Abstract

The out-of-field dose in radiation therapy is a growing concern in regards to the late side-effects and secondary cancer induction. In high-energy X-ray therapy, the secondary neutrons generated through photonuclear reactions in the accelerator are part of this secondary dose. The neutron dose is currently not estimated by the treatment planning system (TPS) while it appears to be preponderant for distances greater than 50 cm from the isocenter. Monte Carlo (MC) simulation has become the gold standard for accurately calculating the neutron dose under specific treatment conditions but the method is also known for having a slow statistical convergence, which makes it difficult to be used on a clinical basis. The nTLE (neutron TLE), a neutron variance reduction technique inspired by the track length estimator (TLE) method has thus been developed for the first time in the Monte Carlo code GATE to allow a fast computation of the neutron dose in radiotherapy. The details of its implementation, as well as the comparison of its performances against the analog MC method, are presented here. A gain of time from 15 to 400 can be obtained by our method, with a mean difference in the dose calculation of about 1% in comparison with the analog MC method.

Keywords : Track length estimator, GATE, Monte Carlo simulation, Neutron dose calculation, Radiotherapy

1 Introduction

Modern radiotherapy techniques based on the use of a linear accelerator aim to achieve better control for deep-seated tumours. However, they also can be responsible for the development of late side-effects and secondary cancers which today is a debated topic among scientific and medical groups. The literature reports mainly information on the organs at risk located next to the target volume (Xu et al. 2008, Takam et al. 2011). These organs are usually irradiated with high doses: this leads to a high probability of normal tissue complications and usually to a small risk of radiation-induced second primary cancer (Takam et al. 2011). During a radiotherapy treatment, besides its therapeutic dose, the patient gets exposed to sources of secondary dose which include the photon secondary dose. Indeed, the use in X-ray therapy of electron accelerators contributes to the out-of-field doses to patient by leakage and scattering of the primary photon beam (Halg et al. 2012). This photon secondary dose can vary considerably depending on the photon energy, treatment modality, irradiation

1 29 geometry, size of the tumour and patient, as well as the distance from the irradiated volume: a typical secondary
2 30 dose is some hundreds of mSv 10 cm away from the target volume ((Gudowska et al. 2014)) over the course
3 31 of a treatment. Adding to that, modern linear accelerators are usually equipped with on-board imaging (OBI)
4 32 devices, allowing 3D on-line patients set-up and verification by using cone beam computed tomography (CBCT)
5 33 (Palm et al. 2010). The additional radiation doses from CBCT can significantly increase out-of-field doses to
6 34 patients in case of frequent patient set-up during the radiotherapy treatment. Depending on the CBCT type,
7 35 the mean delivered dose can range from 3 mGy to 100 mGy (Palm et al. 2010). Besides this photon dose, for
8 36 accelerators operating at energies above photonuclear reactions thresholds (1.66 MeV (Be), 6.5 MeV (W), 10 MeV
9 37 (Cu)), neutrons produced through (γ, n) reactions in the bremsstrahlung target, flattening filter, collimators,
10 38 shielding materials inside the treatment head and inside the patient's body are another source of unwanted
11 39 doses delivered to the patient (D'Errico et al. 1998, Akkurt et al. 2003, Naseri et al. 2010). The patient entire
12 40 body will be exposed to this out-of-field radiation. Several dosimetry studies have been carried out through
13 41 measurement and modelling techniques and have shown the relationship existing between out-of-field dose and
14 42 radiation induced secondary cancer (Brenner et al. 2000, Newhauser et al. 2011, Murray et al. 2014). However,
15 43 through these studies, a whole range of equivalent doses (and thus associated risks) has been reported leading
16 44 to the need for additional studies for these dosimetric concerns. In the literature, regardless of the measurement
17 45 technique and type of accelerator, the neutron dose equivalent per unit photon dose can range from as low as
18 46 0.1 mSv/Gy to as high as 20.4 mSv/Gy (Takam et al. 2011).

19 47 Moreover, it has been reported that at some specific locations the neutron dose becomes larger than the
20 48 photon dose, leading to a larger neutron-to-photon absorbed dose ratio (Carinou et al. 2005). This neutron
21 49 production, which is related to the patient irradiation configuration, has been shown to be more important for
22 50 IMRT (Intensity Modulated Radiotherapy) treatment than for 3D-CRT (3D-Conformal Radiotherapy)(Howell
23 51 et al. 2006, Reft et al. 2006). In regards to their high relative biological effectiveness reflected in their high
24 52 radiation weighting factors (ICRP 2007), it is important to estimate their related dose, especially when we know
25 53 that neutron spectra produced by medical linear accelerators have mean energies between 0.5 and 1 MeV that
26 54 correspond to the highest radiation weighting factors. So far, no current treatment planning system (TPS) is
27 55 computing this neutron dose.

