Abstract

This study focuses on the development of a pressure based method able to capture compressibility effects and phase change in turbulent two-phase flow DNS, using the Coupled Level Set/Volume of Fluid (CLSVOF) interface capturing method. A compressible VOF equation and a new pressure equation are described, including additional terms due to vaporization and compressibility. First, validation cases without phase change such as a gas-water shock tube and an oscillating water column configuration have been performed. Concerning the first case, obtained results suggests that the method is able to capture accurately the shock wave characteristics. For the second case, a reference solution is computed and compared with DNS results, showing the method accuracy and convergence.

Finally, a two-phase Homogeneous Isotropic Turbulence with compressibility and phase change is investigated. Contrary to previous works, the vaporization process has an impact on the flows dynamics. The effects of the vaporization on the gas density is illustrated and compared with a reference solution for a constant vaporization rate. Great agreement is obtained between DNS results and the reference solution. The mass balance between total mass, gas and liquid mass is also shown and demonstrates the efficiency of the CLSVOF interface capturing method regarding mass conservation, even in a turbulent atomization context.

1. Introduction

Compressible or weakly compressible liquid-gas flows occur in many fields such as liquid fuel injection, plunging waves, cavitation, sloshing, drowning damaged nuclear reactor, phase change heat transfer, pipeline of two-phase flows, etc. Liquid-gas flows has a direct impact on gas emissions (atomization in combustion engines), industrial process efficiency (heat exchanger) or coastal engineering (breaking wave). Most numerical simulations dedicated to the aforementioned applications use an incompressible formalism, which does not take into account the compressibility effects and density variation among each phase. However, compressibility can have a significant effect in a wide range of configuration, from liquid jet injection (cavitation inside an injector) to breaking wave configuration (impact of the entrained air or bubbles). Indeed, vapor production or cavitation inside an injector generate a creation of volume (non-zero divergence of the velocity field) incompatible with the standard incompressible hypothesis used mainly in liquid-gas flows simulations. In the framework of violent impact of two-phase flows as for example in an impinging liquid jet or a wave breaking process, it is well known that the presence of bubbles or entrained air close to the wall/structure has important consequences on both the flow, the structure and even the environment through the propagation of sound. In the framework of marine energy development, it has been shown that the violent expansion/compression of the gas due to acoustic wave propagation, which can also develop in shock waves in most dramatic cases, has a strong impact on the incoming wave (See Bredmose et al. (2015); Ma et al. (2016); Hu et al. (2017); Chuang et al. (2017)). Indeed, the breaking wave forces yield the highest hydrodynamic loads on substructures in shallow water, particularly plunging breaking waves. For example, the estimation of the wave impact force (load and pressure) is important in order to design offshore wind turbines substructures. Concerning liquid jet injection, linear stability analysis has shown

that the gas Mach number has a dramatic impact on the growing rate of the
30 instability and the wavelength of the most unstable wave (Zhou and Lin, 1992;
Funada et al., 2006; Tharakan and Ramamurthi, 2010). This demonstrates the
crucial importance of considering the compressibility effects.

The use of a compressible, variable-density solver is also mandatory to de-
scribe phase change in complex configurations such as liquid jet injection or
35 breaking waves. Handling phase change in numerous gas inclusion, each pos-
sessing their own gas density evolution and thermodynamic pressure, is not
straightforward. In our previous works, the phase change description was based
on an incompressible solver : first by using a passive scalar to focus on the mix-
ing process (Duret et al., 2012), then by computing the evaporation rate based
40 on temperature and species equations, allowing to evaluate the velocity jump
condition and gas dilatation (Tanguy et al., 2007; Duret et al., 2014). The lat-
ter formulation is encouraging but is not suitable with the presence of multiple
gas inclusions or in a confined environment, since the gas and vapour density
remains constant in that formalism.

45 The main objective of this article is to break a scientific barrier concerning
the numerical simulation of compressible liquid-gas flows. Indeed, the majority
of accurate numerical methods used in two-phase flows simulation with interface
tracking/capturing method can be categorized in two families: incompressible
(for instance Ménard et al. (2007)) or compressible method (Kuila et al., 2015).
50 Very different formalism are used to solve the governing equations (Poisson
solver versus Riemann solver) and only few collaborations exist between the
“incompressible” and the “compressible” communities. The drawback of these
methods is their inability to capture accurately and smoothly two-phase flows
with a wide evolution of the compressibility effects, from (very) low Mach num-
55 ber to high Mach number.

This issue was solved in the case of single phase flows or reacting flows with
the low Mach approach (reviewed in Schochet (2005)), which has been used to
represent the expansion/compression of gas and density variations. However,
this kind of approach is not straightforward in the context of two-phase flows.

60 The existence of inclusions (bubbles) of gas inside a liquid imposes a complex way to take into account the gas density variation inside each inclusion. Indeed, the thermodynamic pressure difference in each inclusion make the equation difficult to solve with a one-field approach (See Daru et al. (2010)). A solution is to account for the density variation by integrating the incoming fluxes on the
65 boundary of the bubble, or use an extension to take into account the jump of thermodynamics pressure. Nevertheless, gas inclusions and their surface have to be tracked to properly estimate the mean density variation. It means that it will be impossible to simulate realistic large scale configurations with numerous gas inclusions because of the computational cost involved.

