Abstract

This chapter presents changes in relative sea level (RSL) along tropical coastlines (30°N-30°S). Under current and future global changes, 90% of the coastlines are at risk, facing challenges of rising sea level (SL). Since the last century, scientists have attempted to understand processes governing RSL, to separate variations in absolute SL from those due to vertical land movement, and to discover their links to climate change. Recently developed space technologies provide accurate estimates of ongoing SL changes. Combined with tide gauge records, these new instruments (GPS, altimetry, InSAR) offer a new perspective for the science associated with sea level and its changes. This chapter reviews the concept of RSL, of RSL hotspots and describes different RSL measurements. Then, it identifies and maps the hotspots of RSL changes and updates, where possible, previously published estimates of RSL trends. Identification of the RSL hotspots is of paramount importance for climate change mitigation and adaptation in tropical regions.

Keywords: relative sea level ; tide gauge ; Tropics ; GPS ; altimetry ; land movement; delta

32 **4.1. Introduction**

33 The pronounced impact of climate change on natural systems and human societies is a reality.
34 Understanding the extent to which people, societies, ecosystems and economy are exposed to
35 risk under current and future climate is a challenging issue for modern science. One of the major
36 consequences of the ongoing climate change is a rise in sea level (SL). The Intergovernmental
37 Panel on Climate Change reported [*IPCC AR5*, 2013] that the global mean sea level (GMSL,
38 1.6 to 1.8 mm/yr rise over the 20th century [*Church et al.*, 2013]) will continue rising in the 21st
39 century and beyond, at probably a faster rate than observed today, even if the global temperature
40 will be stabilized. Almost 90% of the coastlines worldwide will face challenges of rising sea
41 level [*IPCC AR5*, 2013] although to different extent as the rates of the sea level rise can be
42 several times larger in some regions than the GMSL rise [*Church et al.*, 2013]. Consequently,
43 the part of coastal vulnerability reflecting a high and growing exposure and low adaptive
44 capacity of the coastal populations to sea level rise is not spatially uniform either [*Nicholls et*
45 *al.*, 2011]. Certain regions throughout the world, especially in developing countries, are already
46 recognized as particularly vulnerable to sea level rise; for example, small islands in the
47 Caribbean Sea, Maldives Archipelago in the Indian Ocean, Tuvalu Islands in the Pacific, or the
48 West African coast from Morocco to Namibia, the south Asian coast from Pakistan to Burma
49 as well as the coasts in southeast Asia from Thailand to Vietnam [*Nicholls et al.*, 1999; *Nicholls*
50 *and Cazenave*, 2010]. *Nicholls et al.*, [2011] defined these specific regions as areas where an
51 efficient protection against sea level rise will most likely fail, potentially resulting in a
52 significant portion of environmental refugees. It is worth mentioning here that those cases are
53 related to relative sea level (RSL) changes, which are felt by coastal populations, i.e. the
54 changes in sea level relative to the land on which people live. Focusing on the analysis of the
55 RSL variations is of obvious practical importance, since it makes little difference to a person
56 nearly submerged, whether the ocean is rising or land is subsiding [*Milliman and Haq*, 1996].
57 Pronounced dispersion in the rates of RSL rise calls for detailed investigation of the processes
58 responsible for sea level changes not only at the global scale but also at the regional scale. The
59 RSL changes are induced by a combination of various processes of a different nature and
60 operating at different spatial and temporal scales, originated in the ocean, ice, atmosphere,
61 sediment transport, and the solid Earth deformation inducing land subsidence or uplift
62 [*Stammer et al.*, 2013]. Ocean temperature and salinity variations resulting from water heating,
63 precipitation or freshwater discharge from land can contribute to regional sea level fluctuations
64 by changing the sea water density. Additional freshwater fluxes from river discharge or land

65 ice melting modify ocean currents, which in turn also have significant repercussions on regional
66 sea level variations [*Stammer, 2008*], with signals taking decades to propagate around the global
67 ocean. Atmospheric pressure, at different scales, also plays a role in regional sea level variations
68 [*Ponte, 1994; Wunsch and Stammer, 1997; Piecuch and Ponte, 2015*]. Concerning the vertical
69 land movements, there exists a wide range of natural and anthropogenic processes, which can
70 induce them. The water mass exchanges between land and ocean lead to changes in the Earth's
71 surface and in the geoid that manifest themselves as part of observed RSL variations [*Milne et*
72 *al., 2009; Stammer et al., 2013*]. These result from different processes: (1) ice-water mass
73 redistribution associated with ice cap melting since the Last Glacial Maximum (called post
74 glacial rebound or Glacial Isostatic Adjustment/GIA; [*Peltier, 2004; Lambeck et al., 2010*]),
75 (2) ongoing land ice melting [*Mitrovica et al., 2001; Tamisiea and Mitrovica, 2011*] and (3)
76 land water storage variation [*Riva et al., 2010*]. GIA involves the visco-elastic response of the
77 Earth's mantle to mass redistribution, while processes (2) and (3) involve the elastic response
78 of the Earth's crust. GIA and present-day mass redistributions produce very different response
79 of the solid Earth, and thus regional RSL variations (see, for example, [*Milne et al., 2009;*
80 *Tamisiea, 2011; Tamisiea and Mitrovica, 2011*]). We now call these processes 'static' effects
81 (e.g., [*Stammer et al., 2013*]). The solid Earth also responds to sediment loading, referred to
82 herein as sedimentary isostatic adjustment, that often induces strong subsidence within the
83 deltas [*Blum and Roberts, 2009; Syvitski et al., 2009*]. Many other natural processes, such as
84 tectonics and volcanism, can also generate land movements that are more local when compared
85 to the 'static' effects discussed above. Aside from most of these natural factors, an additional
86 complex dimension to these changes is the non-negligible impact of human activities; For
87 instance, sea level can be modified through building of dams and reservoirs, irrigation and
88 hydrocarbon extraction, groundwater pumping among many other processes [*Fiedler and*
89 *Conrad, 2010; Wada et al., 2012, 2016*]. These anthropogenic forcings affect directly the land
90 water storage, and hence water mass exchange between land and ocean [*Milly et al., 2010*] and
91 consequently can generate locally significant vertical land movement. Several Asian megacities
92 subsided by several meters during the past few decades owing to groundwater withdrawal or
93 hydrocarbon extraction [*Syvitski, 2008*].

94
95 In this chapter, we focus on the RSL changes within the Tropics, defined below as a region
96 from 30°N to 30°S latitude. The Tropics are home to 40% of the world's population, and this
97 proportion is projected to reach 50% by 2050 [*Edelman et al., 2014*]. From today until 2050,

98 the largest coastal population growth is expected to take place in Africa where the population
99 will double [Edelman *et al.*, 2014]. Assessing the vulnerability of tropical coasts to future
100 climate change and elaborating an efficient climate mitigation policy is one of the most
101 important global issues of our time. Developing countries that make up a majority of tropical
102 regions are the most vulnerable to RSL changes, because they have limited resources to adapt
103 themselves socially, technologically and financially. Moreover, it is important to note that the
104 Tropics host the largest deltas in the world. These low-lying delta plains are crucially affected
105 by land subsidence that often makes the sea along the delta coasts to rise much faster than the
106 GMSL rises. As the deltas are a home to tens of millions of people, the densely populated
107 deltaic environments become a suitable site for springing up of megacities (greater than 5
108 million inhabitants) with the associated complex problems of their management.

109
110 One of the objectives of this chapter is to bring together sea level observations in order to
111 analyze similarities and differences in the RSL changes along the tropical coasts. It is crucial
112 for all evaluations of coastal impacts, vulnerability, and adaptation, to account for the RSL rise,
113 especially along the low-lying populated coasts where RSL is rising much faster than its global
114 average rate. We call these sites hotspots of RSL rise [Sallenger *et al.* 2012]. Our primary
115 concern is to review the current knowledge about RSL in the tropical regions and to: (1)
116 comprehensively identify, document and map the hotspots of RSL changes; (2) give an
117 overview of available long-term sea level records, and (3) update, where possible, previously
118 published estimates of RSL trends over recent decades. Section 2 will review the different
119 datasets currently available to study RSL. Then we will dedicate a specific section for each of
120 the Oceans in the tropical band, with a sub-section dedicated to large oceanic sub-basins. For
121 each region, we will document both the societal and physical aspects of RSL. At the end of
122 each section, we summarize the main features of the respective RSL hotspots.

123

124 **4.2.Data sets**

125 **4.2.1. Tide gauge records**

126 Tide gauge (TG) records are the main source of information available to assess coastal sea level
127 changes since the mid-19th century. The TGs were designed to measure RSL, namely, the water
128 level relative to land on which they are installed [Pugh and Woodworth, 2014]. Therefore, the
129 TG measurements reflect absolute sea level (ASL, i.e. in respect to the center of the Earth)
130 changes but also local vertical land movements along with changes in the geoid. The worldwide

131 geographical distribution of TGs is particularly limited and irregular with an obvious lack of
132 stations in the Southern Hemisphere, particularly in developing countries and island states. In
133 our analyses, we use annually averaged sea level series from the Permanent Service for Mean
134 Sea Level (PSMSL) Revised Local Reference (RLR) database [*Holgate et al.*, 2013]. The
135 PSMSL recommends using the RLR records, where the sea level means were reduced to a
136 common datum, for time series analysis. The PSMSL also provides the ‘Metric’ data, without
137 datum continuity checked and with, sometimes, large discontinuities. These metric records
138 should only be used in studies pertaining to the seasonal cycle of mean sea level [*Holgate et*
139 *al.*, 2013]. The length of TG records, as well as the number of missing values, are of crucial
140 importance for estimating long-term trends. *Douglas*, [2001] has concluded that more than 50-
141 60 years of continuous measurements are required for a long-term sea level trend to be reliably
142 estimated. In this study, we reduce this constraint by estimating trends at the stations with
143 records longer than 30 years, and with less than 4 consecutive years of missing data.

144

145 **4.2.2. Satellite altimetry**

146 Since 1993, satellite altimetry has been used for measuring spatial and temporal variations of
147 absolute sea level (hereafter, called ASL) rise. The ASL products, consisting of sea surface
148 heights, are routinely processed and distributed by six groups: Archiving, Validation and
149 Interpretation of Satellite Oceanographic data (AVISO), Commonwealth Scientific and
150 Industrial Research Organization (CSIRO), Colorado University (CU), Goddard Space Flight
151 Center (GSFC), European Space Agency Climate Change Initiative (ESA-CCI) and Delft
152 University of Technology (TUDelft-RADS). Here, we chose to use the newly reprocessed ESA-
153 CCI Sea Level v1.1 gridded altimetry product (hereafter, called ESA) that is freely available
154 at: <http://www.esa-sealevel-cci.org> (see details in *Ablain et al.*, [2015]). In order to remove the
155 seasonal signal in the ASL time series, we used a 12-month running mean filter.

