry, and nitrate fluxes** Isotopic
663 values are widely scattered along a linear trend (Local Groundwater Line, LGL) with a slope of
664 6.06, with averages of -42‰ and -7.1‰ for $\delta^2\text{H}$ and $\delta^{18}\text{O}$ respectively (Figs. 8a and 8b). All
665 samples fall between the Global Meteoric Water Line (GMWL; Craig, 1961) and the Western
666 Mediterranean Meteoric Water Line (WMMWL; Gat and Garmi, 1970), samples collected in or
667 derived from Maro Spring are situated slightly above the WMMWL. Deuterium values ranged
668 from $-33 \pm 1\text{‰}$ to $-46 \pm 1\text{‰}$, while $\delta^{18}\text{O}$ were between $-5.6 \pm 0.1\text{‰}$ and $-7.8 \pm 0.1\text{‰}$
669 (Supplementary material Table A.2). We observed that groundwater collected from Maro Spring
670 (conglomerate section) has the lightest isotopic signature of -46‰ and -7.7‰ for $\delta^2\text{H}$ and $\delta^{18}\text{O}$
671 respectively. Samples collected in the conglomerate section from coastal springs Barranco Maro,
672 Huerto Romero, Maro Beach, and groundwater-fed Maro Creek showed values that ranged from
673 -45 and -7.6 to -43‰ and -7.2‰. At the point of seepage discharge in the sea, Maro Cliff showed
674 slightly higher values of -44‰ and -7.4‰ for $\delta^2\text{H}$ and $\delta^{18}\text{O}$. Coastal springs Doncellas,
675 Alberquillas, and groundwater-fed Miel Creek all located in the schist section, are grouped
676 together with Nerja Cave (conglomerate section), showing average values of -33‰ and -5.5‰
677 for $\delta^2\text{H}$ and $\delta^{18}\text{O}$. Samples collected from GW-Well (Cantarrijan Beach), have the highest values
678 in the study area with averages of -22‰ and -3.8‰ for $\delta^2\text{H}$ and $\delta^{18}\text{O}$.

679
680 **Figure 8: (a) Isotopic composition ($\delta^{18}\text{O}$, $\delta^2\text{H}$) of water samples collected during all sampling**
681 **campaigns. Local Groundwater Line (LGL) represents the linear trend based on all groundwater**
682 **samples collected in the study area. Global Meteoric Water Line (GMWL) is based on Craig, (1961)**

683 **and the Western Mediterranean Meteoric Water Line (WMMWL) on Gat and Garmi, (1970).**
684 **White color represents points of discharge in conglomerate and breccia lithology, while light grey**
685 **are in travertine (conglomerate section); dark grey shows points in schist (schist section); and black**
686 **color show locations in karstic marble (karst section). Maro Spring and Nerja Cave well (not points**
687 **of discharge to the sea) are represented with a black and white star respectively. Water samples**
688 **collected at each section (conglomerate section, schist section, and karst section) are grouped in**
689 **dashed squares. (b) Isotopic composition of samples collected from points of discharge from the**
690 **travertine formation in the conglomerate section. The two groundwater end-members (Maro**
691 **Spring and irrigation waters) are circled, while diffuse seepage in Maro Cliff is represented with**
692 **squares.**

693
694 Groundwater sulphate (SO_4^{2-}) concentrations ranged from $500 \pm 10 \text{ mmol m}^{-3}$ in
695 Alberquillas coastal spring to $3220 \pm 64 \text{ mmol m}^{-3}$ in Cantarrijan Beach ($n = 23$)
696 (Supplementary material Table A.2). Samples collected in the conglomerate section from coastal
697 springs Doncellas, Barranco Maro, Huerto Romero, Maro Beach; groundwater-fed Maro Creek,
698 and diffuse seepage in Maro Cliff had similar SO_4^{2-} concentrations ranging between 1500 and
699 3000 mmol m^{-3} . All samples (including Maro Spring) collected from Sierra Almirajara
700 Alberquillas Aquifer in this area fall within a SO_4^{2-} concentration range of $1700 - 2600 \text{ mmol m}^{-3}$.
701 Miel Creek and coastal spring Alberquillas (schist section) showed lower values ranging from
702 500 ± 10 to $710 \pm 14 \text{ mmol m}^{-3}$. Water collected in Cantarrijan Beach had the highest
703 concentration in the study area, with an average of $3030 \pm 60 \text{ mmol m}^{-3}$ (Supplementary material
704 Table A.2).

705 Nitrate (NO_3^-) concentrations were highest in coastal springs of the conglomerate section
706 including Doncellas, Barranco Maro, Huerto Romero, and Maro Beach with an average of $446 \pm$

707 50 mmol m⁻³ (n = 6). Water samples that were directly derived from Maro Spring (Maro spring,
708 Maro Creek) and did not experience infiltration (i.e. had no fertilizer added), showed NO₃⁻
709 concentration of 5 – 21 mmol m⁻³. NO₃⁻ concentrations in diffuse groundwater seepage in Maro
710 Cliff were consistently near 130 ± 3 mmol m⁻³ (n = 2). Samples collected in the schist section
711 from groundwater-fed Miel Creek and coastal spring Alberquillas, and in the karst section from
712 Cantarrijan Beach, showed levels of NO₃⁻ ranging from 55 mmol m⁻³ in Miel Creek to 168 mmol
713 m⁻³ in Cantarrijan Beach (n = 5) (Supplementary material Table A.2).

714 Nitrate fluxes were unevenly distributed in the three sections of the study site (Table 4).
715 The combination of high NO₃⁻ in coastal springs and high flow groundwater seepage results in
716 NO₃⁻ fluxes in the conglomerate section of 550 ± 140 mol d⁻¹ and 730 ± 190 mol d⁻¹. During this
717 study, NO₃⁻ fluxes in the schist and karst section together were 150 ± 20 mol d⁻¹ during dry and
718 250 ± 40 mol d⁻¹ during wet periods (Table 4).

719

720 **5 Discussion**

721 **5.1 Method selection and assessment of each form of groundwater discharge to the** 722 **sea**

723 *Submarine springs:* Quantifying submarine springs discharge in the karst section was
724 found to be the most difficult part of this study. None of the data collected during the three ²²²Rn
725 boat surveys along the coastline showed tracer anomalies in the areas of submarine spring
726 discharge (Fig. 5). However, we were able to detect ²²⁴Ra and salinity anomalies produced by the
727 three submarine springs discharging from Cantarrijan, Palomas, and Sifon Caves (Fig. 3 and 4).
728 Concentrations of ²²⁴Ra were on average four times higher (20 ± 7 dpm m⁻³, n = 10) compared to
729 offshore waters (8 ± 1 dpm m⁻³, n = 4) in locations where no ²²²Rn signal was detected.

