Using discrete, ultrafine alumina, highly dense transparent (71% real in-line transmission, RIT, $\lambda = 640$ nm) ceramics were achieved with grain size as small as 260 nm using standard SPS sintering. We show that use of La³⁺ as a dopant greatly reduces sensitivity to the sintering temperatures. Transparent alumina were achieved in a large range of sintering temperatures, $1140^{\circ}\text{C} < T < 1200^{\circ}\text{C}$, thus providing better reliability and flexibility into the fabrication of large sintered transparent ceramic bodies.

I. Introduction

DENSE, refractory transparent ceramics are of technological importance in high-temperature light transmitting materials,¹ armor,² IR emitters envelopes, etc.³ Indeed, ideal process routes to the fabrication of such materials will involve use of ultrafine nanoparticles along specific forming and sintering process routes. Large-scale development of such materials has been hindered by the availability of discrete, refractory nanoparticles. Their synthesis represents a challenging task face to the high driving force for sintering and coarsening existing at the high temperatures required for structure crystallization of the nanocrystals. In this context, highly transparent alumina ceramics were developed⁴⁻⁷ because they combine transparency and high mechanical properties. Indeed, sintered transparent α -Al₂O₃ ceramics displaying RIT values of 72% ($e = 0.8$ mm)² were achieved in a two-step process route including presintering under vacuum to close porosity followed by final densification using hot isostatic pressing. Another interesting transparent alumina ceramic displaying a real in-line transmission of ~69% ($e = 0.80$ mm)⁶ was obtained by high-pressure spark plasma sintering involving a uniaxial pressure of 400 MPa and an in-house experimental setup including graphite dies and WC disks. Because the best results to date require sintering processes involving several stages or specific conditions, fabrication of transparent alumina through standard densification process route is highly desirable.

With this objective, routine fabrication of transparent alumina ceramic requires availability of ultrafine Al₂O₃ nanocrystals with controlled physicochemical properties. Various process routes were recently proposed for the fabrication of ultrafine refractory nanoparticles.^{8,9} Indeed, discrete, α -Al₂O₃ ultrafine nanoparticles were recently developed and commercialized. Here, we show that using discrete, ultrafine highly pure α -Al₂O₃ nanoparticles, careful control of feature characteristics such as surface chemistry, interparticle interactions during green body forming, and grain growth during sintering will allow the formation of highly dense α -Al₂O₃ transparent ceramic through standard SPS sintering technique. Interestingly, using a specific dopant addition procedure, we demonstrate that La³⁺, a dopant previously used to improve transmittance of transparent Al₂O₃ ceramics,^{10,11} enlarges the temperature range for achieving high RIT values, providing higher flexibility for the fabrication of transparent refractory alumina ceramics.

II. Experimental Procedure

Baikowski provided α -Al₂O₃ nanoparticles aqueous slurries ($D_{50}^n = 80$ nm). The as-received slurries were centrifuged and redispersed in demineralized H₂O. Control experiments were carried out using a commercial α -Al₂O₃ dispersion displaying polycrystalline nanoparticles with an average size of $D_{50}^n = 140$ nm. Particle size measurements were made using a Mastersizer 2000 (Malvern, Worcestershire, UK) laser diffraction particle size analyzer.

The La³⁺ doping of α -Al₂O₃ nanoparticles was performed by adding La(NO₃)₃ 6 H₂O on a concentrated Al₂O₃ slurry (53 wt% α -Al₂O₃, $d = 1.6$) yielding a 0.1M La³⁺ concentration. After room-temperature stirring overnight, the slurry was centrifuged at 2000 G and redispersed into demineralized H₂O with a final 68 wt% Al₂O₃, $d = 1.95$. A doping concentration of 480 atomic ppm (ppma) La³⁺ was determined by ICP analysis on the resulting dispersion. TEM observation of the nanocrystals was performed on the purified dispersions using a JEOL JEM 1011 (JEOL, Tokyo, Japan). HRTEM was carried out on samples prepared from a small volume of sample (6–7 μ L) deposited on a lacey carbon membrane supported on TEM copper grids, followed by room-temperature drying. Images were recorded at 200 KV on a FEI TITAN G2 60–300 microscope (FEI Europe, Eindhoven, the Netherlands).