156

157 **4.2.3. Reconstruction of sea level in the past**

158 Recently, a new approach was developed to reconstruct the ASL variations in the past. This
159 method combines information from TG records with spatial patterns from altimetry and/or
160 oceanic models [*Church et al.*, 2004; *Llovel et al.*, 2009; *Hamlington et al.*, 2011; *Ray and*
161 *Douglas*, 2011; *Meysignac et al.*, 2012a]. In order to get an overview of the regional ASL
162 variation in the Tropics over a longer period, we employ an updated version of past sea level
163 reconstruction developed by *Meysignac et al.*, [2012a] for the period 1960-2014. This method

164 is based on reduced optimal interpolation, combining long-term TG records with a time varying
165 linear combination of Empirical Orthogonal Functions-based spatial patterns derived from 2-D
166 sea level grids based on oceanic model outputs.

167

168 **4.2.4. GPS stations**

169 The Global Positioning System (GPS) is used for precisely positioning TG benchmarks with
170 respect to the center of mass. These measurements, due to their relatively low cost and easy
171 implementation, and maintenance, have become key components for sea level studies as they
172 provide accurate determination of coastal vertical land movements [*Wöppelmann et al.*, 2007;
173 *Wöppelmann and Marcos*, 2016]. In this study, we use vertical velocities estimated by the
174 University of La Rochelle from its latest GPS data reanalysis (called hereafter ULR6,
175 [*Santamaría-Gómez et al.* 2017]). These estimates are made at the GPS stations that are directly
176 collocated with TGs or situated not further than 15 km from them, provided that the GPS series
177 have more than 3 years of data [*Wöppelmann et al.*, 2007]. The magnitudes of vertical velocity
178 and their associated uncertainties are available (free of cost) at <http://www.sonel.org>; the GPS
179 at tide gauge data assembly center Système d'Observation du Niveau des Eaux Littorales
180 (SONEL).

181

182 **4.2.5. Urban agglomerations and Low Elevation Coastal Zones (LECZ)**

183 We used the Urban-Rural Population and Land Area Estimates v2 dataset, providing the
184 number of people living on contiguous coastal elevations less than or equal to 10 m in 2010.
185 This dataset is from the Low Elevation Coastal Zone collection (LECZ, [*McGranahan et al.*,
186 2007]) and is freely downloadable from <http://sedac.ciesin.columbia.edu/data/collection/lecz>.

187

188 **4.3. Atlantic Ocean**

189 **4.3.1. Eastern South America**

190 The Tropical Atlantic Ocean is bordered in the west by the Brazilian coast extending through
191 the Caribbean Sea to the Gulf of Mexico. The entire Brazilian coastline, extending from latitude
192 4°N to 34°S, has been experiencing erosion, although the erosion rates vary irregularly and are
193 often enhanced within river outlets [*Muehe*, 2010]. Since 1970s, rapid expansion of
194 agglomerations and intensive construction of housing for residence and tourism, bring more
195 people to settle along the coast [*Short and Klein*, 2016]. At the end of the 90s, already 20% of

196 Brazilians live in coastal cities [*Muehe and Neves, 1995*] (Figure 4.1). For example, the
197 population density of the megacity of Rio de Janeiro has nearly doubled in four decades (27
198 inhab/ha in 1960 to 48 inhab/ha in 2000, [*Saglio-Yatzimirsky 2013*]); presently, its population
199 exceeds 12 million people. In the Northeast, Recife is a large metropolitan city with
200 approximately 4 million inhabitants that ranks among the cities in Brazil, with the highest
201 population density at the coast [*Muehe and Neves 1995; Neves and Muehe 1995*]. This city is
202 located at the mouth of two rivers, Beberibe and Capibaribe, within low-lying areas making it
203 particularly vulnerable to RSL rise. All these large coastal cities, where the problems of urban
204 drainage are nowadays permanent, have to deal with floods. In 2008, around 30% of more than
205 5.5 thousand municipalities in Brazil reported having inefficient drainage system and having
206 suffered from floods in the past five years [*Nali and Rigo 2011*]. The consequences of drainage
207 system deficiency in urban areas are important, ranging from impacts on human health, through
208 groundwater contamination and proliferation of mosquitoes, to damage effects, inter alia, on
209 housing, infrastructure and psychological stress. These effects will become even more critical
210 with a rise in RSL [*Muehe 2010*].

211 In the north, the Brazil coastline of the Amazon Delta extends from Cape Orange in the state
212 of Amapa up to the French Guiana's border. Despite deforestation, dam construction and land
213 usage, the delta is in relatively good health [*Syvitski et al. 2009*]. *Mansur et al.* [2016] estimated
214 that over 1.2 million people are under the risk of flooding (fluvial and coastal) in this delta, and
215 that 41% of urban sector inhabitants are exposed to potential flooding risks. The population of
216 the Amazon Delta is projected to grow by more than 60 % over the 15-year period [*Overeem
217 and Syvitski, 2009*], making this region particularly vulnerable to anthropogenic changes. The
218 Orinoco Delta in Venezuela is an area with small population and is less developed. However,
219 it is estimated that by 2050, 21% of this delta population will be potentially inundated due to
220 future RSL rise and 20% of the delta area could be lost [*Ericson et al. 2006*].

221 Over the last few decades, the observed retreat of mangrove vegetation along the delta coastline
222 seems to be compatible with a long-term relative sea-level rise trend [*Cohen and Lara 2003;
223 França et al. 2012*]. *Gratiot et al.* [2008] have shown that the mangrove retreat of the 1500 km-
224 long flat muddy coast from the Amazon to the Orinoco (Venezuela) rivers over the last twenty
225 years has been governed primarily by the lunar 18.6-year low-frequency tide constituent. These
226 findings highlight an extreme sensitivity of this region to global environmental changes in
227 general, and, in particular, to sea level changes.

228 Populations of the northern Brazil neighboring countries will also face sea level rise adaptation
229 problems: thus, in terms of population impacted by a 1 m sea level rise, at least 6% of people
230 living in Guyana, Suriname and French Guiana population would be displaced [*Dasgupta et al.*
231 2009]. These countries are among the top 10 countries/territories worldwide affected by
232 climate-induced massive population relocation.

233 From the PSMSL RLR data set, 11 TG records are available along the Brazilian coast and one
234 recent record from French Guiana (Ile Royale, 10 years, 2006-2015). Of these sea level records,
235 only two from southeastern Brazil cover recent years and are long enough to allow long-term
236 trend estimates: Cananea (53 years, 1954-2006) and Rio de Janeiro (Ilha Fiscal station: 51
237 years, 1963-2013). The length of the other records is less than 21 years. Emery and Aubrey
238 [1991] reviewed all records from Brazil available at PSMSL and noted a coherent RSL rise of
239 about 2-4 mm/yr between 1950 and 1970; this was interpreted as land subsidence except for
240 RSL observations at Recife, Belem and Imbituba, where the trends are close to zero. The lower
241 trends were suggested to result from land movement produced at Recife by the Pernambuco
242 fault, and to sediment-induced subsidence at Imbituba and Belem. More recent work has
243 revisited these long-term trends and estimated RSL trend in the range 3-5 mm/yr over the past
244 50 years [*Neves and Muehe* 1995; *Mesquita* 2003; *Muehe* 2006; *Mesquita et al.* 2013]. We
245 searched for new records in PSMSL to update the Emery and Aubrey results, but have found
246 only two recent series: One at Cananea and another at Ihla Fiscal (Table 4.1). The Ilha
247 Fiscal record exhibits no significant RSL trend over 1967-2013, the signal being dominated by
248 strong multidecadal fluctuations. The presence of the multidecadal sea level signal explains the
249 low statistical confidence of the trend estimate at Ihla Fiscal noticed by Emery and Aubrey
250 (1991). Our estimate of the RSL trend at Cananea over a 50-year span (Table 4.1) is of 4.1
251 mm/yr (Table 4.1) that is surprisingly coherent with 4.2 mm/yr obtained by Emery and Aubrey
252 over the first 30 years of apparently the same sea level record. A different trend was found,
253 however, by *Ducarme et al.* [2007] who estimated a larger RSL trend of 5.6 ± 0.07 mm/year
254 after having identified and corrected two periodicities of 24.2 year and 10.7 year dominating
255 the very low frequency spectrum of sea level at Cananea. This rate, over the last 50 years,
256 largely exceeds the observed GMSL trend from satellite altimetry over the last 22 years (3.1 to
257 3.3 mm/yr, [*Cazenave and Le Cozannet* 2013]) and Cananea should be classed as a strong
258 positive anomaly, a *hotspot*, in the global sea level rise pattern [*Mesquita et al.* 2013]. The
259 reasons of the increased rate of RSL rise at Cananea have not been completely explained yet,
260 but they are unlikely due to land subsidence alone. (It is worth noting here that *Aubrey et al.*

261 [1988], *Muehe and Neves* [1995] and *Mesquita et al.* [2013] previously presented evidence that
262 the Brazilian coast may be sinking.) An apparent contradiction comes from the NEIA GPS
263 station collocated (Table 4.1) with the Cananeia TG (10 m distance from the tide-gauge and 15
264 years in operation). Indeed, no significant trend in vertical movement was detected by the NEIA
265 GPS at the Cananeia TG over the last 15 years (Table 4.1). Yet, it does not exclude an increased
266 RSL rise at Cananeia, as it can also be due to oceanic processes. Notice, however, that the ASL
267 absolute sea level trends near Cananeia vary between 1.8 and 3 mm/yr over 1993-2014 similarly
268 to the sea level trends of about 2.5 mm/yr reconstructed near the Brazilian coast over 1960-
269 2014 (Figure 4.4).

270 The other two GPS stations on the Brazilian coast are collocated with Recife and Imbituba TG,
271 the two sites likely influenced by local land movement [*Emery and Aubrey* 1991]. Land
272 subsidence of 2.4 mm/yr is observed at RECF GPS, at 9 km from the Recife TG, and slower
273 subsidence of 1.1 mm/yr at IMBT GPS, 700m from Imbituba TG. Unfortunately, the lack of
274 modern TG records at Recife and Imbituba does not allow separating the contribution of land
275 movement from oceanic component in the observed RSL. The lack of data and insufficient
276 density of the TG network is a major obstacle for accurate evaluation of regional sea level
277 changes in this region. Since 2007, efforts are being made to implement a Permanent Brazilian
278 Sea Level Monitoring Network called Global Sea Level Observing System (GLOSS)-Brazil
279 Network. Under this program, twelve new TG stations have been installed and are now fully
280 operational (data available on <http://www.goosbrasil.org/gloss>). This gives hope for obtaining
281 more precise and accurate long-term sea-level measurements along the coast of Brazil [*Lemos*
282 *and Ghisolfi* 2011].