730 Considering that ^{224}Ra and ^{222}Rn have similar half-lives and experience similar mixing,
731 we hypothesize that the lower ^{222}Rn concentrations in coastal waters of the karst section must be
732 due to degassing. Similar effects on dissolved ^{222}Rn and ^{224}Ra have been observed in coastal
733 waters by Dulaiova and Burnett (2006) and Stieglitz et al. (2010). As found in this study site,
734 both studies showed a strong correlation between ^{222}Rn concentration and salinity or ^{222}Rn
735 and ^{224}Ra , trends that are consistent with a ^{222}Rn deficiency due to atmospheric evasion (Stieglitz
736 et al, 2010). Furthermore, when combining the ^{222}Rn concentration data with salinity anomalies
737 from all boat surveys along the entire shoreline, we observe that ^{222}Rn concentrations decrease at
738 a faster rate than salinity when closer to the groundwater source (Fig. 9a, b). If wind conditions
739 are constant during the surveys (which there were), following the 1st Fick's Law, degassing due
740 to molecular diffusion through the water-atmosphere interphase must be enhanced when
741 seawater ^{222}Rn concentration is higher (the concentration gradient is higher). Thus, this effect is
742 most likely created because the water column-atmosphere concentration gradient in areas close
743 to the groundwater source is at its highest, favoring atmospheric evasion.

744

745 **Figure 9: Mixing plots of ^{224}Ra (a) and ^{222}Rn versus salinity (b) showing best fit linear and**
746 **exponential mixing lines, respectively, during surface water surveys along the coastline in**
747 **September of 2010, July and December of 2015.**

748

749 Based on these findings, we concluded that ^{224}Ra (Eq. 1) and salinity (Eq. 2) mass
750 balances are the two methods better suited to evaluate groundwater discharge from submarine
751 springs of the ones utilized in this study. However, we found a significant difference between the
752 springs discharge assessments obtained using these two tracers; the flux based on the ^{224}Ra mass
753 balance was $12.8 \pm 1.4 \times 10^3 \text{ m}^3 \text{ d}^{-1}$, whereas using the salinity mass balance we calculated a

754 discharge of $2.3 \pm 0.2 \times 10^3 \text{ m}^3 \text{ d}^{-1}$. We suggest that the difference could be explained by
755 selection of the end-member in the mixing model, which has been previously described by others
756 as a factor in correct determination of groundwater discharge (e.g. Peterson et al., 2008; Moore,
757 1996; Cerdà-Domènech et al., 2017). A critical component in any tracer study is the selection of
758 a representative groundwater end-member (Ra_{SGD} and Sal_{SGD}) collected at the point of discharge.

759 All submarine springs described here are located in submarine caves (Cantarrijan,
760 Palomas, and Sifon Caves) with vents parallel to the surface (i.e. horizontal geometry) at depths
761 of 8 – 15 m below sea level. The springs discharge occurs parallel to the land surface at about 5 –
762 10 m landward from the caves entrance. SCUBA diving to the springs vents for representative
763 groundwater/spring water end-member was challenging, thus the presented estimates of spring
764 discharge are based on groundwater from the closest located well (GW-CG-1, Fig. 1) with
765 a ^{224}Ra concentration of $1260 \pm 90 \text{ dpm m}^{-3}$ and salinity of 2.2 ± 0.1 .

766 Because springs conduits are subject to seawater intrusion, we suggest that the salinity of
767 the discharging spring water could be slightly to significantly higher than groundwater salinity
768 sampled from the inland well (GW-CG-1) which we used as the groundwater end-member
769 (Ra_{SGD} and Sal_{SGD}). While in fresh water, radium is mostly attached to particles and its dissolved
770 concentration is very low, in brackish spring water radium would be mostly dissolved and we
771 would have observed higher ^{224}Ra in the end-member waters (Burnett et al., 2006; Cerdà-
772 Domènech et al., 2017). Based on the correlation between salinity and ^{224}Ra desorption, a
773 salinity increase of 5 to the groundwater end-member (GW-CG-1) would produce an
774 extrapolated ^{224}Ra increase of 60 dpm m^{-3} , resulting in a decrease spring flux of about 65%,
775 which is closer to the salinity mass balance estimation. A salinity of 5 in submarine springs
776 seems reasonable as it is similar to those found by García-Solsona et al. (2010) in a coastal karst

777 aquifer in eastern Spain, where annual average salinity of outflowing brackish submarine springs
778 was 6.8. Furthermore, in well GW-CG-1 located 500 m inland from the submarine springs in the
779 karstic marble, a salinity value of 2.2 was measured, also indicating that a value of 5 was
780 plausible.

781 The salinity mass balance method estimates only the fresh water fraction of the spring
782 discharge. In this way, the difference in discharge estimation using a ^{224}Ra and a salinity mass
783 balance is found because the ^{224}Ra method estimates the total (brackish) discharge, while the
784 salinity method accounts only for the fresh portion. Therefore, only the spring discharge based
785 on the salinity model should be used in the water budget of Sierra Almirajara-Alberquillas Aquifer.

786 *Diffuse groundwater seepage through seabed sediments:* In contrast to the case of
787 submarine spring discharge, we found that groundwater seepage through seabed sediments
788 (Maro Cliff, conglomerate section; and Cantarrijan Beach, karst section) was most adequately
789 detectable using ^{222}Rn as a tracer and direct measurements (i.e. seepage meters). The
790 observed ^{222}Rn concentrations in receiving surface waters were as high as $44 \pm 3 \times 10^3 \text{ dpm m}^{-3}$
791 at both groundwater seepage areas, i.e. Maro Cliff and Cantarrijan Beach (Fig. 4).

792 Although, we also observed high ^{224}Ra concentrations in samples collected near
793 Cantarrijan Beach (Fig. 3), these were associated with nearby discharge from the Cantarrijan
794 Caves submarine spring (Fig. 3, sampling points SW-6, SW-7, and SW-13). Indeed, during one
795 of the dry period sampling events (July of 2016), we did not detect any ^{224}Rn in coastal waters of
796 Cantarrijan Beach giving us confidence that the previously observed signals (September 2010)
797 were from the springs and not from the diffuse seepage. For the same reason, salinity could not
798 be used as a tracer in either of the seepage areas (Maro Cliff and Cantarrijan Beach) because

799 salinity anomalies were also created mostly by nearby coastal and submarine springs
800 respectively, overwhelming the salinity signal that is only due to diffuse seepage.