High-density green compact ($D = 20$ mm) was achieved using a liquid forming procedure.¹² The slurry was slip cast

A. Krell—contributing editor

onto 20 mm diameter porous alumina molds to avoid any contamination. All the green bodies were manually polished to obtain 2 g cylindrical samples.

Densification of the resulting compacts was performed using a standard SPS technique (HP D 25/1, FCT System, Rauenstein, Germany). Samples were sintered with the following cycle: applied uniaxial pressure of 80 MPa throughout the cycle, rapid heating up to 800°C, heating rate of 10°C/min from 800°C to 950°C followed by a slower heating rate (1°C/min) up to the final sintering temperatures. The final sintering temperature was in the 1060°C–1200°C range.

After sintering, the samples ($D = 20$ mm) were carefully mirror-polished on both sides using diamond slurries (to 1 μ m) and the transparency in the center of the pellet (spot size 5 mm $\times$ 2 mm) was determined by a (Jasco V-670, JASCO Easton, MD). Real in-line transmittance (RIT) measurements were conducted using a shield with an appropriate aperture placed between the sample and the detector to avoid scattered light with angle $> 0.5^\circ$. All the RIT values reported in this article were measured for $\lambda = 640$ nm and the RIT were normalized at similar thickness of $t_2 = 0.80$ mm using the following equation $RIT(t_2) = (1 - R_S) [(RIT(t_1)/(1 - R_S))^{t_2/t_1}]^{t_1/t_2}$ where R_S denote the total normal surface reflectance (0.14 for transparent alumina), $RIT(t_1)$ is the RIT for a sample of thickness t_1 .

III. Results and Discussion

(1) α -Al₂O₃ Ultrafine Nanoparticles and Dispersion Properties

Highly pure α -Al₂O₃ nanoparticles dispersions were prepared by HNO₃ peptization followed by post purification using ultracentrifugation and redispersion. Consistently, increased repulsive interparticle interactions as revealed from zeta potential measurement are achieved from complete removal of the residual Al³⁺ cations from the dispersions. Thus,

highly concentrated α -Al₂O₃ dispersions displaying volume fractions, Φ_v up to 0.33 were obtained due to the high degree of nanoparticles individualization.

A similar approach was adopted to the preparation of highly individualized La³⁺-doped α -Al₂O₃ nanoparticle dispersions. Fine tuning of the interparticle interactions involves absorption of La³⁺ cations on α -Al₂O₃ nanoparticles surfaces followed by post removal of the non absorbed La³⁺ cations from the dispersions. Although divalent and trivalent metal cation do not exhibit a high absorption affinity to the Al₂O₃ surface in the pH range, $3 < \text{pH} < 4$,¹³ a La³⁺ dopant concentration of 120 atomic ppm (ppma) corresponding to a surface coverage ratio of 0.01 was achieved by contacting a 0.1M La³⁺ solution and post removal of the residual La³⁺ by centrifugation at 2000 G. Likewise, stable, highly concentrated of La³⁺-doped α -Al₂O₃ nanoparticles dispersions displaying concentration up to $\Phi_v = 0.30$ were prepared.

High purity of these nanoparticles was shown by characterizations performed on solids after H₂O room-temperature evaporation from the dispersions. Chemical analysis reveals low impurity content (Na = 10 ppm, K = 15 ppm, Fe = 7 ppm Si = 18 ppm, Mg = 10 ppm, Ca = 5 ppm). X-ray diffraction performed on dried powder shows peaks attributed to the α -Al₂O₃ structure without any trace of the γ -Al₂O₃. Ordered domains of 58 nm were determined from [012], [104], [110], and [113] diffraction peaks using Debye-Scherrer formula.