70 Moreover, most numerical methods in the literature does not take into account all physical phenomena that can be encountered in two-phase flows: compressibility, interface deformation/breakup, viscosity, surface tension and discontinuities at the interface. For example, the recent 2D study of Bredmose et al. (2015) admits the need to smear out the liquid-gas interface, which has a
75 negative impact on the wave propagation from air to water, and also modeled the compressible gas by considering an homogeneous mixture of incompressible liquid and ideal gas as a first approach. Another example is the diffuse interface method (Saurel and Abgrall (1999)) based on the phase field model. It consists in the resolution of a unique set of equations for all the phases of the flow. The
80 phases are represented by a function that tends toward 0 in the gas part for example and 1 in the liquid part. This function, which follows a Cahn-Hilliard equation, varies continuously around the interface creating an artificial mixing zone of both phases. In order to have the right jump conditions across the interface, relaxation equations are solved and the surface tension is taken into
85 account by modifying the stress tensor. Some works include surface tension in compressible multiphase flows like Perigaud and Saurel (2005) or Braconnier and Nkonga (2009). This kind of interface is often used in parallel of a Riemann solver for high Mach number flows (Petitpas et al. (2009), Chiapolino et al. (2017)) whose numerical diffusion stabilize the interface. However, the
90 lack of interface sharpness is an issue in these methods to apply proper jump

conditions or to evaluate accurately the interface curvature.

In regards to atomization processes, most DNS/LES studies are considered incompressible, despite the fact that the initial injection velocity can be close or higher than the celerity of sound in the gas phase. For instance, in the Engine Combustion network injector called "Spray A" (Knudsen et al. (2017))
95 the injection velocity is around 600 m.s^{-1} . Pressure waves developing in front of the liquid jet are then likely to be observed. Another important topic is the cavitation process inside injectors nozzles, taking into account compressibility will give a new insight into identifying cavitation zones in the liquid phase
100 and understanding the effect of cavitation on the atomization process. This illustrates the need of new and original numerical developments to fully resolve both phases and also acoustic effects.

Some attempts have been made to solve these specific issues. The early pioneering work of Harlow and Amsden (1971) paved the way for the so-called
105 "pressure-based" methods. In their work, they used an ICE (Implicit Continuous fluid Eulerian) method to solve all flow speeds in single-phase flows. They combined both explicit resolution for high flow speeds and implicit resolution for low flow speeds, by using weighted constants which depend on sound speed. More recently, these kind of methods have been extended to two-phase
110 flows applications. Miller et al. (2013) proposed one of the first pressure-based formalism using a Volume Of Fluid (VOF) interface capturing method in OpenFOAM, showing encouraging results on underwater explosions and shock tubes configurations with large density ratio. However, the author admits that mass is not well conserved and jump conditions for variables such as density, viscosity are
115 smeared out over a few cells. Huber et al. (2015) used a primitive formulation of the compressible Navier-Stokes equations to consider compressible two-phase flows, combined with a pressure-based method similar to the one developed in single phase flow context by Kwatra et al. (2009). Acoustics terms were treated implicitly along with a proper description of surface tension forces. This method
120 has been compared with a standard compressible solver (preconditioned explicit HLLC), showing that better results have been obtained with the pressure-based

method on a oscillating bubble configuration (Rayleigh-Plesset theory). Boger et al. (2014) performed a similar study by using a pressure-based method to study shock-droplet interaction. However, these methods are coupled with a
125 Level-Set approach, making turbulent atomization difficult to handle (mass loss) and viscous effects are not taken into account.

This work aims at providing numerical tools, allowing simulations of two-phase flows covering a large range of Mach number, incorporating surface tension, acoustic/compressible effects, large density ratio, proper jump conditions,
130 viscous effects, at High Reynolds and High Weber number. We propose achieving this challenging task by improving the two-phase flows aspect of the pressure-based method proposed by Huber et al. (2015) and Miller et al. (2013) by combining it with an accurate and conservative interface representation : the Coupled Level Set/VOF interface capturing method. The main emphasis of
135 this study is on the computation of Low Mach number configurations but the method can be used as well in shock waves configurations.

In the following part of this work, the constitutive equations and numerical procedures are first described without phase change. Next, validations cases such as a gas-water shock tube and an oscillating water column configuration
140 illustrates the accuracy and robustness of the method. Finally, the potential of the method is shown by studying the impact of compressibility and dilatation induced by a vaporization source term in the pressure and VOF equation in the two-phase flow Homogeneous Isotropic Turbulence (HIT) configuration.