801 In this complex scenario, ^{222}Rn was the only groundwater tracer able to uniquely identify
802 diffuse groundwater seepage to the sea and a ^{222}Rn mass balance was thus used to quantify
803 groundwater seepage fluxes. Based on this mass balance in the Maro Cliff area, we calculated a
804 discharge of $2.9 \pm 0.8 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ (Table 2), whereas using seepage meter deployments ($n = 4$)
805 the discharge was $2.1 \pm 0.4 \times 10^3 \text{ m}^3 \text{ d}^{-1}$. In the Cantarrijan Beach we found very similar seepage
806 flux estimates using the ^{222}Rn approach ($0.9 \pm 0.1 \times 10^3 \text{ m}^3 \text{ d}^{-1}$) and using seepage meters ($0.8 \pm$
807 $0.2 \times 10^3 \text{ m}^3 \text{ d}^{-1}$) with a total of 9 deployments (Table 2). While the two methods agree very well,
808 we recommend using the ^{222}Rn method over seepage meters. The main advantages of the ^{222}Rn
809 technique are (1) fully automatic data collection with very little field efforts, (2) temporal and
810 spatially integrated SGD estimates, which allow capturing small hydraulic conductivity
811 variations over large areas of diffuse seepage (Burnett et al., 2001).

812 *Subaerial forms of groundwater discharge to the sea (coastal springs and groundwater-*
813 *fed creeks):* Coastal springs, and creeks that are primarily groundwater sustained, were only
814 present at the conglomerate and schist sections of the study site that are comprised of
815 conglomerate and schist, where permeabilities are lower than in the marble formation (karst
816 section). During boat surveys ^{222}Rn activity levels in coastal waters of these two sections were
817 always within background offshore values ($1.0 \pm 0.2 \times 10^3 \text{ dpm m}^{-3}$, Fig. 5) even at the points of
818 coastal springs and groundwater-fed creeks discharge that were visually identified. We attributed
819 the observed low ^{222}Rn concentrations to degassing and radioactive decay during groundwater
820 transit from land to the ocean. For instance, ^{222}Rn concentration at the point of the groundwater-
821 fed Maro Creek origin (Maro Spring, $250 \pm 90 \text{ dpm m}^{-3}$) was significantly higher than at the

822 point of the Creek entrance to the sea (Maro Creek 3, 16 ± 7 dpm m^{-3}) (Fig. 1; Supplementary
823 material Table A.2). However, we were able to find groundwater signature of the Miel Creek and
824 the Alberquillas coastal spring in coastal waters of the schist section using ^{224}Ra concentration
825 anomalies; radium was 56 ± 4 dpm m^{-3} and 12 ± 2 dpm m^{-3} respectively at their point of entry to
826 the sea (Fig. 1). While coastal springs were easily located visually, additional field efforts were
827 usually required to determine whether the creeks were solely fed by groundwater inputs from the
828 karst aquifer in order to be considered (or not) in the total groundwater budget of Sierra
829 Almirajara-Alberquillas Aquifer.

830 *Total groundwater discharge to Maro-Cerro Gordo coastal area:* Combining all
831 groundwater fluxes to the sea in Maro-Cerro Gordo, we estimate a daily groundwater discharge
832 that ranged between $9 \pm 2 \times 10^3$ m^3 d^{-1} during dry periods and $12 \pm 3 \times 10^3$ m^3 d^{-1} during wet
833 periods, with an average of $11 \pm 3 \times 10^3$ m^3 d^{-1} . This combined discharge is composed of: 3.6 –
834 4.0×10^3 m^3 d^{-1} in the conglomerate section, $2.4 - 3.6 \times 10^3$ m^3 d^{-1} in the schist section, and $3.3 -$
835 4.7×10^3 m^3 d^{-1} in the karst section (Supplementary material Table A.2). As described above,
836 differences in the geologic settings in each section, have defined the form of groundwater flow to
837 the sea (Fig. 10, Table 4).

838

839 **Figure 10: Total groundwater discharge (TGD) in the study area divided in forms of discharge (GS:**
840 **groundwater diffuse seepage, CS: coastal springs, GC: groundwater-fed creeks, SS: submarine**
841 **springs), showing maximum and minimum flux during wet and dry periods.**

842

843 In the conglomerate section, most of the groundwater flow takes place preferentially
844 through the travertine formation as groundwater seepage and it is 25 - 31% of the total discharge
845 in the study area, whereas small coastal springs dispersed along the section contribute to 5 – 6%,

846 and groundwater-fed creeks for 1 – 2%. The ubiquitous presence of a schist formation in the
847 schist section impedes direct submarine flow and groundwater discharge converges in two
848 points: groundwater-fed Miel Creek, and Alberquillas coastal spring which account for 25 – 30%
849 of the total discharge. In the karst section, where Sierra Almirajara-Alberquillas Aquifer is in direct
850 connection with the sea, SGD takes place as groundwater seepage through marine sediments in
851 Cantarrijan Beach assessed to account for 10 - 18%. Karstic submarine springs in Cantarrijan
852 Caves, Palomas Cave, and Sifon Cave represent 19 - 25% of the total groundwater discharge to
853 the sea.

854 **5.2 Complexity of Sierra Almirajara-Alberquillas karst aquifer hydrodynamics**

855 The large spatial variations in the different forms of groundwater discharge in this coastal
856 karst aquifer were also reflected in the seasonal variability of discharge during contrasting
857 periods (Fig. 2). For instance, in Maro Cliff (conglomerate section, Fig. 1) we expected higher
858 seepage rates in December during the wet period (Fig. 2). However, the discharge estimations for
859 the dry period (July) and the wet period (December) were statistically identical: groundwater
860 seepage in Maro Cliff during the dry period was $2.9 \pm 0.8 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ and $3.0 \pm 0.8 \times 10^3 \text{ m}^3 \text{ d}^{-1}$
861 during the wet period.