A monodisperse size distribution and a mean hydrodynamic diameter of 80 nm were determined on the pure and La³⁺-doped α -Al₂O₃ dispersions by dynamic light scattering. In contrast to the reference powder [Fig. 1(d)], TEM investigation reveals discrete nanoparticles exhibiting isotropic morphology with an average size of 80 nm [Fig. 1(a)]. This average size, slightly larger than the XRD ordered domain suggests that the α -Al₂O₃ nanoparticles are indeed composed of a few number of primary crystallites. HRTEM image

Fig. 1. TEM images of α -Al₂O₃ nanoparticles. (a) Low magnification image showing perfectly discrete Al₂O₃ nanoparticles. (b) High magnification TEM images showing primary crystallites of 80 nm. Inset: Electronic diffraction pattern showing crystalline α -Al₂O₃ structure. (c) HRTEM image revealing highly crystallized interface. (d) Low magnification image of a reference powder showing non-isotropic aggregated particles.

Fig. 2. Pore diameter distribution of α - Al_2O_3 green body formed from 80 nm nanoparticles showing monodisperse pore distribution and a mean pore diameter of 18 nm. Pore distribution of the reference powder (140 nm) is also given for comparison. Inset: Pore volume suggesting a higher green density when using discrete, isotropic ultrafine α - Al_2O_3 nanoparticles.

[Fig. 1(b)] clearly reveals that the nanoparticles are monocrystalline or composed of a few number of primary crystallites.

Because sintering involves surface and grain-boundary diffusion,¹⁴ the α - Al_2O_3 nanoparticle surface was fully characterized. Indeed, peptization of nanosized α - Al_2O_3 usually leads to formation of Al polycations. Although pH of the resulting dispersions was determined around pH 3.75, no trace of $\text{Al}_3\text{O}_4(\text{OH})_{24}(\text{H}_2\text{O})_{12}^{7+}$ polymer was detected by ^{27}Al liquid NMR performed on these dispersions indicating no significant surface deterioration of α - Al_2O_3 nanoparticles after HNO_3 peptization. The well crystalline character of the α - Al_2O_3 surfaces was confirmed through a HRTEM investigation showing perfectly crystallized interface observed without presence of any amorphous phase [Fig. 1(c)].

(2) Forming, Sintering and Optical Properties

Forming of the green body was carried out by slip casting from the concentrated dispersions. Hg porosimetry performed on green compacts reveals a quasi-monodisperse pore size distribution with a mean pore diameter of 18 nm (Fig. 2). Interestingly, a green density of 58% is achieved on compacts formed from these individualized nanoparticles. Note that the reference sample composed of nanoparticles displaying a less isotropic morphology exhibits a lower green density, larger pore size distribution and a much higher mean pore size value of 32 nm.

Sintering of the slip-cast green bodies was performed by standard SPS sintering. Our temperature profile was designed with the objective to achieve full densification while inhibiting grain growth. Although activation energy of densification is generally higher than that of grain growth¹⁴ our temperature profile involves a rather low densification temperature associated with a low heating rate.¹⁵ Indeed, heating rates were shown to strongly influence the spark plasma sintering mechanism of α - Al_2O_3 and grain coarsening was greatly minimized when sintering using the designed temperature profile. Highest RIT values of the non-doped (RIT = 68%) and La^{3+} -doped (RIT = 71%) α - Al_2O_3 compacts were achieved at 1100°C and 1140°C [Fig. 3(a)], respectively. To the best of our knowledge, these values are the highest values obtained in standard SPS sintering. As lower RIT values, RIT = 53% were obtained in similar forming and sintering conditions¹² using the reference powder, characteristic features of the ultrafine α - Al_2O_3 powder such as ultrafine size, size monodispersity, and isotropic morphology are crucial parameters facilitating the formation of α - Al_2O_3 transparent ceramics.