2. Governing Equations

The joint LS/VOF method is coupled with a projection method to carry out the Direct Numerical Simulations of compressible Navier-Stokes equations :

$$\begin{cases} \frac{\partial \rho}{\partial t} + \vec{\nabla} \cdot (\rho \vec{u}) = 0 \\ \frac{\partial \rho \vec{u}}{\partial t} + \vec{\nabla} \cdot (\rho \vec{u} \otimes \vec{u}) = -\vec{\nabla} P + \vec{\nabla} \cdot \left(2\mu \epsilon + \left(\zeta - \frac{2}{3}\mu \right) \vec{\nabla} \cdot \vec{u} \vec{I} \right) + \rho \vec{f} \end{cases} \quad (1)$$

145 with ρ , the density ; \vec{u} , the velocity ; P , the pressure ; μ , the dynamic viscosity ; $\epsilon = \frac{1}{2} \left(\vec{\nabla} \vec{u} + \vec{\nabla} \vec{u}^t \right)$, the strain rate tensor ; ζ , the second viscosity ;

\vec{f} , the force of volume by unit of mass and \bar{I} , the identity matrix. Here, both liquid and gas are considered as compressible. On the interface, surface tension is taken into account by considering the variables jump across the liquid/gas interface :

$$[\vec{n} \cdot (P\bar{I} - \bar{\tau}) \cdot \vec{n}] = \sigma\kappa \quad (2)$$

with σ , the surface tension ; κ , the total curvature ; \vec{n} , the normal to the interface ; $\bar{\tau}$, the viscous strain tensor defined by $\bar{\tau} = 2\mu\epsilon + (\zeta - \frac{2}{3}\mu)\vec{\nabla} \cdot \vec{u}\bar{I}$ and the convention $[A] = A_l - A_g$ for the variables jump across the interface.

Eq.1 is closed by two equations of state (EOS) for each phase. For the liquid, a Tait equation has been used. Concerning the gas phase, an ideal gas and an isentropic process have been considered (Laplace's law) :

$$\begin{cases} \rho_g = \left(\frac{P}{C_\gamma}\right)^{\frac{1}{\gamma_g}} \\ \rho_l = \rho_0 \left(\frac{P-P_0}{B} + 1\right)^{\frac{1}{\gamma_l}} \end{cases} \quad (3)$$

The g and l indexes denote the gas and the liquid, respectively ; γ represents the adiabatic index ; P_0 , a reference pressure ; ρ_0 , a reference density ; C_γ , a constant depending on the initial condition of the ideal gas studied and B , a constant depending on the bulk modulus of the considered fluid.

3. Numerical Methods

3.1. Interface capturing method

The interface is solved using a CLSVOF algorithm. This method allows an accurate representation of the interface with the Level Set function and the mass conservation with the VOF method. The general algorithm can be found in Ménard et al. (2007). However, in this work an additional term due to compressibility has to be taken into account in the liquid volume fraction equation. The new formulation of this equation is :

$$\frac{\partial \alpha_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \vec{u}) = \alpha_l (1 - \alpha_l) D + \alpha_l \vec{\nabla} \cdot \vec{u} \quad (4)$$

with α_l , the liquid volume fraction and D , a term representing the fluid compressibility and defined by

$$D = \frac{1}{\rho_g} \frac{D\rho_g}{Dt} - \frac{1}{\rho_l} \frac{D\rho_l}{Dt} \quad (5)$$

where $\frac{D}{Dt}$ is the material derivative. Eq.4 is derived from the continuity equation of Eq.1 by considering $\rho = \alpha_l \rho_l + \alpha_g \rho_g$ and $\alpha_g = 1 - \alpha_l$. Contrary to most studies using the CLSVOF framework, here the pressure P and the densities ρ_l and ρ_g are local variables. In the incompressible CLSVOF algorithm, the liquid volume fraction and Level Set transport equations have the same formulation and are split in the three space directions. For the sake of clarity, only the VOF transport equation is shown below :

$$\begin{cases} \frac{\tilde{\alpha}_l - \alpha_l^n}{\Delta t} + \frac{(\alpha_l^n u)_{i+\frac{1}{2}} - (\alpha_l^n u)_{i-\frac{1}{2}}}{\Delta x} = \tilde{\alpha}_l \frac{u_{i+\frac{1}{2}} - u_{i-\frac{1}{2}}}{\Delta x} \\ \frac{\hat{\alpha}_l - \tilde{\alpha}_l}{\Delta t} + \frac{(\tilde{\alpha}_l v)_{j+\frac{1}{2}} - (\tilde{\alpha}_l v)_{j-\frac{1}{2}}}{\Delta y} = \hat{\alpha}_l \frac{v_{j+\frac{1}{2}} - v_{j-\frac{1}{2}}}{\Delta y} \\ \frac{\bar{\alpha}_l - \hat{\alpha}_l}{\Delta t} + \frac{(\hat{\alpha}_l w)_{k+\frac{1}{2}} - (\hat{\alpha}_l w)_{k-\frac{1}{2}}}{\Delta z} = \bar{\alpha}_l \frac{w_{k+\frac{1}{2}} - w_{k-\frac{1}{2}}}{\Delta z} \end{cases} \quad (6)$$