862 There are two hypotheses that attempt to explain the observed lack of seasonal variation
863 of groundwater discharge in Maro Cliff. The first hypothesis suggests that the observed steady
864 flow is maintained by continuous infiltration of agricultural irrigation water used by the adjacent
865 greenhouse fields. A second hypothesis, proposed by Espejo et al. (1988) and Castillo et al.
866 (2001) suggests that the surplus of groundwater that maintains the base flow during the dry
867 season originates from the Sierra Almirajara-Alberquillas Aquifer. The authors propose that
868 groundwater is transferred from the Sierra Almirajara-Alberquillas Aquifer to the coast through the

869 adjacent conglomerate unit and travertines near the small town of Maro. These two
870 hydrogeologic units are indeed in immediate contact with the sea (Fig. 1). To test both hypotheses
871 we used two common geochemical approaches.

872 We first differentiated between heavier isotopic ($\delta^2\text{H}$ and $\delta^{18}\text{O}$) compositions (more
873 positive values), associated with evaporation processes or mixing with seawater (Gat, 1971). The
874 isotopic composition of groundwater collected from Maro Spring (i.e. in the conglomerate
875 section) showed the most negative values (-46‰, -7.7‰) on the local groundwater line (LWL) in
876 this area (Fig. 8b). These values correspond to the composition of deep groundwater flow in
877 Sierra Almirajara-Alberquillas Aquifer (Liñán et al., 2000). Groundwater seepage in Maro Cliff
878 presents average isotopic values (-44‰ and -7.4‰) that are similar but slightly higher than Maro
879 Spring, suggesting that water transfer from the marble formation is a plausible option.

880 To differentiate between irrigation water and water transferred from the Sierra Almirajara-
881 Alberquillas Aquifer to the travertines, the water stable isotopes end-members have to be very
882 different than the deep/spring groundwater which has a negative composition compared to more
883 positive values of evaporated irrigation water. We know that the water used for irrigation is
884 withdrawn by farmers from Maro Spring. However, once extracted and in contact with the
885 atmosphere, the water isotopic composition changes to more positive isotopic values. We also
886 found that the collected spring water utilized for irrigation is typically stored in holding tanks
887 and used when needed. During this holding time and in the process of irrigation, the water
888 experiences further evaporation, and as a result, it should result in even more positive isotopic
889 signature such as the waters of the coastal spring Barranco Maro (up to -43 and -7.3). The
890 isotopic signature of irrigation water is thus, very different from the original Maro Spring water,
891 allowing us to define a two-end-member system where coastal spring Huerto Romero represents

892 the most evaporated irrigation water (Fig. 8b). Based on a mixing model using these end-
893 members we found that seeping groundwater at Maro Cliff is indeed composed mostly from
894 infiltrating irrigation water. We also found that the ratio of Maro Spring water to irrigation
895 changes depending on the season with highest percentage (up to 82%) of irrigation water during
896 the dry period compared to the wet period (74%).

897 To further confirm these finding, we utilized water quality parameters, such as sulfate
898 (SO_4^{2-}) and nitrate (NO_3^-) concentrations, to differentiate between these two water sources.
899 Infiltrated irrigation water should have much higher NO_3^- concentrations and constant SO_4^{2-} ,
900 whereas deep groundwater should natural concentrations of NO_3^- . Thus, NO_3^- content can be
901 used as an indication of irrigation origin. The isotopic composition of Sierra Almirajara-
902 Alberquillas Aquifer in this area fall within a narrow SO_4^{2-} concentration range (1700 – 2600
903 mmol m^{-3}) (Fig. 11), being naturally high in Maro Spring groundwater (Liñán et al., 2000).
904 When plotting SO_4^{2-} and NO_3^- concentrations in water, all water samples derived from Maro
905 Spring before infiltration showed low NO_3^- concentration (5 – 21 mmol m^{-3}) and naturally high
906 levels of SO_4^{2-} (Fig. 11). All samples collected from coastal springs that discharge to the sea
907 (Doncellas, Barranco Maro, Huerto Romero, and Maro Beach coastal springs), showed levels of
908 SO_4^{2-} typical of Sierra Almirajara-Alberquillas Aquifer and high levels of NO_3^- (more than 350
909 mmol m^{-3}) indicating fertilizer inputs. On the other hand, samples collected at the area of
910 seepage through seabed sediments in the Maro Cliff, showed NO_3^- concentrations (130 mmol m^{-3})
911 3) that are closer to the observed background levels of Sierra Almirajara-Alberquillas groundwater
912 representative (5 – 21 mmol m^{-3}) than to the contaminated infiltrated water (Fig. 11).

913

914 **Figure 11: Groundwater ionic relationship between NO_3^- and SO_4^{2-} where groundwater samples**
915 **with similar composition are grouped in dashed squares. Symbols are presented as in Fig. 8 based**

916 **on the section and lithology they are located. In the conglomerate section Maro Spring, Nerja Cave,**
917 **and Maro Creek show similar SO_4^{2-} concentration with low NO_3^- , while Doncellas, Barranco Maro,**
918 **Huerto Romero, and Maro Beach present NO_3^- contamination. Samples from the schist section**
919 **(Miel and Alberquillas) present a distinctive signal with low NO_3^- and SO_4^{2-} concentrations.**
920 **Groundwater collected in Cantarrijan Beach (karst section) shows seawater influence from**
921 **saltwater recirculation in beach sediments. Arrows indicate the geochemical change before**
922 **irrigation and after fertilizers application (NO_3^-), where Maro cliff (diffuse seepage) shows mixing**
923 **between both groups.**

924

925 Therefore, we are confident that groundwater seepage to the sea observed and quantified
926 in Maro Cliff is mostly generated as a result of infiltrated irrigation water. We found uniform
927 groundwater flux (independently of rainfall) in this area throughout the year (Fig. 6a) supporting
928 this hypothesis. Irrigation occurs constantly throughout the year, and infiltration through the
929 highly porous travertine constitutes a constant source of water that flows towards the coast and
930 ultimately discharges into the sea as groundwater seepage. Irrigation water from greenhouse
931 farming is collected from the Maro Spring and thus SGD in the Maro Cliff should not be added
932 to the total budget of the aquifer system as it has been already accounted as groundwater from
933 Maro Spring on land. This is a significant new finding and should be considered when compiling
934 the total water budget of the Sierra Almirajara-Alberquillas Aquifer.