28 56 Radiation doses from neutrons can be calculated by the use of a Monte Carlo simulation code such as
29 57 MCNP (Shultis et al. 2006, Carinou et al. 2005, Mesbahi et al. 2009), FLUKA (Ferrari et al. 2005, Huang
30 58 et al. 2005, Chen et al. 2006) and Geant4 (Jarlskog et al. 2008, Athar et al. 2010). The results obtained by
31 59 simulation can have a high degree of precision depending on the accuracy of the data (i.e nuclear cross sections)
32 60 and parameters. However, they can be difficult to use on a clinical basis because a long calculation time is
33 61 required, particularly if low threshold (cut-off) energies of modeled particles are used. That is why, there is a
34 62 real need for developing a tool that will allow a decrease in the neutron simulation time to make neutron dose
35 63 calculation more accessible on a clinical basis.

36 64 The most commonly used standard variance reduction techniques (VRT) such as the absorption suppression,
37 65 splitting and Russian roulette, forced collision, and source biasing have mainly been developed for photon
38 66 dosimetry (Seco & Verhaegen 2013). In MCNP, the comparison of two VRT used for neutron transportation,

the APDT (Adjoint Point Detector Technique known as the DXTRAN technique) and the LEXT (Legendre EXpansion Technique) have showed that the latter is 6 to 20 times faster than the analog MC (Nievaart et al. 2007). In FLUKA, the non-analog neutron absorption technique (also known as survival biasing) and the biased down scattering are also used as VRT techniques. Through all the VRT, the track length estimator (TLE) method is known as an efficient tallying method, suitable for kerma calculations at any given point in photons irradiations cases (Williamson 1987). It has been used for a long time (Williamson 1987, Carlsson 1985) and is implemented in different codes such as MCNPX (DeMarco et al. 2002, Smans et al. 2010) and in some specific tools for external radiotherapy (Van der Zee et al. 2005) and brachytherapy (Chibani et al. 2005, Taylor et al. 2007).

Many Monte Carlo simulation tools have been developed for dosimetry purposes (Pelowitz 2008, Battistoni et al. 2007, Ferrari et al. 2005, Perl et al. 2012, Walters et al. 2002, Kawrakow et al. 2000). GATE (Jan et al. 2004) constitute an open-source MC simulation platform that can support a user-friendly simulation framework of imaging (Jan et al. 2011) and dosimetry (Sarrut et al. 2014) in a same environment. This software is based on the GEANT4 toolkit. GATE is also used in radiotherapy applications for comparisons with MC TPS (Luceski et al. 2013). With the GATE V6.2 release, a specific VRT option based on the track length estimator (TLE) has been implemented for low-energy photon dose calculation (Mittone et al. 2013). This method allows an efficiency gain between 10 and 10^3 depending on the simulation set-up. In the latest release (GATE V7.2), two extra low energy photon VRT, namely force detection (Poludniowski et al. 2009) and exponential TLE (Smekens et al. 2009, Smekens et al. 2014) have been developed. However, no current version of GATE does currently include a VRT for neutron dose calculation.

In such a context, it seemed interesting to develop a tool that will allow a precise calculation of the secondary neutron dose in RT in a shorter time than the analog Monte Carlo simulation. To do so, the treatment planning parameters (field size, beam energy, angulation...) can be retrieved through the generated DICOM files (RTplan). This information would be retrospectively reprocessed after each treatment to be used as an input for MC calculations of 3D neutrons (and photons) dose maps.

While many VRT are available in MC TPS and used in clinical routine for photon dose calculation, the objective of our work was to add a neutron VRT in the GATE framework in order to set up a tool that would generate neutron dose maps (to be systematically recorded during the treatment). In such a way, we aim to achieve the generation of a dosimetric database on out-of-field dose that can be used for future epidemiological studies in order to improve low dose-risk models.

1.1 Method

1.1.1 TLE method in GATE for photons

The TLE method has been implemented in GATE for low energy X-rays (Mittone et al. 2013) and prompt γ (Huisman et al. 2016). It allows to calculate the particle fluences, kerma and absorbed dose.