Then, a final equation couples the three directions. To be coherent with the Level Set equation that has no additional term in compressible formulation, the compressibility term D of Eq.4 is only added in the final equation and Eq.6 is solved following the incompressible formalism of M enard et al. (2007). The $\alpha_l (1 - \alpha_l) D$ term in Eq.4 is implicited in two ways according to the sign of D :

$$\begin{aligned} \frac{\alpha_l^{n+1} - \bar{\alpha}_l}{\Delta t} &= -\bar{\alpha}_l \frac{w_{k+\frac{1}{2}} - w_{k-\frac{1}{2}}}{\Delta z} - \hat{\alpha}_l \frac{v_{j+\frac{1}{2}} - v_{j-\frac{1}{2}}}{\Delta y} - \tilde{\alpha}_l \frac{u_{i+\frac{1}{2}} - u_{i-\frac{1}{2}}}{\Delta x} \\ &+ \alpha_l^{n+1} \left(\frac{w_{k+\frac{1}{2}} - w_{k-\frac{1}{2}}}{\Delta z} + \frac{v_{j+\frac{1}{2}} - v_{j-\frac{1}{2}}}{\Delta y} + \frac{u_{i+\frac{1}{2}} - u_{i-\frac{1}{2}}}{\Delta x} \right) + A_{comp} \end{aligned} \quad (7)$$

$$\text{with } \begin{cases} A_{comp} = \alpha_l^{n+1} (1 - \bar{\alpha}_l) D & \text{if } D < 0 \text{ and } \alpha_l < 1 \\ A_{comp} = \bar{\alpha}_l (1 - \alpha_l^{n+1}) D & \text{if } D > 0 \text{ and } \alpha_l > 0 \end{cases}$$

A reinitialization step of the Level Set function is performed at each time step, similar to previous works done in the incompressible framework (Tanguy

et al., 2007; Ménard et al., 2007). All the geometrical informations of the interface are obtained with the Level Set function ϕ . The curvature κ is calculated
 185 by $\kappa = \vec{\nabla} \cdot \vec{n}$ with $\vec{n} = \vec{\nabla} \phi / |\vec{\nabla} \phi|$, the normal to the interface.

3.2. Projection method

Then, to compute velocity and pressure, the momentum equation of Eq.1 is solved using a projection method adapted to compressible formulation. This method allows to decouple velocity and pressure. An intermediate velocity is
 190 first calculated without the pressure term $-\vec{\nabla} P$ and the surface tension term :

$$\vec{u}^* = \underbrace{\frac{\rho^n \vec{u}^n}{\rho^*} - \Delta t \frac{\vec{\nabla} \cdot ((\rho \vec{u})^n \otimes \vec{u}^n)}{\rho^*}}_I + \underbrace{\Delta t \frac{\vec{\nabla} \cdot (2\mu \epsilon - \frac{2}{3}\mu \vec{\nabla} \cdot \vec{u}^n \vec{I})}{\rho^*}}_{II} + \Delta t \vec{f} \quad (8)$$

ρ^* corresponds to the density calculated with $\rho = \alpha_l \rho_l + \alpha_g \rho_g$ but with the new value of α_l obtained after the interface resolution. The viscous term II is solved accordingly with the method presented in Sussman et al. (2007). This method takes into account directly the viscous tensor jump across the
 195 interface. It was originally developed in a incompressible formalism, so the term $(-\frac{2}{3}\mu \vec{\nabla} \cdot \vec{u} \vec{I})$ was added in this formulation. The second viscosity ζ is neglected in this work. Moreover, no artificial viscosity has been added in this work.

Regarding the convection term I , the method of Vaudor et al. (2017) has been used ensuring consistent mass and momentum fluxes computation. The
 200 mesh is an eulerian staggered grid so the velocity is computed on the faces of the cells and the other variables (pressure, density, liquid volume fraction, ...) are computed in the center of the cells. This method initially proposed by Rudman (1998) consists in calculating the mass flux $\rho \vec{u}$ in the center of the cell by using the continuity equation. The mass flux has to be known in the center of the cell
 205 in order to have a second order centered scheme for the divergence operator. A detailed explanation of the algorithm can be found in Vaudor et al. (2017).

Then, the momentum equation is discretized in the following way by using

the intermediate velocity obtained previously.

$$\vec{u}^{n+1} = \vec{u}^* - \Delta t \frac{\vec{\nabla} P}{\rho^*} \quad (9)$$

By applying the divergence operator to Eq.9, an Helmholtz equation for the
 210 pressure is obtained (Eq.10). Contrary to the projection method used in incompressible solvers, the divergence of the velocity is no longer zero. Further details regarding the development of the pressure equation are available in Appendix A.

$$\begin{aligned} -\vec{\nabla} \cdot \left(\frac{\vec{\nabla} P^{n+1}}{\rho^*} \right) + \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) P^{n+1} = \\ \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) \left(P^n - \Delta t \vec{u} \cdot \vec{\nabla} P^n \right) - \frac{\vec{\nabla} \cdot \vec{u}^*}{\Delta t} \end{aligned} \quad (10)$$

with c_l and c_g , respectively the sound speed for liquid and gas. The $\vec{\nabla} \cdot \vec{u}^*$
 215 term is solved with a second order centered scheme and $\vec{u} \cdot \vec{\nabla} P$, with a fifth order WENO scheme (Shu, 1997). A Ghost Fluid Method (GFM) is used to apply the pressure jump due to surface tension forces (Ménard et al., 2007). The advantage of the GFM is a more realistic representation of the interface (sharp, infinitely thin) : jump conditions are directly added at the interface position
 220 through a local modification of the numerical scheme. The distance of the interface is provided by the Level Set function. The final velocity is computed by Eq.9 using a second order centered scheme for the pressure gradient. A second order predictor-corrector Runge Kutta scheme have been used for temporal integration. Finally, the density and sound speed for liquid and gas and the
 225 total density are updated with the EOS Eq.3. The compressibility term D used in Eq.4 is solved to be coherent with the pressure term :

$$D^{n+1} = \left(\frac{1}{\rho_g c_g^2} - \frac{1}{\rho_l c_l^2} \right) \left(\frac{P^{n+1} - P^n}{\Delta t} + \vec{u} \cdot \vec{\nabla} P \right) \quad (11)$$