283 **4.3.2. Caribbean Sea**

284 The Caribbean Sea is bounded in the west by Central America and, in the south, by Venezuela
285 and Colombia. It is connected to the Gulf of Mexico through the Yucatan straits in the north.
286 Cuba, the Greater Antilles and the Lesser Antilles, separate the Caribbean Sea from the Atlantic
287 Ocean to the north and northeast. The Caribbean Sea includes more than 7000 islands that are
288 particularly vulnerable to sea level rise because of high population density. Indeed, about half
289 of the island population lives within 1.5 km from the sea [*Mimura et al.* 2007] because of its
290 dependence on coastal and sea resources [*Nicholls and Cazenave* 2010]. *Dasgupta et al.* [2009]
291 identified, among 84 coastal developing countries, the Bahamas is one of the 5 most impacted

292 countries of 1-meter SL rise. In terms of potential land loss, Belize, Puerto Rico, Cuba and
293 Jamaica are ranked in the top 10 in the sea level vulnerability classification (from 1 to 2% of
294 loss, *Dasgupta et al.* 2009). Similarly, Jamaica and Belize are among the top 5 in the
295 classification of the largest wetland loss triggered by sea level rise (~30% of loss, *Dasgupta et*
296 *al.* 2009). Moreover, the unique biodiversity of the Caribbean Sea islands [*Mittermeier et al.*
297 2011] appears to be particularly threatened by the projected sea level rise. With a 1-m of sea
298 level increase, ~9% of the islands (i.e. 63 islands among the 723 identified as biodiversity
299 hotspot by *Bellard et al.* 2014) is expected to be entirely submerged, and the worst-case
300 scenario of a 6-m increase would lead to a loss of half of the islands (i.e. 356 islands).

301 Updating *Palanisamy's et al.* [2012] work, over the 1960-2014 reconstruction period, we
302 observed strong positive ASL trends in the Caribbean of about 2.5-3 mm/yr (Figure 4.4), except
303 for Cuba, the Lesser and Greater Antilles where the ASL trends are lower, at around 1.8-2.5
304 mm/yr (Figure 4.4). The RLR TG records from the PSMSL dataset corroborate these findings.
305 Only seven sea level records span more than 30 years (Table 4.2). Two stations are located on
306 the continent: Cartagena (1949-1992, 44yr) in Colombia shows an RSL trend of 5.2 mm/yr, and
307 Cristobal (1909-1979, 71yr) in Panama shows an RSL trend of 1.5 mm/yr. The former trend is
308 the fastest of the long-term Caribbean sea level observations (Figure 4.2) that places Cartagena
309 among the cities directly threatened by rising sea level. The RSL measurements along the
310 Antilles chain reveal trends of: i) about 3 mm/yr in the Virgin Islands; and ii) about 2 mm/yr in
311 Puerto Rico and Cuba. Over the 1993-2014 altimetry period, we observe strong positive ASL
312 trends from Nicaragua, southward through Venezuela to the Lesser Antilles, in the range of 3-
313 5 mm/yr (Figure 4.3), which is greater than the GMSL trend over the same period. In the eastern
314 part of the Caribbean Sea, the ASL trends are smaller; they range from 1.8 to 3 mm/yr (Figure
315 4.3) along the Greater Antilles islands, in particular along the coasts of Cuba, Jamaica, Haiti
316 and Puerto Rico. It is worth noting here that the seismically active Lesser Antilles subduction
317 zone is a potential source of tsunami-induced flooding all along the Caribbean coasts [*McCann*
318 2006].

319 GPS stations (Table 4.2) are concentrated in the US Virgin Islands with the only station
320 available on the continental coast, at Cartagena. All GPS records span about 9 years, except the
321 station in Lime Tree Bay where the record is for 21 years. Analysis of the GPS data at Cartagena
322 reveals a trend of 1.7 mm/yr that is most likely due to land movement along the fault [*Emery*
323 *and Aubrey* 1991]. In this case, the ocean contribution to the 5.2 mm/yr RSL trend at Cartagena

324 would be about 3.5 mm/yr. It is difficult to answer whether the 9-year long GPS series are long
325 enough for estimating land movement in these regions. In order to get an insight into this issue,
326 we compared the trends derived from two GPS stations in Lime Tree Bay. The 21-year long
327 CR01 GPS station shows a trend of 2.9 mm/yr while another one, which has a 9-year long
328 record, has a much smaller trend of 1.1 mm/yr. This points out to a possible non-stationary
329 character or significant spatial variation in vertical land movements in Lime Tree Bay.

330 Along the Bahamas Islands, the ASL trends range from 0 to 3 mm/yr, but some trends in this
331 region are statistically insignificant, and some have high uncertainty (Figure 4.3) due to
332 pronounced interannual sea level variability in the Caribbean region. *Torres and Tsimplis*
333 [2013] show that the interannual fluctuations in this region can be partly explained by the
334 influence of El Niño–Southern Oscillation (ENSO) at different time and space scales; however,
335 they found no significant link with the North Atlantic Oscillation (NAO).

336 **4.3.3. Gulf of Mexico**

337 Along the U.S. Gulf coast, the population grew up 150% and housing construction by 246%
338 from 1960 to 2008 [*Wilson and Fischetti* 2010]. In August 2005, hurricane Katrina (followed
339 by hurricane Rita a few days later), resulted in the largest natural disaster in US history and
340 devastated human and economic landscape along the U.S. Gulf Coast. This disaster brought to
341 the forefront a problem, recognized for decades, of adaptation to the Mississippi Delta sinking,
342 which results in extensive wetland loss and increases the exposure of population, economic
343 activities and infrastructure to hurricane-induced storm surges [*Syvitski et al.* 2009]. *Dai et al.*
344 [2009] have shown that during the twentieth century approximately 25% of the Mississippi
345 wetlands were lost to the ocean. The largest factor contributing to the wetlands loss is the
346 construction of artificial levees, reducing the number of sediment pathways into adjacent flood
347 plain basins [*Kesel* 2003]. This land-loss problem is exacerbated by trapping of 50% of the total
348 sediment load by upstream dams, and there is not enough supply to keep pace with subsidence
349 and accelerated sea-level rise [*Blum and Roberts* 2012]. Assuming an acceleration of sea level
350 rise from 3 to 4 mm/yr and a subsidence rate from 1 to 1.7 mm/yr, coupled with the absence of
351 sediment input, *Blum and Roberts* [2009] projected a potential submergence of 25%-30% of
352 the delta (~10,000–13,500 km²) by the year 2100. *Blum and Roberts* [2012], concluded that
353 significant drowning is inevitable, even if sediment loads are restored, because the sea level is
354 now rising at least three times faster than during the period of the delta-plain formation.

355 Moreover, anthropogenic effects including locally accelerated subsidence can exacerbate this
356 problem. *Becker et al.* [2014] estimated that 68% (~ 4 mm/yr) of the sea level rise recorded at
357 Galveston over the last century is too large to be due to natural sea level variability and, by
358 consequence, should be dominated by land subsidence probably induced by extraction of
359 subsurface fluids, hydrocarbons, and groundwater withdrawal [*Morton et al.* 2006; *Kolker et*
360 *al.* 2011].

361 *Kolker et al.* [2011] used the Grand Isle, Galveston and Pensacola TG records from the RLR
362 PSMSL dataset to investigate the subsidence rate in the northern part of U.S. Gulf over 1947-
363 2006. They assumed that the Pensacola record, located on a stable carbonate platform,
364 experiences a linear land movement and therefore subtracted the Pensacola from the others
365 records to remove interannual variability. In doing so, they underlined three distinct significant
366 subsidence phases i) 1947-1958: 3.1 mm/yr and 2.6 mm/yr; ii) 1959-1991: 9.8 mm/yr and 6.2
367 mm/yr; and iii) 1992-1996: 1 mm/yr and -2 mm/yr at Grand Isle and Galveston respectively.
368 They argued that the recent subsidence rates are lower than predictions of the subsidence
369 scenario suggested by *Blum and Roberts* [2009] and, perhaps, future land losses linked to the
370 subsidence will be limited. However, in updating *Kolker et al.* [2011] work we obtained a
371 subsidence rate of ~3 mm/yr at Grand Isle over 1992-2015 (and ~0.8 mm/yr at Galveston, Table
372 4.3). This result is closer to the estimation of *Morton et al.* [2006] who reported a subsidence
373 rate of ~4 mm/yr over 1993-2006. Moreover, our estimates agree with recent work by *Letetrel*
374 *et al.* [2015], who combined satellite altimetry data and the long-term Grand Isle TG record and
375 estimated a subsidence rate of ~5 mm/yr over 1992-2008 and ~7 mm/yr over 1947-2011. These
376 values are close to the GPS-derived vertical velocity of ~ -6.5 mm/yr over 2005-2016, estimated
377 from GRIS GPSstation, 100 m from the Grand Isle TG.

378 The observed subsidence results from a combination of different processes such as tectonics,
379 sedimentation, glacial isotactic adjustment, and anthropogenic fluid withdrawal [*Douglas,*
380 2001]. Various studies estimated present-day subsidence rates in the range of 2-10 mm/yr, as a
381 response to the delta sedimentary load [*Jurkowski et al.* 1984; *Ivins et al.* 2007; *Syvitski* 2008;
382 *Törnqvist et al.* 2008]. However, *Wolstencroft et al.* [2014] argued that the viscoelastic
383 deformation due to sediment loading alone is unlikely to exceed ~0.5mm/yr. Thus, the current
384 high rates of observed subsidence are likely to be linked to sediment compaction and fluid
385 extraction.

386 In the RLR PSMSL dataset, we found 20 TG stations, with time spans of more than 30 years,
387 distributed along the coast of the Gulf of Mexico. 17 stations are located in the United States,
388 two in Mexico and one in Cuba. The long-term RSL trends are gathered in three clusters. The
389 first one represents the western coast from Progresso to Rockport (4 TGs) where the sea level
390 rises at 3-5 mm/yr. The fastest RSL rise is observed at 6 TG situated along the northern coast
391 from Freeport to Grand Isle in the Mississippi delta. Conjugation of land subsidence with rising
392 ASL results in an RSL of 6-10 mm/year. The third cluster contains moderate RSL trends of 2-
393 4 mm/yr observed at 10 TGs in the eastern Gulf, from Dauphin Island to Key West. As in other
394 regions, the main driver of the enhanced sea level rise in the Gulf of Mexico is in the deltaic
395 region, and is due to land subsidence.

396 **4.3.4. Atlantic Eastern border: Gulf of Guinea**

397 The Gulf of Guinea, located in the eastern Equatorial Atlantic, is constituted of eighteen coastal
398 States from Senegal to Angola. Its 12000 km-long coastline is characterized by typical low-
399 lying topography, coastal lagoons and by two large deltas: The Niger Delta and the Volta River
400 Delta (Figure 4.1).