935 In contrast to the groundwater seepage dynamics in Maro Cliff (conglomerate section),
936 the seepage rates in the Cantarrijan Beach (karst section) were seasonally modulated; the
937 groundwater flux that the Cantarrijan Beach area received in the dry period was $0.9 \pm 0.1 \times$
938 $10^3 \text{ m}^3 \text{ d}^{-1}$ which was half of its wet period discharge ($2.3 \pm 0.3 \times 10^3 \text{ m}^3 \text{ d}^{-1}$). Differences in
939 aquifer recharge and sea level variations between the dry and wet periods have control on the

940 magnitude of SGD (Carrasco et al, 1998; Santos et al., 2009). During dry periods precipitation
941 was absent for up to two months, decreasing the recharge from infiltrated meteoric water in
942 Sierra Almirajara-Alberquillas Aquifer. Although during December of 2015 the area did not
943 receive any rainfall, rain events occurred during September-November contributed to the
944 recharge of Sierra Almirajara-Alberquillas Aquifer, deriving in higher seepage fluxes in
945 Cantarrijan Beach (Fig. 2). Additionally, the mean sea level measured during 2010-2016 near the
946 study area (Permanent Service for Mean Sea Level,
947 <http://www.psmsl.org/data/obtaining/stations/1940.php>) showed seasonal fluctuations, with
948 lower sea levels during January-May compared to higher levels during August-December (Fig.
949 2). The observed moderate increase of 15 cm during the dry periods has contributed to the
950 observed higher salinity of groundwater in Cantarrijan Beach, as well as the overall lower
951 groundwater seepage rates during the dry periods.

952 Based on the salinity mixing model (Eqs. 9 and 10), we calculated that the fresh fraction
953 of SGD was 48% of the total groundwater seepage, which means that during July of 2016, only
954 $0.4 \pm 0.1 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ should be taken into account as part of the Sierra Almirajara-Alberquillas
955 Aquifer water budget.

956 The salinity gradient observed from GW-Well to GW-Pz-4 is an indication that there is
957 saltwater recirculation in the beach sediments and with the ^{222}Rn approach we have captured
958 both the fresh and recirculated SGD (Fig. 6c). We did not repeat these measurements during the
959 wet period, but we can hypothesize that this percentage was very similar based on the salinity
960 measured in GW-Well during December of 2015 (Supplementary material Table A.2).

961 **5.3 Importance of groundwater discharge for the water budget of Sierra Almirajara-**
962 **Alberquillas Aquifer and nitrate loading to Maro-Cerro Gordo coastal area**

963 To estimate the portion of the annual fresh groundwater discharge to the sea from Sierra
964 Almirajara-Alberquillas Aquifer water budget, we extrapolated average daily fluxes to obtain an
965 annual range for the wet and dry periods (Table 4). During this study, we found that the total
966 groundwater discharge to the sea was $1.9 \pm 0.5 \times 10^6 \text{ m}^3 \text{ y}^{-1}$ during the dry period, and $2.6 \pm 0.8 \times$
967 $10^6 \text{ m}^3 \text{ y}^{-1}$ wet period (Table 4). Based on Pérez-Ramos and Andreo (2007) and Castillo et al.
968 (2001) the total annual groundwater budget of the Sierra Almirajara-Alberquillas Aquifer is $50 \times$
969 $10^6 \text{ m}^3 \text{ y}^{-1}$, and thus the flux we estimated represents 4 - 5% of the water resources of this karst
970 system. This is a conservative estimate and should be considered as groundwater flow at base
971 conditions because sampling campaigns were purposely not conducted after big rain events (Fig.
972 2).

973 In these calculations, we do not account for groundwater seepage in Maro Cliff
974 (conglomerate section), coastal springs Doncellas, Barranco Maro, Huerto Romero, and Maro
975 Beach, and groundwater-fed Tierras Nuevas Creek as they are originated from irrigation water
976 that has been already accounted as outputs from Maro Spring.

977 Based on the groundwater discharge to the sea, NO_3^- fluxes per unit of shore length in the
978 conglomerate section were $205 \pm 90 \text{ mmol m}^{-1} \text{ d}^{-1}$, while the schist and karst sections together
979 receive between $15 \pm 3 \text{ mmol m}^{-1} \text{ d}^{-1}$ on average. When normalized by shore length, NO_3^-
980 discharge in the conglomerate section is $3.5 \text{ mmol m}^{-2} \text{ d}^{-1}$, which compared to other
981 anthropogenically impacted sites of coastal karst aquifers in the Mediterranean, is very similar.
982 For example, García-Solsona et al. (2010) estimated a nitrate flux of $8.3 - 1.5 \text{ mmol m}^{-2} \text{ d}^{-1}$ in
983 eastern Spain, and Rodellas et al. (2014) found $0.97 \text{ mmol m}^{-2} \text{ d}^{-1}$ in Majorca Island (Balearic
984 Islands), whereas in a site in Menorca Island the flux was $18 \text{ mmol m}^{-2} \text{ d}^{-1}$ (García-Solsona et al.,
985 2010b). It is important to note that while it only represents 20% (or 3 km) of the total shoreline

986 length (16 km), the conglomerate section receives about 75% of the total NO_3^- delivered to
987 Maro-Cerro Gordo coastal waters (Supplementary material Table A.2).

988 Since 1989 the Maro-Cerro Gordo Natural Area (schist and karst sections), has been
989 protected due to the presence of endemic and endangered flora and fauna by the Council of
990 Environment of Andalusia. The European Commission designated the area as a Special
991 Protection Area (SPA), Specially Protected Area of Mediterranean Importance (SPAMI), Site of
992 Community Importance (SCI), and Special Area of Conservation (SAC) (Aranda and Otero,
993 2014). Specifically, the conservation area hosts three species of marine phanerogams (*Zostera*
994 *marina*, *Posidonia oceanica*, and *Cymodocea nodosa*), included in the IUCN Red List of
995 Threatened Species. Seagrass provides a unique habitat for a wide range of species (Hughes et
996 al., 2009); including the largest bivalve in the Mediterranean *Pinna nobilis* (Theodorou et al.,
997 2015), endangered fish *Epinephelus marginatus* (Gallego et al., 2015), and marine turtle *Caretta*
998 *caretta* (Tomas et al., 2001) among others. As other studies have demonstrated, nitrate surplus
999 loading often alters the primary producers community (Rapport and Whitford, 1999), and fast
1000 growing micro and macroalgae can proliferate preventing seagrasses *Zostera marina* and
1001 *Posidonia oceanica* from having enough sunlight and space (Hauxwell et al., 2001; Deegan et
1002 al., 2002). For example, Valiela et al. (2002) demonstrated that seagrass production could
1003 decrease up to 90% when nitrogen inputs are higher than $500 \text{ kg N ha}^{-1} \text{ y}^{-1}$. Only in the
1004 groundwater seepage area of Maro Cliff we have found that nitrogen fluxes (as nitrate) was
1005 about $2500 \text{ kg N ha}^{-1} \text{ y}^{-1}$, which is five times higher than the Valiela et al.'s assessment and
1006 should be a major concern for the ecological status of the marine system in the conglomerate
1007 section (Fig. 1). However, to further understand the implications of nutrients fluxes to the sea on

1008 the marine ecosystem (particularly on endemic seagrass and fauna), additional investigation in
1009 the area must be conducted.