Concerning the time step calculation, a CFL condition similar to the one used by Kang et al. (2000) is used. Thanks to the implicit resolution of the

acoustics terms in the pressure equation, the CFL condition is the same used
 230 for incompressible two-phase flows DNS. Consequently, the time step is larger
 than the one obtained with an acoustic CFL based on the sound speed. For
 $CFL = 1$, the CFL condition can be written as :

$$\Delta t \left(\frac{(C_{cfl} + V_{cfl}) + \sqrt{(C_{cfl} + V_{cfl})^2 + 4(G_{cfl})^2 + 4(S_{cfl})^2}}{2} \right) \leq 1 \quad (12)$$

$$\text{with } C_{cfl} = \frac{|u|_{max}}{\Delta x} + \frac{|v|_{max}}{\Delta y} + \frac{|w|_{max}}{\Delta z}, V_{cfl} = \left(\frac{2}{\Delta x^2} + \frac{2}{\Delta y^2} + \frac{2}{\Delta z^2} \right) * max \left\{ \frac{\mu_l}{\rho_l}, \frac{\mu_g}{\rho_g} \right\},$$

$$G_{cfl} = \sqrt{\frac{|g|}{\Delta y}} \text{ and } S_{cfl} = \sqrt{\frac{\sigma|\kappa|}{min\{\rho_g, \rho_l\} * (min\{\Delta x, \Delta y, \Delta z\})^2}}.$$

235 4. Results

4.1. Gas-water shock tube

This validation case is an underwater explosion configuration, based on the
 case III-A shown in Hu and Khoo (2004). Bubbles are generated by the ex-
 plosion, and then expands quickly into water. A shock wave develops into the
 240 water and a rarefaction wave is reflected back into the explosive bubble. This
 case presents high density and pressure ratio, which are difficult to handle with-
 out robust numerical methods. The initial conditions are the following :

$$(\rho, u, p, \gamma) = \begin{cases} (0.01, 0, 1000, 2), & \text{if } x < 0.5 \\ (1, 0, 1, 7.15) & \text{if } x > 0.5 \end{cases}$$

Figure 1 compare our results with the analytical solution, showing a good
 agreement with the theory. The wave speed is correctly captured as well as
 245 the density profile. The pressure profile is also well captured (Figure 2) with-
 out oscillations. This results demonstrate the accuracy and robustness of our
 pressure-based method in a two-phase flows context.

4.2. Oscillating water column configuration

In order to validate the method, an oscillating water column test case has
 250 been realized (See Figure 3). It consists in the oscillation of a water column

Figure 1: Velocity (left) and density (right) profiles at $t = 8 \times 10^{-4}$ s. The solid line represents the theory and the circles represent the numerical results for a 256 cells mesh and $dt = 8 \times 10^{-6}$ s. The dashed line represents the liquid-gas interface location

between two air columns due to an initial pressure gradient. The liquid compresses a first air column and then, when the pressure in this column exceeds the liquid inertia, the air pushes the water column toward the second air column and so on. This test case can be seen as a Rayleigh-Plesset test case, representing the oscillation of an air bubble inside liquid, but in a 1D cartesian geometry.

255 This test case has been studied previously in Daru et al. (2010); Kadioglu et al. (2005); Koren et al. (2002) by imposing an initial velocity to the liquid column instead of a pressure gradient. However, no reference solution exists to compare our numerical results although a theoretical solution can be derived by using

260 mass and momentum conservation and by considering the liquid incompressible. The mass conservation expressed with the flow rate conservation gives :

$$\rho_l S u = \rho_l S \frac{dR}{dt} \quad (13)$$

with S , a plane surface at a given position x ; R , the first gas-liquid interface position ; ρ_l the liquid density and u , the velocity of the liquid in x direction. By considering the liquid incompressible, we have :

$$u = \frac{dR}{dt} \quad (14)$$

265 So the velocity in the liquid is only a function of time. Then, the momentum

Figure 2: Pressure profiles at $t = 8 \times 10^{-4}$ s. The solid line represents the numerical result for a 256 cells mesh and $dt = 8 \times 10^{-6}$ s. The dashed line represents the liquid-gas interface location

equation in 1D without surface tension and viscosity, can be written as follow :

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = -\frac{1}{\rho_l} \frac{\partial P}{\partial x} \quad (15)$$

By injecting Eq.14 in Eq.15, we obtain :

$$\frac{d^2 R}{dt^2} = -\frac{1}{\rho_l} \frac{\partial P}{\partial x} \quad (16)$$

Finally, by integrating Eq.16 between the position of the first interface gas-liquid R_1 and the position of the second interface R_2 , the equation for the evolution of the first interface position in function of time is obtained :

$$\frac{d^2 R}{dt^2} = \frac{P|_{R_1} - P|_{R_2}}{\rho_l L} \quad (17)$$

with $L = R_2 - R_1 = cst$, the liquid length. The pressures in R_1 and R_2 are obtained with an equation of state. Then, the velocity is calculated with Eq.14. No analytical solution was found but a reference solution can be easily computed. It is worth mentioning that the reference solution is considering no

275 pressure fluctuation (Incompressible hypothesis), which is not the case of the numerical method presented here. Consequently, slight differences should be observed on the results when comparing both approaches.