401 This coastline hosts 12 townships, each with a population of over 1 million, which is highly
402 vulnerable to the impacts of climate change [UN-HABITAT 2014]. *Moriconi-Ebrard et al.*
403 [2016] highlight the formation of an urban band of high population density by 2020, in the
404 coastal area of the Gulf of Guinea. Yet, this region is already extremely vulnerable to projected
405 sea level rise impacts (erosion, submersion, saline intrusion into coastal aquifers and
406 agricultural areas, fisheries, mangrove degradation) [Nicholls and Mimura 1998].

407 *Jallow et al.* [1999] estimated, by modeling the effects of coastal erosion and a rise in sea level,
408 that Banjul, the capital of the Gambia, can disappear by 2050. *Dasgupta et al.* [2009] ranked
409 Benin in the top ten, of 84 developing coastal countries worldwide, which would be most
410 impacted by a 1-m sea-level rise in terms of population to be displaced (4%) and wetland area
411 loss (14%) and Gambia in terms of land area loss (1%). According to *Brown et al.* [2011],
412 Cameroon ranks in the top ten African countries likely to be impacted by flooding and forced
413 migration by 2100. *Hinkel et al.* [2012] concluded that Nigeria is one of the most vulnerable
414 African countries both in terms of the people-based sea level impacts as well as in terms of
415 economic costs. Some 25 million people are estimated to live currently within its coastal zones,
416 with about 8.5 million beneath the two-meter inundation contour [French et al. 1995]. The

417 largest city, Lagos, is expanding rapidly across the land standing below a meter above sea level.
418 As much as 70% of the city's population live in slums characterized by extremely poor
419 environmental conditions, including regular flooding of homes that lasts several hours and that
420 sweeps raw sewage [Adelekan 2009]. In the Niger delta region, even in absence of acceleration
421 in absolute sea-level rise, the land loss through edge erosion alone can cause shoreline recession
422 of 3 km by the year 2100 [French et al. 1995]. Moreover, the Niger Delta is sinking much faster
423 than global sea level is rising [Syvistki et al. 2009]. The high subsidence rate (25-125 mm/year,
424 [Abam, 2001]), due to oil and gas extraction, combined with a reduction in sediment deposition
425 plus accelerated compaction of sediment, makes this delta along with the Nile River Delta the
426 most threatened of the African deltas [Syvistki et al. 2009].

427 Relatively little research on long term sea level change has been undertaken previously over
428 the African continent, because the existing African dataset is shorter than that in other parts of
429 the world [Emery and Aubrey 1991; Woodworth et al. 2007]. The lack of historical data on sea-
430 level rise in Africa makes it difficult to assess coastal impacts and vulnerability with accuracy.

431 Woodworth et al. [2007] reviewed the African sea level changes by using the PSMSL data set.
432 In the Gulf of Guinea, some records exist but with less than 20 years of data available and no
433 recent data. In the RLR PSMSL data bank, only two TG records from this region have relatively
434 recent data but with substantial missing or inconsistent data: Dakar 2 (1992-2014, 73% of
435 completeness, Senegal) and Takoradi (1929-2012, 79% of completeness, Ghana). In
436 conclusion, along of the Gulf of Guinea coastline, only the Takoradi TG record, with reliable
437 datum continuity, can be used to estimate a long-term RSL trend over 36 years (1930-1965),
438 which is ~ 3 mm/yr [Woodworth et al. 2007].

439 In this context of lack of data, Wöppelmann et al. [2008] have initiated investigations at Dakar
440 (Senegal) to find and rescue past sea-level records. Several decades of sea level observations at
441 Dakar have been found, the earliest dating back to 1889. The secular RSL trend estimated from
442 this long reconstructed TG is 1.6 ± 0.2 mm/yr from 1900 to 2011. Using satellite synthetic
443 aperture radar interferometry (SAR), Le Cozannet et al. [2015] showed that despite a complex
444 geology, a rapid population growth and development in Dakar, the historical TG does not seem
445 to be affected by local vertical coastal land motion, and therefore can be a good candidate for
446 sea level studies in the Gulf of Guinea as well as for past sea level reconstruction. The rate of

447 ASL rise along the coast of the Gulf of Guinea is in the range 1.8-3 mm/yr (Figures 4.3 and
448 4.4) during the shorter (1993-2014) and longer periods (1960-2014).

449 Due to the lack of TGs, it is difficult to assess all the causes of sea level variations along the
450 West African coast. *Melet et al.* [2016] determined the processes responsible for coastal sea
451 level variability in the Gulf of Guinea over the 1993-2012 period. They showed that in Cotonou
452 (Benin), the sea level trend is largely dominated by the same ocean signal as observed in the
453 altimetric data and, to a lesser extent, by interannual variability of the wave run-up height.

454 In the late 1990s, the Ocean Data and Information Network for Africa (ODINAFRICA,
455 www.odinafrica.org) project was initiated in order to develop an African sea level observing
456 network as part of the GLOSS Core Network, and rescue historical sea level data. Today, this
457 project brings together more than 40 marine-related institutions from 25 African countries to
458 address the challenges of accessing data and information for coastal management.

459 **4.3.5. Tropical Atlantic RSL hotspots: Summary**

460 • ***Guyana, Suriname and French Guiana*** are in the world top 10 countries mostly impacted
461 by a 1-m sea-level rise [*Dasgupta et al.* 2009]. About 6% of people in these regions would
462 be displaced, leading to high probability of climate-induced massive population
463 displacements.

464 • ***Brazilian coast:*** The enhanced sea level rise at Cananeia makes it a sea level hotspot. Is
465 the RSL trend at Cananeia a local anomaly or should it be seen as a typical value along the
466 Brazilian coast? It is difficult to answer this question now, as the number of long-term TGs
467 is insufficient to resolve RSL trends variations along the western South America coast.

468 • ***Cartagena in Colombia:*** With a RSL trend faster than 5 mm/yr and 1 million inhabitants,
469 this is a site of great concern. The problem is complicated by the fact that contribution of
470 land movement to the observed RSL is not yet reliably established. Consequently, any
471 projections of future RSL changes should be assessed with due care.

472 • ***Northeastern coast of the Gulf of Mexico:*** The region within and around Mississippi delta
473 is experiencing the fastest RSL rise measured by TGs in the tropical Atlantic. Land
474 movement, due to sedimentation processes and water/oil/gas withdrawals, drives the long-
475 term RSL changes in this region.

- 476 • **Niger Delta** is sinking much faster than GMSL is rising [Syvistki *et al.* 2009]. The high
477 subsidence rate (25-125 mm/year), due to oil and gas extraction, combined with reduction
478 in aggradation plus accelerated compaction of sediment, makes this delta, along with the
479 Nile River Delta, the most threatened among the African deltas [Syvistki *et al.* 2009].

480 **4.4.Pacific Ocean**

481 **4.4.1. Central America and South America**

482 The Pacific coast of South America is a tectonically active zone driven by subduction of the
483 Pacific plate. Little information about the long-term RSL trends along this coast is available,
484 except from the earlier analysis by *Aubrey et al.* [1988] and *Emery and Aubrey* [1991] who
485 have reported highly variable sea level trends with changing signs all along the coast of Chile
486 and Peru. These trend variations were attributed to non-uniform tectonism, faulting and
487 segmentation of subducting lithosphere. Inspecting the updated PSMSL RLR data set, we found
488 9 TG records spanning more 30 years from Mexico to Chile. An interesting result is that, along
489 the west coast of South America, 5 of 6 long-term stations (Figure 4.2 and Table 4.4) reveal a
490 decreasing RSL with a trend of about -1 mm/yr. This value indicates a coastal uplift at a rate
491 of ~ 2 mm/yr provided that we take ~ 1 mm/yr as a trend of ASL rise along the coast of Chile-
492 Peru from altimetry (Figure 4.3). Obviously, this evaluation should be taken with care because
493 trend uncertainties are quite large (Table 4.4 and Figure 4.3). Notice, nevertheless, that a 2
494 mm/yr land emergence was detected by GPS at Callao, although this value was estimated from
495 5-year long measurements (Table 4.4). As to the southern most tropical Chilean TG Caldera, it
496 manifests a positive RSL trend of about 2.8 mm/yr, which is larger than 1.7 mm/yr estimated
497 by *Emery and Aubrey* [1991] from a shorter period. The noticeable difference between our
498 estimates and those of *Emery and Aubrey* [1991] might result from significantly longer time
499 series used in our analysis. The long-term series are necessary to separate the trend from
500 interannual and, especially, decadal sea level fluctuations that are particularly strong in this
501 region. These low-frequency sea level variations are driven by El Niño and have been
502 extensively investigated since 1960s [Rodén 1963; Wyrski 1973, 1975; Mitchum and Wyrski
503 1988; Enfield 1989; Clarke 2014]. Recently, *Losada et al.* [2013] estimated that ENSO explains
504 more than 65% of the mean sea level variance along the Peruvian coast. According to *Reguero*
505 *et al.* [2015], the number of inhabitants affected by El Niño events, in addition to future sea
506 level rise, will be substantial not only in Peru and Ecuador but in Panama, El Salvador, Costa
507 Rica and Guatemala impacting more than 30% of population in these countries. *Hallegatte et*

508 *al.* [2011], in a global study of losses due to future floods in coastal cities, identified Guayaquil,
509 the largest and the most populated city in Ecuador, to be at particularly high risk.

510 Farther northward, in Central America, the century-scale Balboa record, the longest on the
511 American tropical coast, shows a RSL trend of about 1.5 mm/yr that is comparable to the ASL
512 trend measured by altimetry (Figure 4.3). The two available 30-year long Mexican TGs have
513 large, statistically significant, RSL trends. Acapulco, with more than 700 000 inhabitants, faces
514 sea level rising at a rate of 8.4 mm/yr that places this city as a RSL hotspot: the RSL is rising
515 here at the rate among the fastest measured worldwide. A smaller (4.4 mm/yr) but yet
516 appreciable RSL trend was estimated at Guaymas, a low-lying city in northwestern Mexico.
517 Along the Mexican South Pacific coast, the altimetry dataset has non-significant ASL trend
518 over the last 22 years. *Buenfil-López et al.* [2012] showed that the RSL in this region is affected
519 by seismic activity that can generate instantaneous fall in sea level. The GPS stations in Mexico
520 have not yet provided reliable long-term estimates and we cannot reliably evaluate the land
521 movement contribution to the observed RSL rise at Acapulco and Guaymas.