1010 **5.4 Sensitivity analysis of methods applied**

1011 To further compare the applicability of methodologies utilized in the presented multi-
1012 method approach, we constructed a sensitivity analysis including each method's main
1013 assumptions.

1014 **5.4.1 Parameter sensitivity of ^{224}Ra and salinity mass balance methods for** 1015 **determining discharge of submarine springs**

1016 Three terms represent the major source of uncertainty in the ^{224}Ra and salinity mass
1017 balances we used to calculate submarine spring discharge, including (1) the residence time of the
1018 receiving coastal waters (t), (2) the volume of the SGD plume (V), and (3) the uncertainty in the
1019 determination of groundwater end-member (Ra_{SGD}) (Table 5).

1020 The largest uncertainty in this model is given by the assumption of a one day residence
1021 time (t). A common technique for assessing water ages of coastal waters is based on short-lived
1022 radium isotopes, ^{223}Ra and ^{224}Ra (Moore, 2000). However, during this study we could not
1023 measure both radium isotopes and we were unable to apply this method. The karst section of
1024 Maro-Cerro Gordo displays rocky cliff areas spread across the geographically exposed to
1025 prevailing west winds coastline which reflects the influence of high energy waves. The karst
1026 aquifer has very high secondary porosity and permeability which provides the opportunity for
1027 extensive groundwater-surface water exchange. The estimate of a one day residence time for this
1028 study is based on a comparison to similar high-energy coastal environments that are typical for
1029 the Mediterranean coastline. Under similar hydrogeological conditions in eastern Spain, using
1030 the methodology presented in Moore (2000), García-Solsona et al. (2010) assessed residence

1031 time (t) between 1.1 d and 2.7 d, whereas Tovar-Sánchez et al. (2014) found residence times of
1032 1.7, and 1.2 days in three coves in a karst system in the eastern shore of the Majorca Island.
1033 Considering these studies and specifics of this study site, we suggest using residence times of
1034 0.25, 0.5, 1.0, and 3.0 days in the sensitivity analysis.

1035 To determine the volume ($V = \text{plume area} \times \text{depth}$) of the SGD plume, we used areas of
1036 salinity sea surface anomalies created by the submarine springs discharge at Maro-Cerro Gordo.
1037 Specifically, we utilized salinity anomalies of -0.3, 0.0, 0.3, and 0.6 isolines. For vertical scale
1038 we use water depths acquired from the bathymetry database of the Andalusia Council of
1039 Environment (<http://www.juntadeandalucia.es/medioambiente/site/rediam>) assuming a well-
1040 mixed water column. However, Garcia-Solsona et al. (2010) found in eastern Spain that although
1041 complete mixing in the water column could be found near the karst springs vents, the salinity
1042 anomaly measured in surface waters was limited to the 0.5 m upper most layer. Similar settings
1043 are possible in Maro-Cerro Gordo; thus, we also calculated V based on the 0.0 salinity anomaly
1044 isoline and considering a depth of 0.5 m (Table 5)

1045 There are only two groundwater wells in the karst section of Maro-Cerro Gordo, (GW-
1046 CG-1 and GW-CG-2). For the sensitivity analysis we used ^{224}Ra concentration in GW-CG-1
1047 ($1260 \pm 90 \text{ dpm m}^{-3}$) and GW-CG-2 ($1020 \pm 80 \text{ dpm m}^{-3}$) as end-members, both sampled in
1048 September of 2006.

1049 After tabulating these parameters, both the ^{224}Ra and salinity mass balance models
1050 showed the highest sensitivity to variations in the volume affected by SGD (V). We found that
1051 the total discharge from submarine springs decreases by 80% when using salinity isolines of 0.6
1052 to -0.3 in a well-mixed water column; however, if the fresh plume is limited to the 0.5 m top
1053 layer of the water column, the decrease is up to 97%. Residence time (t) was the second most

1054 important variable affecting the variability of discharge from submarine springs, increasing by
1055 92% when changing the residence time from 0.25 to 3.0 days (Table 5). The ^{224}Ra mass balance
1056 showed limited sensitivity to varying groundwater end-member values (Ra_{SGD}), when using the
1057 GW-CG-2 value instead of GW-CG-1, all estimations increased only by 20%. The maximum
1058 variation utilizing the three variables simultaneously in the ^{224}Ra mass balance was 100% with a
1059 total discharge of $0.2 - 90.5 \times 10^3 \text{ m}^3 \text{ d}^{-1}$. The salinity mass balance presented a total variation of
1060 100% to changing t and V , with a total discharge of $0.03 - 13.5 \times 10^3 \text{ m}^3 \text{ d}^{-1}$, which represents
1061 the purely fresh discharge (Table 5).

1062 **5.4.2 Parameter sensitivity of the ^{222}Rn mass balance and seepage meters** 1063 **measurements in determining diffuse seepage**

1064 In the ^{222}Rn model, we considered that only the seepage area (A) could be subject to
1065 ambiguity because all terms in the model (including the groundwater end-member) have been
1066 carefully measured. To delineate the size of the seepage face we used the following ^{222}Rn
1067 concentration isolines: for the Cantarrijan Beach we used the 10, 8, 6, and 5 dpm m^{-3} , while in
1068 Maro Cliff we used the 25, 30, 35, and 45 dpm m^{-3} (Table 5). For comparison reasons, were used
1069 the same seepage areas to calculate SGD when using the seepage meters approach. Using the 25
1070 $\times 10^3 \text{ dpm m}^{-3}$ ^{222}Rn concentration isoline in Maro Cliff produces 86% higher for both dry and
1071 wet periods, compared to seepage area based on the $45 \times 10^3 \text{ dpm m}^{-3}$ isoline. The discharge
1072 ranged from $0.9 - 6.7 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ and $0.9 - 7.5 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ during dry and wet periods
1073 respectively. In Cantarrijan Beach we found an increase of 82%, with a discharge estimation that
1074 ranged between $0.2 - 1.2 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ and $0.5 - 2.9 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ during dry and wet periods. The
1075 radon method showed higher sensitivity (89%) than the seepage meter assessments (87%) (Table
1076 5).