Figure 3: Oscillating Water Column test case

The initial values for density and pressure are referenced in Table 1. The pressure in the first air column is twice the pressure in the second air column and it follows a linear profile in the water column. The water column is located
 280 and it follows a linear profile in the water column. The water column is located between $R_1 = 0.1 \text{ m}$ and $R_2 = 0.8 \text{ m}$ and the total domain measures 1 m . For the Tait equation in Eq.3, the parameters are $B = 3.31 \times 10^8 \text{ Pa}$, $P_0 = 10^5 \text{ Pa}$ and $\rho_0 = 1000 \text{ kg.m}^{-3}$.

Air $0 \leq x \leq R_1$	Water $R_1 \leq x \leq R_2$	Air $R_2 \leq x \leq 1$
$\gamma_g = 1.4$	$\gamma_l = 7$	$\gamma_g = 1.4$
$\rho_L = 1.169 \text{ kg.m}^{-3}$	$\rho = 1000 \text{ kg.m}^{-3}$	$\rho_R = 0.5845 \text{ kg.m}^{-3}$
$P_L = 10^5 \text{ Pa}$	$P = \frac{P_R - P_L}{R_2 - R_1} x + \frac{P_L R_2 - P_R R_1}{R_2 - R_1}$	$P_R = 5 \times 10^4 \text{ Pa}$

Table 1: Initial conditions for the oscillating water column test case. The L and R indexes mean respectively left and right.

285 For this configuration, the Mach number reaches a maximum value of $M_a = 4.45 \times 10^{-3}$. All the boundary conditions are considered as symmetric.

Figure 4 compares the evolution in function of time of the velocity of the liquid for different mesh size to the incompressible reference solution. As expected, the velocity oscillates ; initially, the liquid accelerates in the positive x

290 direction due to the pressure gradient until the moment when the pressure is
 the same in all the domain. Then, the liquid decelerates because the pressure
 is higher in the second air column, but its velocity is still positive owing to its
 inertia. Finally, there is again an acceleration followed by a deceleration for the
 same reasons but in the opposite x direction, hence the negative value of veloc-
 295 ity. A mesh convergence is observed in this graph. A $CFL = 0.1$ is performed
 here ; however, this CFL condition is based on the convective speed (similar to
 Kwatra et al. (2009) and Huber et al. (2015)). The corresponding time step is
 about 100 times greater than the one obtained from the CFL condition based
 on the sound speed.

Figure 4: Evolution of the velocity in function of time for different meshes, $CFL=0.1$.-.- 32
 cells,--- 64 cells, --- 128 cells, . . . 256 cells, - - - 512 cells. The solid line is the reference
 solution

300 Regarding the mass conservation, a better accuracy is obtained by refining
 the mesh (Figure 5) and the relative error is less than 0.1% for meshes with
 more than 256 cells, as shown in Figures 5 and 6.

By using a $CFL = 0.01$ condition, namely a time step about 10 times greater
 than the one obtained with the acoustic CFL , a convergence is also observed
 305 both for velocity (Figure 7) and mass conservation (Figure 8). For the velocity,

Figure 5: Relative mass of liquid error in function of time for different meshes, CFL=0.1.--- 32 cells,--- 64 cells, --- 128 cells, \cdots 256 cells, - - - 512 cells

the curve is closer to the reference solution but with a slight delay in terms of frequency. Concerning the mass conservation, an error about 10 times lower is noticed for both liquid and air.

The relative errors for the different meshes are shown in Table 2 for the first
 310 maximum for the velocity and for the frequency calculated between the two first maximum of velocity. In all cases, the relative error decreases by refining the mesh, illustrating the method accuracy and convergence.

N_x	32	64	128	256	512
Amplitude Error	5.82	3.66	2.19	1.30	0.49
Frequency Error	1.49	0.87	0.65	0.43	0.35

4.3. HIT configuration with phase change

315 Similarly to Duret et al. (2012), the idea is to investigate the influence of the
vaporization process inside the two phase flows HIT, but this time the impact
of vaporization on the flow dynamic (pressure, velocity) is considered. Contrary
to the study of Duret et al. (2012) that used a passive scalar to represent the
vaporization and mixing process, in this work a vaporization source term is
320 directly introduced in the continuity and pressure equation. Consequently, the
gas density will increase due to the vaporization process.