522 **4.4.2. Southeast Asia**

523 Approximately 20% (~ 134 million) of the world's population living in a contiguous area along
524 the coast, within less than 10 meters above sea level, can be found in seven Southeast Asian
525 countries: Vietnam, Cambodia, Thailand, Indonesia, Philippines, Malaysia, and Singapore
526 (LECZ database, Figure 4.1). The first four are among the top 10 countries in the world with
527 the highest number of people living within less than 10 m above sea level [*McGranahan et al.*
528 2007]. Most of the megacities in this region are located either in coastal areas or within a large
529 delta, with rich alluvial soils used for agriculture and aquaculture. A series of rapidly
530 developing megacities is located in large deltas, such as Bangkok (~6 million inhabitants), the
531 capital of Thailand in the Chao Phraya River delta (Figure 4.1) and Ho-Chi-Minh city
532 (Vietnam), of ~8 million inhabitants situated in the Mekong River Delta (Figure 4.1). The
533 natural resources in this region will also be profoundly impacted by RSL. Thus, concerning the
534 mangrove forest persistence in Indo-Pacific region, *Lovelock et al.* [2015] projected that some
535 sites subject to sea level rise, with low tidal range and low sediment supply, could be submerged
536 by 2070s. This is the case in Chao Phraya and Mekong deltas, where vulnerability to sea level
537 rise is exacerbated by anthropogenic activities, as groundwater extraction and dam construction
538 [*Lovelock et al.* 2015]. In southern China, the Pearl River Delta, one of the most populated areas

539 in the Chinese mainland [*Wolanski* 2006], is home to several megacities (~8 million inhabitants
540 each) as Shenzhen, Guangzhou, and Hong Kong. *Hanson et al.* [2011] evaluated the exposure
541 of the population of the world's large cities to coastal flooding hazard by 2070s, and concluded
542 that only twelve countries contain 90% of the total of 148 million people exposed. (China
543 (21%), Vietnam (9%), Thailand (3%), and Indonesia (2%) are among the top 10 countries.)
544 They also pointed that the exposure in 2070s varies disproportionately in deltas among the top
545 10 cities: Guangzhou (~10 million people exposed), Ho Chi Minh City (~9 million), Bangkok
546 (~5 million) and Hai Phòng (~5 million, Vietnam).

547 We updated analyses of TG records from eastern Asia previously performed by *Emery and*
548 *Aubrey* [1986, 1991] and *Yanagi and Akaki* [1994]. The sea level records selected from the
549 PSMSL database are the RLR series spanning at least 30 years, except for two stations Kota
550 Kinabalu and Tawau (28 years) which are the only available data from Borneo Island (Table
551 4.5). We investigated for significant RSL trends in this region, from Vietnam to South China.
552 In Vietnam, we found 3 significant RSL trends: in the North at Hondau, 2 mm/yr, and in the
553 South at Danang and Vungtau, on an average, 3.4 mm/yr. There are no TGs from Cambodia
554 available at PSMSL; the same is the case with the Mekong delta, though more than 20% of the
555 national population lives in this area, which is also a vital agricultural zone. *Fujihara et al.*
556 [2015] analyzed water level trends from 24 river gauge stations (over 1987-2006) managed by
557 the Mekong River Commission. These stations located in the delta, and influenced by both
558 inflow from upstream and tidal action from the South China Sea and the Gulf of Thailand, can
559 also deliver relevant information about the RSL. *Fujihara et al.* [2015] estimated a RSL trend
560 of ~ 7.4 mm/yr over 1987-2006 in the Mekong Delta, attributing 20% of this trend to ASL rise
561 and 80% to land subsidence. *Erbani et al.* [2014], using interferometric synthetic aperture radar
562 (InSAR), estimated a rate of land subsidence, mainly due to groundwater pumping, throughout
563 the Mekong Delta in the range 10–40 mm/yr during 2006-2010. Their projection is that, if
564 pumping continues at this rate, a land subsidence of ~0.9 m (0.35–1.4 m) is to be expected by
565 2050.

566 There are 3 long-term TG records available from Thailand. In the cities of Ko Sichang and Ko
567 Lak, we estimated an RSL rate of 0.8+/-0.5 mm/yr. The Fort Phrachula TG is located at the
568 coast of the Chao Phraya delta, just south of Bangkok, and it has an RSL trend of ~15 mm/yr.
569 This very fast RSL rise, is due to land subsidence induced partly by natural compaction of
570 deltaic sediments and amplified by overpumping of groundwater, changing non-linearly with

571 time since 1955 [*Emery and Aubrey, 1991; Phien-wej et al. 2006*]. Over the past 35 years, the
572 land subsidence rate reached 120 mm/year and nowadays ranges from 20 to 30 mm/yr [*Phien-
573 wej et al. 2006*]. The work of *Phien-wej et al. [2006]* suggests that for each 1 m³ of groundwater
574 pumped out in the Bangkok Plain, it is approximately 0.10 m³ of ground that is lost at surface.

575 In Peninsular Malaysia, the average RSL trend, estimated from 4 TGs, in operation since 1980s
576 to 2015, is about ~3 mm/yr. At the southern tip of the Malaysian Peninsula, in Singapore, the
577 RSL trend is about 2-3 mm/yr since 1970s. These estimates are consistent with the results of
578 *Tkalich et al. [2013]* who reported an RSL trend of ~2.3 mm/yr. The Singapore mainland is
579 subsiding at a rate of 1.5-7 mm/yr [*Catalao et al. 2013*].

580 Along the Indonesian Pacific Coast, there are no RLR TGs available at PSMSL. However,
581 *Fenoglio-Marc et al. [2012]* used two TGs located on the Pacific coast of Java province from
582 the Metric PSMSL database: Jakarta (1993–2011) and Surabaya (1993–2009). In Surabaya,
583 they estimated an RSL trend of 8.8 mm/yr and -21.3 mm/yr at Jakarta, compared to an ASL
584 trend of 3.8 mm/yr from altimetry at both locations. Combining these two techniques, they
585 detected a high land subsidence rate at Jakarta of -19.7 mm/yr and of -5.3 mm/yr at Surabaya.
586 The megacity of Jakarta (~ 10 million inhabitants) is located in a lowland area in the northern
587 coast of West Java and is subject to land subsidence mainly induced by excessive groundwater
588 extraction [*Abidin et al. 2010*]. From levelling surveys, GPS observations and InSAR analysis,
589 *Abidin et al. [2015]* estimated the rate of land subsidence in Jakarta in the range 30-100mm/yr
590 during 1974-2010. *Chaussard et al. [2013]* performed a global survey of Sumatra and Java,
591 using a method of differential SAR interferometry (D-InSAR), and identified land subsidence
592 in 5 major coastal cities, mainly due to groundwater extraction, in the range 20-240 mm/yr
593 during 2006-2009. Moreover, at Jakarta, *Hanson et al. [2011]* estimated that more than 2
594 million people will be exposed to coastal flooding by 2070s. Considering the Coral Triangle
595 countries, including Indonesia, Malaysia, Philippines, East Timor, Papua New Guinea, and the
596 Solomon Islands, *Mcleod et al. [2010]* demonstrated that the sea level rise (scenario: sea level
597 rises up to 0.4 m by 2100 and without adaptation) will significantly affect coastal population
598 and habitats, and Indonesia will be a country which is likely to be most affected by coastal
599 flooding, with ~ 6 million people impacted annually by 2100.

600 In East Malaysia, located on the island of Borneo, only two long TGs are available and both
601 they manifest a strong RSL trend of ~ 4 mm/yr since 1990s, consistent with the ASL trend from
602 altimetry (Figure 4.3) over the same period.

603 In Philippines, 5 acceptable TGs (Figure 4.2) are available, and they span 44 to 68 years. The
604 3 TGs located on the eastern side of the archipelago have high RSL trends of: ~ 5.5 mm/yr at
605 Davao and Legaspi; and ~ 14 mm/yr in Manila. In the west, the Cebu TG has a RSL trend of
606 0.9 mm/yr. These differences in trend can be explained by land subsidence, which is larger on
607 the eastern side of the subduction zone, and there is a marginal land uplift on the opposite side
608 [Emery and Aubrey 1991]. In Manila, Rodolfo and Siringan [2006] showed that a much higher
609 rate of RSL is induced by land subsidence, linked with the increase in groundwater pumping
610 and consistent with the population growth curve over the same period. The GPS station (PIMO
611 2.7 mm/yr, Table 4.5), located 13 km northeast from the TG, and the DORIS station (3.2
612 mm/yr), located 10 km southeast from the TG, show, in agreement, an uplift rather than
613 subsidence [Santamaría-Gómez et al. 2017]. This indicates a significant spatial variation in
614 vertical displacements around the TG. Raucoules et al. [2013] demonstrated, from D-InSAR,
615 that Manila was locally affected by vertical ground motions of about 15 cm/yr from 1993 to
616 2010. Therefore, the impact related to human-induced subsidence is already evident in Manila
617 city. In this context, the results of Perez's et al. [1999] on vulnerability analysis suggest that
618 most areas along the coast of Manila Bay (including Manila city) could succumb, from both
619 physical and socio-economic standpoints, to a 1 m sea level rise by 2100.

620 In South China, we found 3 TGs with a time span of at least 50 years. We estimated RSL trends
621 of: ~ 2 mm/yr at Kanmen and Zhapo, and ~ 1 mm/yr at Xiamen. Tseng et al. [2010] estimated
622 from TGs, around Taiwan, an RSL trend of 2.4 mm/yr from 1961 to 2003 and 5.7 mm/yr during
623 the period 1993-2003. Ding et al. [2001] estimated an RSL trend at Hong Kong around ~ 2
624 mm/yr over 1954-1999. Two TG records in Hong Kong from the RLR PSMSL dataset have
625 similar RSL trends of ~ 3 mm/yr (Table 4.5). Guo et al. [2015] estimated vertical land movement
626 along the South China coast from TGs and satellite altimetry, and found subsidence rates
627 varying from 6 to 17mm/yr. At Shenzhen, land subsidence at a rate of 25mm/year was detected
628 over 2007-2010, by the method of Small Baseline Subset InSAR (SBAS-InSAR, Xu et al.
629 2016). In the Pearl River Delta, the RSL changes seem to be essentially controlled by vertical
630 movements of active faults [Mei-e, 1993]. He et al. [2014] reconstructed the regional sea level,
631 by combining TGs and altimetry, over the period 1959-2011 and estimated that sea level has

632 risen at a rate of 4 mm/yr in the Pearl River Delta. They determined different spatial patterns
633 of variability in the river mouth and along the coastline. In this region, there is no clear
634 consensus on the causes of long-term RSL changes. Many more studies are urgently needed to
635 understand the causes of observed RSL changes in order to mitigate potential disasters
636 associated with future SL rise

637 In light of the results mentioned above, the major concern of this region is that the rates of RSL
638 rise are one to two times higher (and much more at Bangkok and Manila) than the GMSL trend
639 over the 20th century. These results are confirmed by estimates from the sea level reconstruction
640 (Figure 4.4) that vary around ~3 mm/yr since 1960 and 3-5 mm/yr since 1993 (Figure 4.3).