In charged particle equilibrium (CPE), for a monoenergetic photon beam the absorbed dose is (Carlsson

1 1985, Berger et al. 2010):

$$D = \phi E \frac{\mu_{en}}{\rho} \quad (1)$$

6 with ϕ the particle fluence and $\frac{\mu_{en}}{\rho}$ the mass energy absorption coefficient.

8 The total track length dL of all particles crossing a given elementary volume dV around point \mathbf{r} in the space
9 (Carlsson 1985) gives us the fluence:

$$\phi(\mathbf{r}) = \frac{dL(\mathbf{r})}{dV} \quad (2)$$

16 Thus, for a given photon crossing a voxel with volume V , a good estimate of the contribution to the fluence
17 will be given by (DeMarco et al. 2002, Williamson 1987):

$$\phi = \frac{L}{V} \quad (3)$$

23 with L being the length of the photon path within the given voxel. With such a method the dose is equal to:

$$D = \frac{EL\mu_{en}}{V\rho} \quad (4)$$

29 Unlike the MC analog estimator in which only the simulated collisions occurring within the voxel contribute
30 to the dose, the use of the TLE will improve the efficiency of the simulation since every voxel intersected by a
31 photon path will produce a non-zero dose score leading to a large increase of information that can be extracted
32 from a finite sample of histories. For low energy photons, when considering the CPE, such a method uses
33 the kerma approximation for which electrons are assumed to deposit their energy locally within a single voxel
34 (thus, MC transport of secondary electrons can be switched off). Systematic deviations of the dose distributions
35 can be minimized with this approach if the maximum range of secondary electrons is smaller than the spatial
36 resolution of the calculation grid. That is why this approximation is valid only if the electron range is smaller
37 than the voxel size or the required spatial accuracy (Seco & Verhaegen 2013).

44 For low energy photons, the linear energy-absorption (μ_{en}) and energy-transfer (μ_{tr}) coefficients can be
45 considered to be the same quantity due to the fact that the radiative loss (factor g in Eq 5) approaches zero for
46 low values of atomic numbers and energy (Attix 2004, Berger et al. 2010, Freud et al. 2008):

$$\mu_{en} = \mu_{tr}(1 - g) \quad (5)$$

53 In human tissues, (made of elements with atomic numbers $Z \leq 20$), the relative difference between μ_{tr} and
54 μ_{en} remains below 1% for energies up to 3 MeV and reaches a value of 3% for 10 MeV photons (Attix 2004).

123 1.1.2 Neutron dose calculation and CPE equilibrium validity

124 The photoneutron energies involved in radiotherapy ranges from thermal (0.025 eV) to fast (mean energy of
125 1 MeV). Since the human body consists of about 95% of hydrogen, carbon, oxygen and nitrogen (ICRU 2000),

126 the neutron dose will be deposited in the tissue through different processes. The elemental contribution to the
 127 kerma in soft tissues depends on neutron energy (Chadwick et al. 1999).

128 For a single neutron energy E , a single type of target atoms and a single type of interaction, the kerma K
 129 that results from a neutron fluence ϕ [n/cm²] at a point in a medium is given by (Caswell et al. 1980):

$$K = \phi E \frac{\mu_{tr}}{\rho} = \phi \frac{N_t E_{tr} \sigma}{m} \quad (6)$$

130 where σ is the interaction cross section per target atoms, N_t is the number of target atom in the irradiated
 131 sample, m is the sample mass, and E_{tr} is the total kinetic energy given to charged particles per interaction.
 132 When considering the usual CPE conditions, the absorbed dose D is thus equal to the kerma K as:

$$D = K = \phi F_n \quad (7)$$

133 where F_n the kerma factor [cGy cm²/n] is defined as

$$F_n = 1.602 \times 10^{-8} N_t E_{tr} \sigma / m \quad (8)$$

134 which σ in [cm²/(target atom)], m in [g] and E_{tr} in [MeV/n].

135 Tables of F_n values are found in the 46 ICRU report for energies between 0.025 eV to 20 MeV (Caswell et al.
 136 1980) for several elements, compounds, and mixtures principally calculated from the ENDF/B-IV cross section
 137 library. The 63 ICRU report includes kerma coefficients determined from the latest ENDF/B-VI evaluated data
 138 libraries (Rose 1991) below 20 MeV and uses advanced nuclear model calculations and experimental information
 139 from 20 MeV to 150 MeV (the "LA150 data library" (Chadwick et al. 1999)). However, this update of kerma
 140 factors produced only a very small (<2%) difference in kerma calculations (Goorley et al. 2002) meaning that
 141 finally the use of either kerma databases is suitable