4.3.1. Representation of the evaporation process

In this configuration, phase change is considered. By splitting the continu-
ity equation in Eq.1 into a liquid density equation and a gas density equation
325 (Eq.18), a mass source term is introduced :

$$\begin{cases} \frac{\partial \alpha_l \rho_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \rho_l \vec{u}) = \dot{m} \\ \frac{\partial \alpha_g \rho_g}{\partial t} + \vec{\nabla} \cdot (\alpha_g \rho_g \vec{u}) = -\dot{m} \end{cases} \quad (18)$$

with \dot{m} , the mass source term in $[kg.m^{-3}.s^{-1}]$. It is negative when there is
an evaporation of the liquid. Then, liquid and gas volume fraction equations
are obtained by developing Eq.18.

$$\begin{cases} \frac{\partial \alpha_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \vec{u}) = -\frac{\alpha_l}{\rho_l} \frac{D\rho_l}{Dt} + \frac{\dot{m}}{\rho_l} \\ \frac{\partial \alpha_g}{\partial t} + \vec{\nabla} \cdot (\alpha_g \vec{u}) = -\frac{\alpha_g}{\rho_g} \frac{D\rho_g}{Dt} - \frac{\dot{m}}{\rho_g} \end{cases} \quad (19)$$

By adding these two equations, the divergence of velocity is obtained :

$$\vec{\nabla} \cdot \vec{u} = -\frac{\alpha_l}{\rho_l} \frac{D\rho_l}{Dt} - \frac{\alpha_g}{\rho_g} \frac{D\rho_g}{Dt} + \dot{m} \left(\frac{1}{\rho_l} - \frac{1}{\rho_g} \right) \quad (20)$$

330 Finally, by adding and deducting $\alpha_l \vec{\nabla} \cdot \vec{u}$ in the liquid volume fraction equa-
tion and replacing the different terms by their expression, the liquid volume
fraction equation containing phase change is expressed as followed :

$$\frac{\partial \alpha_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \vec{u}) = \alpha_l (1 - \alpha_l) D + \alpha_l \vec{\nabla} \cdot \vec{u} - \alpha_l \dot{m} \left(\frac{1}{\rho_l} - \frac{1}{\rho_g} \right) + \frac{\dot{m}}{\rho_l} \quad (21)$$

The pressure equation is also modified when phase change occurs :

$$\begin{aligned}
 & -\vec{\nabla} \cdot \left(\frac{\vec{\nabla} P^{n+1}}{\rho^*} \right) + \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) P^{n+1} = \\
 & \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) \left(P^n - \Delta t \vec{u} \cdot \vec{\nabla} P^n \right) - \frac{\vec{\nabla} \cdot \vec{u}^*}{\Delta t} + \frac{\dot{m}}{\Delta t} \left(\frac{1}{\rho_l} - \frac{1}{\rho_g} \right)
 \end{aligned} \tag{22}$$

The new term in the pressure equation (Eq.22) comes from the new formulation of the divergence of velocity.

4.3.2. Numerical configuration

For this Homogeneous Isotropic Turbulence (HIT) validation case, the forcing and the physical parameters used in previous work (Duret et al., 2012) are applied but with a 256^3 mesh and an initial liquid volume fraction $\phi = 10\%$. The initial densities are $\rho_g = 25.0 \text{ kg.m}^{-3}$ and $\rho_l = 753.0 \text{ kg.m}^{-3}$. The pressure is $P = 9.06 \times 10^6 \text{ Pa}$ and for the Tait equation, the parameters used are $B = 1.038 \times 10^9 \text{ Pa}$, $P_0 = 10^5 \text{ Pa}$ and $\rho_0 = 750 \text{ kg.m}^{-3}$. The adiabatic index for the liquid is $\gamma_l = 1.215$ and for the gas is $\gamma_g = 1.4$. For the evaporation, a constant vaporization rate $\dot{m} = -1 \text{ kg.cm}^{-3}.\text{s}^{-1}$ is chosen. This value is only applied in cells containing an interface ; in all other cells, \dot{m} is null. Consequently, the gas density is increased locally by the additional source term in the pressure equation, this can only be achieved by using a compressible or weakly-compressible formalism such as the one presented in this work. Moreover, the liquid-gas interface is directly influenced by the vaporization process through the VOF equation, meaning that the liquid mass diminishes, the gas mass increases and the total mass is conserved.

4.3.3. Results

Similarly to the incompressible HIT configuration presented in previous works, many breakup and coalescence events are observed (See Figure 9). Since the Mach number is very low in both phases, compressible effects are negligible : the gas density remains constant during the computation without evaporation.

Figure 9: Surface representation of the HIT configuration with $\phi = 10\%$.

However, if phase change is considered, the gas density increases with time and a dilatation (Stefan flow) is generated close to the interface.

On Figure 10, the evolution of the mean gas density is represented. As
 360 expected, the density remains constant if no evaporation occurs and increases if
 the mass source term is not zero. Even if \dot{m} is constant, the profile of the density
 is not linear because the surface quantity is not constant during the process.
 Consequently, the number of cells containing an interface varies. However, it is
 still possible to predict the gas density variation $\frac{\partial \rho_g}{\partial t}$ induced by vaporization
 365 if \dot{m} is constant and evaporating cells are identified. Then the time evolution
 of ρ_g is deduced, as shown on Figure 10. The density profile obtained is very
 close to the reference one showing the capability of the algorithm to represent
 the evaporation process.

During evaporation, the total mass should be conserved ; the mass won
 370 by the gas should be lost by the liquid. This balance is observed on Figure

Figure 10: Evolution of the mean gas density in function of time. \circ : results with evaporation, \times : results without evaporation. Solid line : theoretical solution with evaporation.