641 Recent analysis of the regional sea level variability in the Gulf of Thailand, including GPS-
642 derived rate of vertical land movements, provides a rate of ASL rise of about 5 mm/yr since
643 1940s and 3-6 mm/yr over the altimetry era [*Trisirisatayawong et al.* 2011]. In this region, the
644 impact of the post-seismic motion due to the 2004 Sumatra-Andaman earthquake on the RSL
645 rate is of the order of -10 mm/yr [*Trisirisatayawong et al.* 2011]. Furthermore, there are
646 indications that RSL rates increased significantly at all locations (20–30 mm/y almost
647 everywhere [*Saramul and Ezer* 2014]) after this earthquake.

648 Many studies have shown that in South China Sea, the interannual sea level variations are linked
649 to ENSO [*Rong et al.* 2007; *Han and Huang* 2009; *Peng et al.* 2013] and to the Pacific Decadal
650 Oscillation (PDO, [*Deng et al.* 2013; *Wu et al.* 2014; *Strassburg et al.* 2015]). The Indian Ocean
651 Dipole (IOD) influences interannual sea level variations in the southwestern (Malaysia
652 Peninsula and Singapore Strait) and southeastern (Borneo Island) coastal regions [*Soumya et*
653 *al.* 2015]. The sea level trends are greatly masked by a low-frequency variability associated
654 with the PDO [*Strassburg et al.* 2015; *Cheng et al.* 2016]. Since 1990s, there has been a major
655 phase shift of PDO; this phase shift is associated with an intensification of the trade winds at
656 the equator, storing warm water and increasing sea level in the western tropical Pacific, and
657 reducing it along the west coast of the Americas [*Merrifield et al.* 2012]. Hence, the accelerated
658 sea level rise seems to be a part of global adjustment to this PDO phase shift [*Cheng et al.*
659 2016]. Thus, it is important to take into account this natural decadal variability in the future sea
660 level trend estimates in the South China Sea, where sea level rise expected to be much more
661 intense.

662 4.4.3. Western Tropical Pacific (WTP) Islands

663 Over the past several decades, there is a large scientific consensus on the threat hanging over
664 small islands, and, particularly, on the western tropical Pacific (WTP) islands, due to rising sea
665 levels associated with global warming [*Nurse et al.* 2014]. The future stability, and survival, of
666 the nations of these small islands is a major international concern. A large number of studies,
667 using TG data, altimetry observations, past sea level reconstruction and global models, have
668 revealed patterns of a recent enhanced sea level trend in the WTP (among others [*Church et al.*
669 2004; *Merrifield* 2011; *Becker et al.* 2012; *Merrifield et al.* 2012; *Meysignac et al.* 2012b;
670 *Zhang and Church* 2012]). Inspecting the updated PSMSL RLR data set, we found 22 TG
671 records spanning more than 30 years in the WTP region. Interestingly, 12 out of 22 long-term
672 stations (Table 4.6) reveal an increasing RSL, with a trend greater than the 20th century GMSL.
673

674 *Merrifield* [2011] highlighted an abrupt sea level rise in WTP since the early 1990s, compared
675 to the last 40 years. *Becker et al.* [2012] showed that the RSL rate at Funafuti Island (Tuvalu)
676 is ~5 mm/yr over 1950–2009, which is about 3 times larger than the GMSL rise over the same
677 period. These results are confirmed by our estimates from the sea level reconstruction that
678 estimates the trends in the range 4–5 mm/yr since 1960 (Figure 4.4) and 5–11 mm/yr since 1993
679 (Figure 4.3). In the WTP region, superimposed on these trends are transient interannual and
680 decadal sea level variations of the order of ± 20 –30 cm [*Becker et al.* 2012]. This interannual
681 and decadal sea level variability is attributed to low-frequency Pacific trade wind fluctuations,
682 associated with low-frequency modulations of ENSO and PDO [*Merrifield*, 2011; *Zhang and*
683 *Church* 2012; *Moon et al.* 2015; *Palanisamy et al.* 2015]. However, the processes operating
684 over longer timescales, and especially the influence of the Indian Ocean, are still under debate
685 [*Han et al.* 2014; *Moon et al.* 2015; *Mochizuki et al.* 2016]. *Han et al.* [2014] argued that the
686 intensified decadal and multidecadal sea level variability results from a phase shift in sea
687 surface temperature between the Indian Ocean and tropical Pacific. In addition, at many islands
688 in this region, the RSL can be affected by crustal deformation due to volcanic and tectonic
689 activities. For example, *Ballu et al.* [2011] reported large earthquake-related land subsidence at
690 the Torres Islands (Vanuatu) between 1997 and 2009, which added to the absolute sea level,
691 generating RSL rise of ~20 mm/yr.

692
693 The increased island sensitivity to changes in human settlement patterns, and in socioeconomic
694 and environmental conditions, makes it far more difficult to detect and attribute climate change
695 effects. This also remains a source of debate in the scientific community [*Nurse et al.* 2014].

696 Over the past few decades, from a limited number of studies, no clear linkage between WTP
697 island shoreline recession and recent sea level rise was found [*Webb and Kench* 2010; *Le*
698 *Cozannet et al.* 2013; *Kench et al.* 2015; *McLean and Kench* 2015; *Duvat and Pillet* 2017] but
699 net changes in shoreline position have been observed. However, *Kench et al.* [2015] question
700 the islands' capacity to continue maintaining their current dynamic adjustment to higher rates
701 of sea level change, as those expected by 2100. A recent study by *Albert et al.* [2016] highlights
702 that the rates of some Salomon Islands shoreline recession are substantially higher in areas
703 exposed to high wave energy, indicating a synergistic interaction between sea level rise and
704 waves. Therefore, shoreline changes and floods seem to result from extreme events, and from
705 maladaptive trajectories exacerbated by the sea level rise [*Duvat et al.* 2013].

706 4.4.4. Tropical Pacific RSL hotspots: Summary

- 707 • *Acapulco (Mexican South Pacific coast)* with more than 700 000 inhabitants faces a sea
708 level rise at a rate of 8 mm/yr, one of the fastest rates along the Pacific coast of America.
709
- 710 • *Mekong Delta* is a hotspot with an RSL rise of 7 mm/yr over 1987-2006. *Fujihara et al.*
711 [2015] estimated that 80% of this rate is due to land subsidence. The delta is likely to
712 subside even faster, at a rate of 10-40 mm/yr, as revealed by InSAR analysis over 2000-
713 2010.
- 714
- 715 • *Chao Phraya Delta (Bangkok)* faces an RSL rise of 15 mm/yr, but the current subsidence
716 is probably larger, being about 20 to 30 mm/yr [*Phien-wej et al.* 2006] with a milder ASL
717 trend of 3-5 mm/yr.
- 718
- 719 • *Jakarta megacity (Indonesia)* is one of the world's cities most threatened by rising RSL
720 with a high population density, fast land subsidence of 20 mm/yr or larger (InSAR 20-240
721 mm/yr), and an enhanced ASL rate of 5-7 mm/yr.
- 722
- 723 • *Manila megacity (Philippines)* is an indisputable RSL hotspot due to land movement
724 induced by a variety of processes in this region. The contribution of ASL rise (5-7 mm/yr)
725 and the interannual variations due to ENSO are not negligible either.
- 726

727 • ***Almost all the Western Tropical Pacific Islands*** are subject to pronounced ASL rise. In
728 combination with land subsidence induced by tectonic faults and the Pacific subduction
729 zone (e.g. Vanuatu), some of the WTP islands can face rapid coastal submergence in the
730 future.

731

732 **4.5.Indian Ocean**

733 **4.5.1. Bay of Bengal**

734

735 The Bay of Bengal (BoB), located in the northern Indian Ocean is surrounded to the east by
736 Bangladesh and Myanmar, and to the west by India. The BoB is the largest bay in the world,
737 and is unique in many ways. Today, a quarter of the world's population lives in its vicinity
738 (~1.5 billion people from World Development Indicators, Mundial 2014) and more than 170
739 million people live below 10 m of coastal elevation (from LECZ, India - 7%, Bangladesh -
740 40%, Myanmar - 25% and Sri Lanka - 13% in percentage of the respective national population,
741 Figure 4.1). The population is being concentrated in megacities such as Kolkata (India, ~15
742 million inhabitants), Chennai (India, ~10 millions), and Dhaka (Bangladesh, ~18 millions), and
743 in large urban agglomerations (~ 4.5 millions) such as Chittagong in southeastern Bangladesh
744 and Yangon in Myanmar (Figure 4.1). Additionally, Dhaka and Kolkata are megacities located
745 in the low-lying Ganges-Brahmaputra-Meghna (GBM) Delta, and Yangon in the Irrawaddy
746 River Delta. Other major deltas along the India's east coast are the Krishna, Godavari and
747 Mahanadi. *Syvitski et al.* [2009] revealed that all these deltas are already threatened by rising
748 RSL. They classified the deltas as subject to: (i) high risk for the Krishna delta, due to virtually
749 no deposition of sediment and accelerating compaction, (ii) greater risk: GBM and Irrawaddy
750 deltas due to compaction of the soil exacerbating the low rate of sediment deposition; and (iii)
751 significant risk: the Mahanadi and Godavari deltas, due to lower sediment deposition rates than
752 that of ASL rise. The geographic and socio-economic situation of the BoB coast places it among
753 the most vulnerable to climate change, and to RSL rise not only in South East Asia, but also in
754 the world. *Rao et al.* [2008] demonstrated that, over the four past decades, pronounced coastal
755 erosion along the Krishna and Godavari deltas is apparently due to sediment retention at dams.
756 This result was confirmed by *Gupta et al.* [2012], who showed that increasing number of mega
757 dams and reservoirs between 1978 and 2003 on the Krishna River (9 mega-dams), Godavari (9
758 mega-dams) and Mahanadi (2 mega-dams) could be an obvious reason for the observed
759 decrease (>70%) in sediment supply. Concerning the GBM delta, *Sarwar and Woodroffe*
760 [2013], using 20 years of Landsat satellite images, noticed that the entire delta coast changed

761 little and erosion and accretion are relatively balanced. However, *Wilson and Goodbred* [2015]
762 highlighted three regions where sediment supply is insufficient to offset subsidence or erosion:
763 in the northeast (Sylhet Basin), along the Indian tidal delta plain and the fluvio-tidal transition
764 in the western and central parts of the delta. *Shearman et al.* [2013] documented, from 20 years
765 of Landsat satellite images, a net contraction of delta mangrove area, including the Sundarbans
766 region.