1077 **5.4.3 Implications for the water budget of Sierra Almirajara-Alberquillas**

1078 **Aquifer**

1079 Using the presented ranges of fluxes of each methodology, we calculated a total
1080 groundwater discharge to the sea of $4.3 - 105.1 \times 10^3 \text{ m}^3 \text{ d}^{-1}$ from all forms of discharge (Table
1081 6). The fresh water component of the total discharge can be obtained from the salinity mass
1082 balance in submarine springs, ^{222}Rn mass balance and seepage meters for diffuse seepage in
1083 Cantarrijan Beach (47% fresh, based on the salinity mixing model), Caleta and Miel Creeks, and
1084 Alberquillas Spring (see sections 5.2 and 5.3). Applying a residence time of 0.25 d, the lowest
1085 estimated volumes affected by the SGD plume (V) at each submarine spring ($0.2 \times 10^5 \text{ m}^3$, 0.18
1086 $\times 10^5 \text{ m}^3$, $0.19 \times 10^5 \text{ m}^3$) derived from a 0.5 m water column, and the largest estimates for
1087 seepage face in Cantarrijan Beach ($A = 1.0 \times 10^3 \text{ m}^2$) for the ^{222}Rn model and seepage meter
1088 methods, the minimum fresh groundwater discharge is $0.9 \times 10^6 \text{ m}^3 \text{ y}^{-1}$. Applying the assumption
1089 of a 3-days residence time, the largest V at each submarine spring ($4.6 \times 10^5 \text{ m}^3$, $8.7 \times 10^5 \text{ m}^3$,
1090 $7.1 \times 10^5 \text{ m}^3$), and the largest A in cantarrijan Beach ($5.7 \times 10^3 \text{ m}^2$) for the ^{222}Rn model and
1091 seepage meter methods, the maximum fresh groundwater discharge from Sierra Almirajara-
1092 Alberquillas Aquifer is $6.8 \times 10^6 \text{ m}^3 \text{ y}^{-1}$. A total groundwater discharge of $6.8 \times 10^6 \text{ m}^3 \text{ y}^{-1}$ seems
1093 plausible but unlikely during base flow conditions when compared to the total water budget of
1094 Sierra Almirajara-Alberquillas ($50 \times 10^6 \text{ m}^3 \text{ y}^{-1}$). However, a residence time of 1 day seems more
1095 realistic based on other studies conducted in similar areas. The application of this sensitivity
1096 analysis including all terms and applying a 1-day residence time gives a total discharge of $1.0 -$
1097 $3.5 \times 10^6 \text{ m}^3 \text{ y}^{-1}$.

1098 **5.5 Global applicability of the presented methodology approach**

1099 The modes of discharge found in Maro-Cerro Gordo are commonly observed in other
1100 areas worldwide independent of climate. About half of the Mediterranean and Adriatic coastline
1101 is comprised of karst aquifers and hydrogeological settings similar to Maro-Cerro Gordo can be
1102 expected (Fleury et al., 2007, 2005; Surić et al., 2015). In most scenarios authors often point out
1103 that groundwater discharge was not quantified due to the complex settings where at least two
1104 forms of discharge occur in multiple locations (e.g. Fleury et al., 2007; Burnett et al., 2008).
1105 Similar problems are encountered in karst coastlines in the Yucatan Peninsula (Mexico), a karst
1106 platform located in the Caribbean Sea. Gonnee et al. (2014) assumed that submarine springs
1107 were representative of the total SGD in the study area, but pointed out that diffuse discharge
1108 away from springs was not measured. Null et al. (2014) assessed SGD in the eastern shore of the
1109 Yucatan Peninsula where submarine springs and diffuse seepage are present. Due to the lack of a
1110 field method to quantify groundwater seepage, they used analytical calculations to establish a
1111 first order approximation of SGD. Furthermore, SGD in volcanic systems, although geologically
1112 different than karst, have comparable dynamics due to the similar intrinsic porosity and
1113 permeability (Burnett et al, 2008; Johnson et al., 2008; Peterson et al, 2009, Dimova et al, 2012).

1114 Common characteristics of these sites include (1) simultaneous groundwater discharge to
1115 the sea occurring in two or more forms due to highly heterogeneous geological settings, (2) high
1116 infiltration rates resulting in negligible riverine freshwater inputs, and (3) significant
1117 groundwater inputs.

1118

1119 **6 Conclusions**

1120 Work presented here demonstrates that determining total groundwater discharge to the
1121 ocean from coastal karst aquifers is not trivial and it requires a very good understanding of the

1122 geology and groundwater origin to constrain an adequate water budget. Specifically, as a result
1123 of the complex geology of Maro-Cerro Gordo coastal area and highly heterogeneous Sierra
1124 Almirajara-Alberquillas coastal karst aquifer, we found that groundwater discharge manifests in
1125 four different forms: (1) groundwater-fed creeks, (2) coastal springs, (3) groundwater seepage
1126 through seabed sediments, and (4) submarine springs. These expressions of discharge are typical
1127 for karst systems and should be expected in similar geological settings elsewhere including
1128 volcanic systems, which although having different rock composition, behave hydrologically very
1129 similar. We found that only the application of a set of methods specific for each form of
1130 discharge adequately characterizes and gives a realistic evaluation of groundwater discharge to
1131 the sea and thus recommend the following approaches (Table 6).

1132 Continuous ^{222}Rn measurements in coastal waters via boat surveys proved to be the most
1133 reliable method for detecting diffuse groundwater seepage through seabed sediments. The
1134 technique complements well with a ^{222}Rn mass balance model based on time-series
1135 measurements performed with the same instrumentation. We found that this method gives
1136 similar results to direct measurements carried out from Lee-type seepage meters.

1137 The presence of submarine springs was reliably detected using continuous salinity
1138 measurements and discrete ^{224}Ra sampling. However, because negative salinity anomalies in
1139 coastal waters could be the result of discharge of other freshwater inputs (e.g. groundwater-fed
1140 creeks and coastal springs) which are likely to occur in karst systems, salinity alone is not a
1141 reliable tracer for SGD in coastal karst systems. We were able to confirm the presence of
1142 submerged springs only when combined with high concentrations of ^{224}Ra concentrations and
1143 direct observations via SCUBA diving. Direct flowmeter measurements or applying the ^{222}Rn

1144 method would have been technically and economically challenging, given the springs depth and
1145 their lateral vent geometry.