11, where the mass of liquid is decreasing while the mass of gas is increasing with time. By adding these two masses, the total mass is estimated. The difference between the initial total mass and the final total mass obtained at the end of the computation is less than 0.2%. This demonstrates the excellent
 375 mass conservation provided by the CLSVOF interface capturing method and the accurate computation of the mass transfer between liquid and gas phase due to vaporization.

5. Conclusion

A pressure based method is developed for low Mach number two-phase flows
 380 applications. The use of a projection method to decouple pressure and velocity allows a greater time step than the one imposed by the acoustic CFL condition. Indeed, the acoustic terms are solved implicitly in the pressure equation. This formalism takes into account the local variation of density in both phase due to compressibility and with (or without) phase change.

385 Besides, the Navier-Stokes equations are coupled with a CLSVOF method to

Figure 11: Evolution of the liquid mass m_l and gas mass m_g divided by the total mass m_{tot} in function of time. Dashed line (left axis) : $m_l(t)$, solid line (right axis) : $m_g(t)$.

ensure mass conservation and a sharp description of the interface. The standard incompressible VOF equation has been modified to take into account compressibility effects and the vaporization process.

The accuracy of the method is shown by comparing a reference solution with
 390 results obtained by this compressible DNS formulation in an oscillating water
 column configuration and a gas-water shock tube. Finally, the implementation
 of evaporation on a three-dimensional two-phase HIT configuration gives en-
 couraging results that have to be pursued. An excellent mass conservation has
 been obtained by using this formalism, confirming the accuracy of the mass
 395 transfer estimation between liquid and gas phase due to vaporization. More-
 over, this last configuration includes more complex phenomena like collisions
 and breakups, showing the robustness of this formalism in atomization context.
 Further works will be dedicated on coupling the vaporization rate to the species
 and energy equation in this compressible framework.

400 **Appendix A. Pressure equation**

By applying the divergence operator on Eq.9, the following relation produced :

$$\vec{\nabla} \cdot \vec{u}^{n+1} = \vec{\nabla} \cdot \vec{u}^* - \vec{\nabla} \cdot \left(\Delta t \frac{\vec{\nabla} P}{\rho^*} \right) \quad (\text{A.1})$$

First, $\vec{\nabla} \cdot \vec{u}^{n+1}$ is obtained by decomposing the density in the continuity equation into a liquid and gas density :

$$\frac{\partial (\alpha_l \rho_l + \alpha_g \rho_g)}{\partial t} + \vec{\nabla} \cdot (\alpha_l \rho_l \vec{u} + \alpha_g \rho_g \vec{u}) = 0 \quad (\text{A.2})$$

405 Then, the liquid phase and the gas phase are separated in Eq.A.2 and phase change is ignored in order to have :

$$\begin{cases} \frac{\partial \alpha_l \rho_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \rho_l \vec{u}) = 0 \\ \frac{\partial \alpha_g \rho_g}{\partial t} + \vec{\nabla} \cdot (\alpha_g \rho_g \vec{u}) = 0 \end{cases} \quad (\text{A.3})$$

By developing the derivatives and gathering the different terms :

$$\begin{cases} \frac{\partial \alpha_l}{\partial t} + \vec{\nabla} \cdot (\alpha_l \vec{u}) = -\frac{\alpha_l}{\rho_l} \frac{D \rho_l}{Dt} \\ \frac{\partial \alpha_g}{\partial t} + \vec{\nabla} \cdot (\alpha_g \vec{u}) = -\frac{\alpha_g}{\rho_g} \frac{D \rho_g}{Dt} \end{cases} \quad (\text{A.4})$$

Then, by adding the two equations in Eq.A.4, the divergence of velocity is expressed as:

$$\vec{\nabla} \cdot \vec{u} = -\frac{\alpha_l}{\rho_l} \frac{D \rho_l}{Dt} - \frac{\alpha_g}{\rho_g} \frac{D \rho_g}{Dt} \quad (\text{A.5})$$

410 By considering density as a function of pressure only, Eq.A.5 can be written as follow :

$$\vec{\nabla} \cdot \vec{u} = -\left(\frac{\alpha_l}{\rho_l c_l^2} + \frac{\alpha_g}{\rho_g c_g^2} \right) \frac{DP}{Dt} \quad (\text{A.6})$$

with $c^2 = \frac{\partial P}{\partial \rho}$. Finally, by injecting Eq.A.6 in Eq.A.1, developing the material derivative and dividing by Δt , an Helmholtz equation for pressure is obtained :

$$\begin{aligned} & -\vec{\nabla} \cdot \left(\frac{\vec{\nabla} P^{n+1}}{\rho} \right) + \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) P^{n+1} \\ & = \left(\frac{\alpha_l}{\rho_l c_l^2 \Delta t^2} + \frac{\alpha_g}{\rho_g c_g^2 \Delta t^2} \right) \left(P^n - \Delta t \vec{u} \cdot \vec{\nabla} P^n \right) - \frac{\vec{\nabla} \cdot \vec{u}^*}{\Delta t} \end{aligned} \quad (\text{A.7})$$