767
768 The RSL changes along the eastern coast of India, from West Bengal to Sri Lanka have been
769 previously estimated from two long-term (>60 years) TGs at Vishakhapatnam and Chennai
770 (RLR PSMSL) analyzed by: *Emery and Aubrey* [1989]; *Unnikrishnan and Shankar* [2007]; and
771 *Palanisamy et al.* [2014]. These studies found consistent RSL trends equal to 0.6 and 0.8 mm/yr
772 at Chennai and Vishakhapatnam (Table 4.7), respectively. Both values are significantly smaller
773 than the 20th century GMSL trend (still valid if GIA correction of ~ -0.4 mm/yr is applied).
774 Both stations are located at the border of the tectonically stable Precambrian shield and their
775 lower RSL trends were interpreted by *Emery and Aubrey* [1991] as consequence of land
776 submergence. However, the altimetry-derived and reconstructed ASL trends (Figure 4.3 and
777 4.4) near the eastern coast of India are about 1 mm/yr or larger than the RSL trends at Chennai
778 and Vishakhapatnam. Thus, the subsidence of the eastern coast of India does not seem to be
779 supported by these long-term RSL measurements.

780
781 In the northwest BoB, along the Hooghly River in West Bengal, *Emery and Aubrey* [1989]
782 found erratic RSL rates between -7 to 6 mm/yr at Saugor (1937-1982, 45yr, 4 mm/yr), Diamond
783 Harbour (1948-1982, 35yr, -7 mm/yr), Kidderpore (1881-1931, 24yr, 6 mm/yr) and Kolkata
784 (1932-1982, 50yr, -7 mm/yr). They finally omitted all these records because of a great influence
785 of cyclonic storm surges, floods, sediment compaction and datum shifts. *Nandy and*
786 *Bandopadhyay* [2011] estimated RSL trends based on three TGs (>30 yr) from the RLR PSMSL
787 dataset (Table 4.7): 1.2 mm/yr at Gangra (31 km from the sea coast), 2.8 mm/yr at Haldia (43
788 km from the sea) and 4 mm/yr at Diamond Harbour (70 km from the sea). They argued that this
789 trend variability appears to originate from the morphology of the landward-narrowing estuary,
790 with some contribution from sediment compaction. *Brammer*, [2014] detected a shift in 1975
791 in the Diamond Harbour TG, coinciding with the construction of the Farakka barrage across
792 the Ganges. This construction, and probably other upstream engineering works, may have
793 altered the RSL at Diamond Harbour, increasing the dry-season volume of freshwater

794 discharge, extending toward the freshwater zone to the mouth of the estuary and impacting the
795 tidal regime [*Sinha et al.* 1997].

796
797 Shared by India and Bangladesh, in the north of BoB, the Sundarbans region is the world's
798 largest contiguous mangrove forest that covers approximately ~10 000 km² of the GBM delta,
799 with 60% in Bangladesh and 40% in India [*Iftekhar and Saenger* 2008]. This area, directly
800 threatened by sea level rise and alteration of freshwater flux, is recognized as a global priority
801 for biodiversity conservation, especially regarding the Royal Bengal Tiger [*Loucks et al.* 2010].
802 *Brown and Nicholls*, [2015] reviewed available data, literature and documentary sources and
803 created a database of subsidence rates in the Bengal delta. They concluded an average
804 subsidence rate of 2.8 mm/yr in Sundarbans region, the lowest rate observed in GBM delta.
805 *Loucks et al.* [2010], using high resolution elevation data and a scenario of sea level increasing
806 (by 28 cm), warned that in 50 years the Sundarbans tigers could join the Arctic's polar bears
807 on the list of victims of climate change-induced habitat loss. *Rahman et al.* [2011], using
808 Landsat images, showed that the Sundarbans coastline is currently in net erosion and was losing
809 on-an-average about 5 km²/yr over 1973-2010 (~170km², i.e ~2%). *Payo Garcia et al.* [2016],
810 through a numerical model with different sea level rise scenarios (rise by 46 cm or 75 cm) and
811 taking a net subsidence of ±2.5 mm/yr, estimated that between 1 to 6% of Bangladesh
812 Sundarbans area could be lost by 2100. The results obtained in this framework suggest that
813 erosion, rather than inundation, may remain the dominant land loss driver by 2100. *Pethick and*
814 *Orford* [2013] showed a rapid rise in RSL in the Sundarbans area. They used the only three
815 available TGs, provided by Institute of Water Modelling of Bangladesh: Hiron Point (34yr),
816 Mongla (20yr) and Khulna (72yr). In the RLR PSMSL dataset, we could find the Hiron Point
817 and Khepupara TG records, but they turned out to be too short (<24 years) for long-term
818 analysis. *Pethick and Orford* [2013] found strong RSL trends of: ~8 mm/yr at Hiron Point (at
819 the mouth of Pussur Estuary), ~6 mm/yr at Mongla and ~3 mm/yr at Khulna (located 120 km
820 inland). Moreover, they argued that the mean high water level was increasing at a much faster
821 rate (14-17 mm/yr) and a large part of the signal can be attributed to tide amplification,
822 constricted by embankments.

823
824 Along other low-lying coastal regions of Bangladesh, high population density, inadequate
825 infrastructure and low adaptive capacity have made the urban residents highly vulnerable to
826 climate change [*Milliman et al.* 1989; *Choudhury et al.* 1997; *Warrick and Ahmad* 2012]. Over

827 28% of the total population (~48 million) live in urban agglomerations (World Bank indicators
828 [*Mundial* 2014]). This percentage, which was below 5% in 1974, is expected to reach to 45%
829 in 2030. At least 50% of the urban population (~23 million) live in three major cities: Dhaka,
830 Khulna, and Chittagong, where the land elevation, in whole or in part, is less than 10 meters
831 above sea level. *Hanson et al.* [2011] estimated that more than 11 million people will be
832 exposed to coastal flooding in 2070s at Dhaka, ~4 million at Khulna and ~3 million at
833 Chittagong.

834
835 *Higgins et al.* [2014], using InSAR satellite-based technique and GPS over 2007-2011, mapped
836 the subsidence within GBM delta in a region covering ~10000 km² of irrigated cropland
837 surrounding Dhaka city. The subsidence rate is about 10 mm/yr around Dhaka and may reach
838 18 mm/yr elsewhere in the area. *Brown and Nicholls* [2015] reported subsidence rates in the
839 range -1 to 44 mm/yr, with a mean of ~3 mm/yr. These rates are associated with four principal
840 processes: i) tectonics, ii) sediment compaction, iii) sedimentation, and iv) human activities
841 such as groundwater extraction, drainage and embankment building.

842
843 Some studies tried to estimate the effect of future RSL rise on Bangladesh coast. *Huq et al.*
844 [1995], among others, estimated that a 1-meter rise can flood ~17% of land area and lead to
845 displacement of more than 13 million people. *Arfanuzzaman et al.* [2016] estimated that with a
846 71 cm rise (with respect to 1980–1999 levels), up to 25% of Bangladesh wetlands could be lost
847 by 2100. *Ruane et al.* [2013] studied the impact of climate changes through different parameters
848 on agricultural production in Bangladesh. They show that the agriculture production in southern
849 Bangladesh is severely affected by sea level rise. The projections of production lost due to
850 coastal inundation, associated with 27 cm of sea level rise, could reach 20% in southern
851 Bangladesh (and 40% with 62 cm sea level rise).

852
853 Finally, there is no clear consensus about the response of the GBM delta to natural and human
854 forcings over decadal to century timescales. Moreover, all the studies on climate change
855 impacts focused on coastal flooding by applying a simplified sea level rise scenario, yet an
856 uncertainty of 10 centimeters of RSL rise may result in major consequences for local people
857 [*Lee* 2013]. Despite the crucial importance of this problem, very few studies have focused on
858 assessing the actual RSL rates along the Bangladesh coast.

859

860 *Singh* [2002] estimated RSL trends from three TG records (22-year, 1977-1998) provided by
861 the Bangladesh Inland Water Transport (BIWTA): in the west, at Hiron Point ~4 mm/yr, in the
862 center, at Char Changa ~6 mm/yr and, in the east, at Cox's Bazar ~8 mm/yr. They argued that
863 difference between these three RSL trends is probably due to local land subsidence in the
864 eastern Bangladesh region (around Cox's Bazar). *Lee* [2013] used the Hiron Point TG record
865 over 1990-2009 to reconstruct, by using ensemble empirical mode decomposition technique,
866 the past RSL over 1950-2009 and found an RSL trend of ~8mm/yr. *Sarwar* [2013] used TG
867 records, collected from the Bangladesh Water Development Board (BWDB), BIWTA and the
868 Metric PSMSL dataset, and provided a comprehensive analysis of sea level changes in the
869 region. They considered 13 TG records having at least 14 years of data, but a lot of
870 discrepancies appeared in the trend analysis.

871
872 Along the Myanmar coast and within the Irrawady Delta, where ~11 million people live, only
873 one long-term RLR TG record is available at PSMSL: the Yangon TG, operated during 1916-
874 1962. Unfortunately, about 47% observations are missing in this record. There are also 3 old
875 stations but with the record length under 10 years (Akyab, Moulmein and Amherst). It is an
876 encouraging fact that since 2006 these locations have been re-instrumented and current data are
877 now available from the Metric PSMSL dataset. The delta coast seems to be, more or less in
878 equilibrium, and sediment deposition currently balances subsidence and sea level rise [*Hedley*
879 *et al.* 2010]. This can be explained by fewer numbers of large dams relative to its Asian
880 neighbors. However, this situation is now rapidly changing with extensive damming projects
881 in the basin. At Yangon, *Hanson et al.* [2011] project that, by 2070s, more than 5 million people
882 could be exposed to coastal flooding.

883
884 A large part of the recent RSL trends estimated in the eastern BoB can be attributed to the ASL
885 rise. Over 1993-2014, the rate of ASL trend is in the range 3-5 mm/yr along the GBM coast
886 and in the eastern part of the BoB, and 1.8-5 mm/yr along the eastern coast of India (Figure
887 4.3). Over 1960-2014, the sea level reconstruction gives an ASL trend of 2.5-3 mm/yr along
888 the GBM coast and the eastern part of the BoB, and in 1.8-2.5 mm/yr along the east coast of
889 India (Figure 4.4), which is greater than the 20th century GMSL.

890
891 This finding was previously reported by *Church et al.* [2004], who found the fastest rate of ASL
892 rise (4-5 mm/yr) in the north-eastern Indian Ocean over the period 1955–2003. *Han et al.*

893 [2010], combining *in situ* and satellite observations with climate model simulations, identified
894 a significant sea-level rise since 1960s in Indian Ocean (except in its southern tropical region).
895 They demonstrated that changing surface winds, linked to the strengthening of the Indian Ocean
896 Walker and Hadley circulations, drive this pattern. However, a recent decadal reversal in the
897 upper-ocean-temperature trends is observed in the North Indian Ocean (north of 5°S, [*Nieves*
898 *et al.* 2015]). An increase in the sea surface height decadal rate of ~6 mm/yr was estimated
899 between the period of 1993-2003 and that of 2004-2013 from analysis of satellite altimetry data
900 [*Thompson et al.* 2016]. *Thompson et al.* [2016] showed, through numerical model simulations,
901 that this reversal has resulted from the combined effects of changing upper-ocean heat
902 redistribution and the cross-equatorial heat transport, both being associated with decadal
903 changes of surface winds.