142 If we consider a continuous spectrum with a differential fluence distribution $\phi'(E)$ [n·cm⁻²·MeV⁻¹], the
 143 kerma contribution by j -type interactions with i -type target atoms is (Attix 2004):

$$K_{ij} = 1.602 \times 10^{-8} \frac{N_i}{m} \int_0^{E_{max}} \phi'(E) \sigma_{ij}(E) [E_{tr}(E)]_{ij} dE \quad (9)$$

144 with N_i/m the number of target atoms of type i per gram of the medium, $\sigma_{ij}(E)$ the cross section for j -type
 145 interactions with i -type atoms by neutrons of energy E , and $[E_{tr}(E)]_{ij}$ the total kinetic energy transferred to
 146 charged particles per type- j interactions with type- i atoms by neutrons of energy E .

148 For the same units as in Eq 6, K_{ij} [cGy] can be summed over all atoms i and all interactions j to get the
 149 kerma (or dose) due to all types of interactions and target atoms:

$$D = K = \sum_i \sum_j K_{ij} \quad (10)$$

150 When it comes to neutron interactions in tissue, we will have to consider thermal neutron reactions and fast

neutron reactions (Figure 1).

For the thermal neutrons reactions, there are two important interactions with tissues: neutron capture by nitrogen, $^{14}\text{N}(n,p)^{14}\text{C}$, and neutron capture by hydrogen, $^1\text{H}(n,\gamma)^2\text{H}$. The nitrogen interaction releases a kinetic energy of $E_{tr} = 0.62$ MeV that is shared by the proton (0.58 MeV) and the recoiling nucleus (0.04 MeV). Since the range of the secondary proton approximates 10 μm in tissue, CPE exists and $K = D$ even in very small tissue samples.

Thermal neutrons have a larger total probability of capture by hydrogen atoms than by nitrogen atoms in muscle even though $\sigma_H = 3.32 \times 10^{-25} \text{ cm}^2/\text{atom} < \sigma_N = 1.84 \times 10^{-24} \text{ cm}^2/\text{atom}$, because, there are 40 times more H atoms than N atoms in tissue. The γ -ray photon energy released in each neutron capture is 2.2 MeV. This of course will not directly contribute to the kerma, since the γ -rays must interact and transfer energy to charged particles to produce kerma. If we consider an irradiated tissue mass, small enough to allow the γ -rays to escape, the kerma due to thermal neutrons is only that resulting from the nitrogen (n,p) interactions. In larger masses of tissue the γ -rays are increasingly reabsorbed before escaping, thus contributing to the kerma. The human body has an intermediate size, but it is large enough so the $^1\text{H}(n,\gamma)^2\text{H}$ process dominates the kerma (and dose) production, not only for thermal neutrons but for intermediate energy neutrons as well, as they become thermalised in the body.

For neutron energy above 10^{-4} MeV, elastic scattering from hydrogen nuclei contribute nearly all of the kerma.