Fig. 3. (a) Dependence of RIT of nondoped and La^{3+} -doped sintered α - Al_2O_3 on sintering temperature showing a larger range of densification temperatures with La^{3+} dopant. Inset: photographs of samples taken at 2.8 cm above the text (i) non-doped sample sintered at 1100°C. (ii) La^{3+} -doped sample sintered at 1140°C. (b) RIT and grain size of sintered alumina. RIT model curves calculated from Ref. 1 versus grain size are reported suggesting full densification of our sintered α - Al_2O_3 . The model curves (continuous line: 0.00 vol% porosity, dotted line: 0.01 vol% porosity) were obtained with an average refractive index change $\Delta n = 0.005$ with a pore diameter = 100 nm. RIT values from literature were renormalized for $e = 0.80$ mm.

Comparison of our experimental RIT values to theoretical RIT¹ values determined at different grain sizes [Fig. 3(b)] suggests a full densification for the compacts sintered at 1100°C for the nondoped samples. Using the same argument, La^{3+} -doped samples sintered between 1140°C and 1200°C display full densification. Indeed, a higher sintering temperature¹⁶ was observed for the La^{3+} -doped samples indicating diffusion blocking in the presence of La^{3+} . Note that this shift in sintering temperature for the La^{3+} -doped α - Al_2O_3 material was previously observed in natural sintering. This shift was attributed¹⁴ to reduced grain-boundary diffusivity arising from strong segregation of La^{3+} to the grain boundary. From a HRTEM investigation carried out on La^{3+} -doped α - Al_2O_3 materials at various La^{3+} content, a similar effect of the La^{3+} dopant in α - Al_2O_3 spark plasma sintering was found. Indeed, presence of secondary phase $\text{LaAl}_{11}\text{O}_{18}$ at triple junction and along some grain boundaries was only observed on samples doped at high La^{3+} content (600 ppma) while no inclusion was observed on samples doped below that concentration.

More interestingly, compared with the non-doped samples, a larger plateau of sintering temperatures yielding RIT values higher than 67% was observed with La^{3+} dopant. Although similar RIT values were determined in the range of sintering

Fig. 4. SEM images showing pure and La^{3+} -doped $\alpha\text{-Al}_2\text{O}_3$ microstructures. (a) nondoped Al_2O_3 sintered at 1100°C , (b) La^{3+} -doped $\alpha\text{-Al}_2\text{O}_3$ sample sintered at 1140°C , (c) 1160°C , (d) 1200°C .

temperatures, $1140^\circ\text{C} < T < 1200^\circ\text{C}$, fine inspection of the corresponding microstructures [Fig. 4(a)] reveals a grain growth with average grain sizes ranging from 260 to 390 nm with increased sintering temperature. In contrast, a smaller window of sintering temperatures, $1080^\circ\text{C} < T < 1100^\circ\text{C}$, was determined for non-doped materials. Indeed, for these latter samples sintered at 1060°C and 1120°C , large variations of RIT values were observed inside a same sample, depending on the region investigated. These variations of RIT values were shown to arise from different grain size probably due to slight local variations of green density. All these observations highlight the beneficial use of La^{3+} reducing sensitivity to sintering temperature.

From these results, future work aimed to the fabrication of high RIT transparent $\alpha\text{-Al}_2\text{O}_3$ ceramics will involve dispersion of agglomerate-free, mono-crystalline, ultrafine, La^{3+} -doped $\alpha\text{-Al}_2\text{O}_3$ building blocks.

IV. Conclusions

Highly dense transparent (RIT 71%) $\alpha\text{-Al}_2\text{O}_3$ ceramics were achieved using discrete, ultrafine high purity $\alpha\text{-Al}_2\text{O}_3$ nanoparticles sintered by standard SPS technique. Crucial effects of the nanoparticle characteristics, such as size monodispersity, isotropic morphology, and surface chemistry were emphasized. We demonstrate the beneficial use of La^{3+} as a dopant, reducing the sensitivity of sintering temperature, thus increasing flexibility to fabricate large homogenous transparent $\alpha\text{-Al}_2\text{O}_3$ ceramics.