904
905

906 **4.5.2. Arabian Sea, Persian Gulf and Maldives**

907 The Arabian Sea is a region, in the northwest part of Indian Ocean, at strikingly intense
908 geopolitical and economic crossroads, notably via marine trade route for oil and gas resources
909 export. We find the major harbors of Kochi and Mumbai on the southwest coast of India, and
910 further in the northwest, the largest and most frequented ports serving the Arabian Sea, and, in
911 the northeast, the major port of Karachi in Pakistan. Mumbai and Karachi are two large global
912 megacities (with more than 10 million inhabitants, Figure 4.1). The city of Karachi had a high
913 population growth rate of 5.3% over 1960-2010 [*Singh* 2014]. On average, over the same
914 period, Asian megacities faced an annual population growth rate of 3.7% against a rate of 2.6%
915 in in the rest of the world [*Singh* 2014]. Mumbai, with a current population of about 20 million,
916 expects to achieve a 35%-growth rate by 2025, and in Karachi, the current population of 14
917 million is expected to see an increase of 45% by 2025 [*Kourtit and Nijkamp* 2013]. These cities
918 already face major challenges of flooding and aquifer salinization, amplified by regional sea
919 level rise. The situation is being further aggravated in the Indus Delta along Pakistan's coast, in
920 Sindh province. This river system, among the largest deltas on Earth, is dominated by human
921 activity since 19th century and is presently affected by (1) artificial flood levees, (2) barrages
922 and their irrigation canals, (3) sediment impoundment behind upstream reservoirs, and (4) inter-
923 basin diversion [*Syvitski et al.* 2013]. Consequently, there is a drastic reduction of sediment flux
924 by more than 90% [*Giosan et al.* 2006; *Syvitski and Kettner* 2011], which increases coastal
925 retreat, seawater intrusion and flooding. Moreover, *Ferrier et al.* [2015] showed that, in the

926 Indus delta over the past 100 years, as much as ~ 0.5 mm/yr of the sea level trend can be linked
927 to erosion and deposition of sediment since the last glacial–interglacial cycles. Another
928 important process occurs in this specific region: the influence of the groundwater depletion,
929 deforming the Earth’s solid surface and depressing the geoid and slowing sea level rise near
930 areas of significant groundwater loss [Veit and Conrad 2016]. Veit and Conrad [2016] define
931 important groundwater depletion regions in Northwest India, Northeast Pakistan and in the
932 Arabian Peninsula, with a consequential slowdown in sea level rise by $\sim 0.5 \pm 0.1$ mm/yr since
933 1930. Their work suggests that RSL in this region is currently as much as ~ 50 mm lower than
934 it would be in the absence of global groundwater depletion.

935 *Emery and Aubrey* [1989] investigated the relative long-term sea level from the Indian TGs
936 during 1878-1982. On the west coast of India, they selected 3 TGs from the PSMSL dataset at
937 Mumbai (also known as Bombay), Mangalore and Kochi (or Cochin) with a time length
938 sufficient to detect significant changes. The longest and most coherent is the record of Mumbai
939 (105 years, 1878-1982) presenting a significant linear sea level trend of -0.9 mm/yr, followed
940 by the Kochi record (43 years, 1878-1982) with a trend of 1.3 mm/yr and the Mangalore series
941 (24 years, 1953-1976) that has a -2.1 mm/yr trend. These trends show a strong discrepancy,
942 probably due to differences in the record lengths. *Unnikrishnan and Shankar* [2007] conducted
943 complete reanalysis of these records. They estimated significant RSL trends from PSMSL TGs
944 having at least 40 years length. In Arabian Sea, the TGs of Aden (58 years, 1880-1969), Karachi
945 (44 years, 1916-1992), Mumbai (113 years, 1878-1993), and Cochin (54 years, 1939-2003)
946 were selected. The RSL rise estimated from these stations is between 1.1 – 1.7 mm/yr. We
947 updated the RSL trends at Cochin to be 0.7 mm/yr and at Mumbai to be 1.5 mm/yr (Table 4.8),
948 and ~ 1.8 – 2.5 mm/yr from the sea level reconstruction (Figure 4.4). Over 1993-2014, the rate
949 of sea level rise over the Arabian Sea from satellite altimeter is ~ 1.5 – 3.5 mm/year (Figure 4.2).
950 Although slightly lower, these estimates are consistent with GMSL rates.

951 *Alothman et al.* [2014] focused on the long-term sea level rise in the northwestern Persian Gulf.
952 The average of 15 TGs records, obtained from PSMSL, produces a RSL rate of 2.4 mm/yr for
953 the period 1979–2007. Using 6 GPS stations, they estimated a subsidence rate of -0.7 mm/yr
954 in this region, in part due to excessive pumping in agricultural areas and wetting of unstable
955 soils [*Amin and Bankher* 1997].

956 The Maldives, located from 7°N to 0.5°S in the northeastern Arabian Sea, consists of 1190
957 small islands with 80% of the land area to be less than 1 m above sea level [*Khan et al.* 2002].
958 These atoll islands are morphologically sensitive to floods, tsunamis, and sea-level changes
959 [*Kench et al.* 2006]. Several studies detected a recent trend of sea level rise at the Maldives
960 [*Khan et al.* 2002; *Woodworth* 2005; *Church et al.* 2006; *Palanisamy et al.* 2014]. *Palanisamy*
961 *et al.* [2014] compared two longest TGs: Malé and Gan (~20 years of length, available from
962 PSMSL dataset), with satellite altimetry and past sea level reconstruction. They inferred a
963 significant rate of ASL rise at these two sites of $\sim 1.4 \pm 0.4$ mm/yr over 1950-2009. This rate is
964 slightly lower than the GMSL rate over the same period. However, it only represents the
965 climatic-component of sea level changes, and therefore does not take into account local
966 subsidence that can amplify the RSL change, i.e., directly felt by the population. Now, it is
967 crucial more than ever to estimate with accuracy the rate of vertical land motion at these sites,
968 because the ongoing and future sea level rise subjects the population of the low-lying Maldives
969 to enhanced vulnerability.

970 The nation of Mauritius, in the southwest, lives on a group of islands consisting of the main
971 islands of Mauritius, Rodrigues and Agalega and the archipelago of Saint Brandon. Two TG
972 records with 30-years length are available from the RLR PSMSL dataset in: the capital of
973 Mauritius Port Louis, where we found an RSL rate of ~ 4 mm/yr, and the Rodrigues Island with
974 an RSL trend of ~ 6 mm/yr (Table 4.8). These high rates are confirmed by the ASL trends from
975 the sea level reconstruction (3-4 mm/yr, Figure 4.4) and from altimetry (5-7 mm/yr, Figure 4.3).

976 Globally, long-term, interannual and decadal changes in the sea level of the Arabian Sea have
977 rarely been a subject of specific studies, probably due to the lack of historical quality data; the
978 focus has primarily been on the regional physical oceanography of the northern Indian Ocean
979 or that of the Bay of Bengal.

980 An important feature was highlighted by *Clarke and Liu* [1994] who pointed that the
981 interannual sea level signal along the Indian west coast, from the equator to Mumbai, is
982 generated by zonal interannual winds blowing along the equator. *Shankar and Shetye* [1999]
983 demonstrated that the interdecadal sea level variations recorded by the Mumbai TG closely
984 follow the monsoon rainfall over the Indian subcontinent. They explained this by the changes
985 in salinity in coastal waters, due to the seasonal fluctuations in river runoff, related to the
986 strength of the monsoon, and to the dynamics of ocean currents along the Indian coast.

987 *Shankar et al.* [2010] pointed to a much weaker interannual variability, in terms of low
988 frequency, of the Indian west coast compared to the east coast. *Aparna et al.* [2012]
989 demonstrated that the dominant climatic signals, IOD and ENSO, do not display any coherent
990 response along the eastern Arabian Sea, in contrast to the Bay of Bengal. *Suresh et al.* [2013]
991 showed that the Indian west coast intraseasonal sea level variations are mostly remotely forced
992 by the winds from equatorial region and *Suresh et al.* [2016] demonstrated that winds near Sri
993 Lanka drive 60% of Indian west coast and eastern Arabian Sea seasonal sea level. The Mumbai
994 TG, the unique century-long TG record in the Indian Ocean, was used by *Becker et al.* [2014]
995 to detect human influence on sea level rise. They provided statistical evidence, from the power-
996 law statistics framework, that 64% (i.e., ~0.7 mm/yr) of the observed sea level trend at Mumbai
997 over the 20th century could be induced by externally driven changes in the Indian Ocean
998 currents.

999 4.5.3. Indian Ocean RSL hotspots: Summary

- 1000 • **Bangladesh coast** is a sea level hotspot because of high density of coastal population
1001 that experiences devastating impact of cyclones on interannual time scale and RSL rise
1002 is enhanced by land subsidence on the decadal scale.
- 1003 • **Irrawaddy Delta** is another sea level hotspot with 11 million people living in the region.
1004 A combination of 3-5 mm/yr in the ASL rise with land subsidence of 6 mm/yr [*Syvitski*
1005 *et al.* 2009] leads to an RSL rise of more than 10 mm/yr.
- 1006 • **Mauritius Island**: A site potentially threatened by an RSL rise of 4-6 mm/yr over the
1007 past 30 years, and an indication of the ASL rising 2 to 3 times faster than the 20th century
1008 GMSL.

1009 4.6. Conclusion

1010 This chapter brings together sea level observations, and analyzes similarities and differences in
1011 past RSL changes along the tropical coasts. We first reviewed the concept of RSL and the
1012 drivers of its regional variations. We defined the RSL hotspots and described the different types
1013 of observations used to estimate it. Second, we have identified a number of RSL hotspots per
1014 oceanic basin. We highlighted the vulnerability of the tropical deltaic coasts, more specifically
1015 those of Asia, and a current knowledge gap for priority-populated areas such as Brazil,
1016 Indonesia, Philippines and Bangladesh. Obviously, this hotspot list is far from being exhaustive,

1017 because most of these regions are still not sufficiently well instrumented with quality TGs and
1018 collocated GPS stations. While waiting for obtaining in the future precise and accurate long-
1019 term sea level *in situ* measurements, new space missions are expected to provide
1020 unprecedentedly precise observations of sea level changes along the tropical coasts (e.g. the
1021 satellite missions Saral/Altika, Sentinel-3/6, Jason-CS, SWOT).

1022 Understanding and forecasting of the RSL critical thresholds along low-lying heavily populated
1023 tropical coastlines are among the most vital societal issues. High priority should be given to the
1024 development of integrated, multidisciplinary approaches to understanding the imprint of
1025 different geophysical coastal processes on the present-day RSL changes. Assessment of coastal
1026 vulnerability, in order to take appropriate measures to protect populations, can only be
1027 determined if the RSL threshold, and even more its uncertainty, are properly estimated.