1146 Subaerial coastal springs and groundwater-fed creeks are easily detectable visually in the
1147 field. However, we found that tracer surveys are helpful to identify sources of springs and
1148 assessing the total discharge from both forms of subaerial groundwater discharge.

1149 We found that the combination of hydrochemistry (SO_4^{2-} and NO_3^-) and water stable
1150 isotopes ($\delta^2\text{H}$ and $\delta^{18}\text{O}$) was ideal to decipher the origin of each point of groundwater discharge
1151 to the sea.

1152 Nitrate fluxes, in an area where endemic and protected seagrasses *Zostera marina*,
1153 *Posidonia oceanica* are present, were found to be comparable with other coastal karst aquifers
1154 environmentally impacted by anthropogenic activities in the Mediterranean.

1155 Based on our experience, we strongly recommend the application of the described
1156 methodology approach in coastal karst systems to assess total groundwater discharge to the sea
1157 and associated nutrients fluxes.

Table 6

1 **List of figures**

2

3 Figure 1: Study site location and geological map showing water table contour lines (from Pérez-
4 Ramos and Andreo, 2007), groundwater flow direction, important wells and piezometers,
5 sampling points, and terrestrial springs. Groundwater discharge to the sea (TGD) is represented
6 in purple and is based on this study. Coastal springs are represented as CS, groundwater-fed
7 creeks as GC, diffuse groundwater seepage as GS, and submarine springs as SS. The study area
8 is divided in three sections: conglomerate section, schist section, and karst section. The
9 distribution of seagrass beds are based on Bañares-España et al. (2002), and Aranda and Otero
10 (2014).

11

12 Figure 2: Average monthly precipitation and sea level change during 2010, 2015, and 2016. Error
13 bars show the monthly rainfall variability during this study. In December of 2015 slight
14 precipitation occurred only during the first week, however, abundant rainfall took place during
15 September-November. Sea level showed minima values during January-May and maxima during
16 August-December. Sampling campaigns were conducted during May-July (dry periods) and
17 December (wet periods).

18

19 Figure 3: Interpolated ^{224}Ra activity concentrations in September of 2010 along the schist and
20 karst sections. Two areas of high ^{224}Ra in coastal waters were identified in the schist section near
21 groundwater-fed Miel Creek ($56 \pm 4 \text{ dpm m}^{-3}$), and the three clustered submarine springs
22 discharging from Cantarrijan Caves ($51 \pm 4 \text{ dpm m}^{-3}$) located in the Cantarrijan area (karst
23 section).

24

25 Figure 4: Salinity anomaly map showing combined results from May, July, and December of
26 2015. Two areas of negative salinity anomalies were found in the conglomerate (salinity
27 anomaly = -1.2 to -1.7) and karst (salinity anomaly = -0.3 to -1.0) sections almost perfectly
28 aligned with their delineated extent.

29

30 Figure 5: Radon-222 distribution map based on surveys during July and December of 2015, and
31 July of 2016. Two radon peaks were in found in Maro Cliff (conglomerate section) and
32 Cantarrijan Beach (karst section) with maximum concentrations of $44 \pm 3 \times 10^3$ dpm m⁻³ and 30
33 $\pm 2 \times 10^3$ dpm m⁻³ respectively.

34

35 Figure 6: (a) Groundwater seepage velocity averaging results from radon mass balance and
36 seepage meters in areas of diffuse seepage (Maro Cliff and Cantarrijan Beach). Radon
37 distribution in (b) Maro Cliff (conglomerate section) and (c) Cantarrijan Beach (karst section)
38 where cylinder symbols represent seepage meter locations and the star radon time series stations.

39

40 Figure 7: Radon fluxes result of each component of the mass balance box model during all
41 sampling campaigns in Maro Cliff (conglomerate section) and Cantarrijan Beach (karst section).
42 The largest tracer losses occurred via mixing due to the high exposure of both areas to waves and
43 currents. Greater difference in SGD-²²²Rn fluxes was found between wet periods (December)
44 and dry periods (July) in Cantarrijan Beach compared to Maro Cliff.

45

46 Figure 8: (a) Isotopic composition ($\delta^{18}\text{O}$, $\delta^2\text{H}$) of water samples collected during all sampling
47 campaigns. Local Groundwater Line (LGL) represents the linear trend based on all groundwater

48 samples collected in the study area. Global Meteoric Water Line (GMWL) is based on Craig,
49 (1961) and the Western Mediterranean Meteoric Water Line (WMMWL) on Gat and Garmi,
50 (1970). White color represents points of discharge in conglomerate and breccia lithology, while
51 light grey are in travertine (conglomerate section); dark grey shows points in schist (schist
52 section); and black color show locations in karstic marble (karst section). Maro Spring and Nerja
53 Cave well (not points of discharge to the sea) are represented with a black and white star
54 respectively. Water samples collected at each section (conglomerate section, schist section, and
55 karst section) are grouped in dashed squares. (b) Isotopic composition of samples collected from
56 points of discharge from the travertine formation in the conglomerate section. The two
57 groundwater end-members (Maro Spring and irrigation waters) are circled, while diffuse seepage
58 in Maro Cliff is represented with squares.

59

60 Figure 9: Mixing plots of ^{224}Ra (a) and ^{222}Rn versus salinity (b) showing best fit linear and
61 exponential mixing lines, respectively, during surface water surveys along the coastline in
62 September of 2010, July and December of 2015.

63

64 Figure 10: Total groundwater discharge (TGD) in the study area divided in forms of discharge
65 (GS: groundwater diffuse seepage, CS: coastal springs, GC: groundwater-fed creeks, SS:
66 submarine springs), showing maximum and minimum flux during wet and dry periods.

67

68 Figure 11: Groundwater ionic relationship between NO_3^- and SO_4^{2-} where groundwater samples
69 with similar composition are grouped in dashed squares. Symbols are presented as in Fig. 8
70 based on the section and lithology they are located. In the conglomerate section Maro Spring,

71 Nerja Cave, and Maro Creek show similar SO_4^{2-} concentration with low NO_3^- , while Doncellas,
72 Barranco Maro, Huerto Romero, and Maro Beach present NO_3^- contamination. Samples from the
73 schist section (Miel and Alberquillas) present a distinctive signal with low NO_3^- and SO_4^{2-}
74 concentrations. Groundwater collected in Cantarrijan Beach (karst section) shows seawater
75 influence from saltwater recirculation in beach sediments. Arrows indicate the geochemical
76 change before irrigation and after fertilizers application (NO_3^-), where Maro cliff (diffuse
77 seepage) shows mixing between both groups.