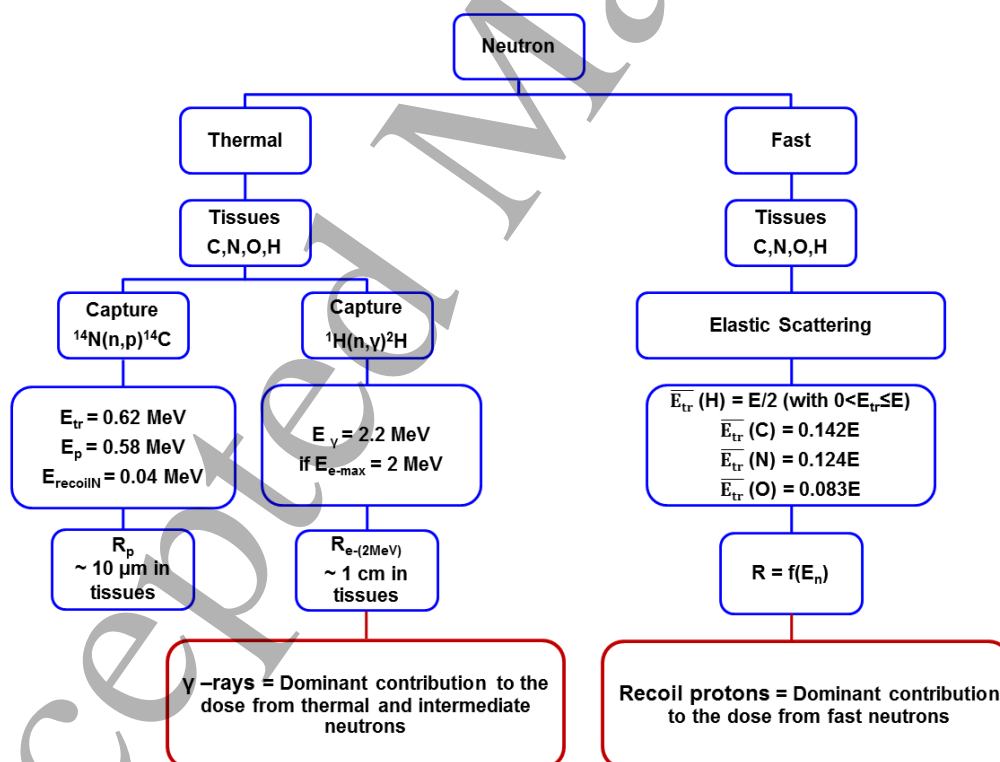

Figure 1: Main neutron interactions involved in soft tissue dose deposition

Given the energy range of the secondary neutrons produced in the radiotherapy accelerator head, for all dose components except the photon dose, the charged particles involved in the dose delivery to the tissues have ranges smaller than the general mesh element size (1 mm) of the dose scoring grid, leading to a good

172 approximation of the dose by the kerma. However, energetic electrons that can be produced through secondary
 173 photons interactions in tissue can have a range over 1 cm, similar to or larger than the dose grid element
 174 size. For example 2.2 MeV photons, mainly generated in soft tissues due to the capture of thermal neutron
 175 by Hydrogen nuclei, will induce the production of 2 MeV electrons (maximal Compton electron energy from
 176 the 2.2 MeV gamma). For the ICRP and cylindrical phantom simulation, the range of the 2 MeV generated
 177 electrons (maximal range of 1 cm and mean range of about 5 mm) can be larger than the spatial resolution of
 178 the phantom. The charged particle equilibrium hypothesis and the kerma approximation in each voxel could
 179 thus be not totally respected which can lead to a (small) dose overestimation in the voxel by the nTLE.

180 1.2 Implementation of Neutron TLE (nTLE) in GATE

181 1.2.1 Kerma factor

182 Similarly to the low energy photon, for a neutron crossing a volume V a good estimate of the dose is also
 183 given by Eq 7 ($\phi = L/V$) thus:

$$D = \frac{L}{V} F_n \quad (11)$$

184 To proceed with the neutron dose calculation, kerma factor tables have been generated for the different
 185 elements contained in the ICRU report 46 (Caswell et al. 1980). These factors are available for a large choice of
 186 human tissues, and within an energy interval ranging from 0.0253 eV to 29 MeV. For energies between 0.0253 eV
 187 and 29 MeV, as mentioned in (Chadwick et al. 1999), a linear interpolation has been used to obtain kerma
 188 coefficients at energies not tabulated.

189 The accuracy of the ICRU 46 (ICRU 1992) report kerma factors is estimated to be:

- 190 • Below 10 MeV: 1% for hydrogen and 5% for carbon, nitrogen and oxygen
- 191 • From 10 MeV to 30 MeV: 1 to 2 % for hydrogen and 10 to 25 % for carbon. For nitrogen and oxygen,
 192 uncertainties may be even higher at some energies.

193 An important issue in relation with these neutron kermas is the treatment of neutrons below 0.0253 eV since
 194 this is the lowest reported data point. Indeed, with a neutron capture cross section inversely proportionnal
 195 to the neutron kinetic energy ($1/v$ law), the thermal neutron kerma values will increase in the same way as
 196 $E_n^{-0.5}$ (with E_n the neutron energy (Siebert & Schuhmacher 1995)), making the energy region below 0.0253 eV
 197 a significant contributor to kerma. Two methods are available in the literature for the evaluation of neutron
 198 kerma below 0.0253 eV. The first one is to proceed with a log-log extrapolation of the kerma data points below
 199 1 eV down to an energy where there are very few neutrons, such as 10^{-4} eV (Goorley et al. 2002). The second
 200 one, which was used in this work, is to assign to the neutrons below 0.0253 eV the kerma values corresponding
 201 to the lowest tabulated energy point (the same way as the default treatment in MCNP) (Goorley et al. 2002).

1.2.2 Photon dose calculation

To accelerate their simulations, some studies on the secondary neutron dose in radiotherapy calculations (Kry et al. 2009, Martínez-Ovalle et al. 2012) have been carried out without considering the secondary photon dose resulting from the thermal neutron capture by hydrogen nuclei. Only the so-called “genuine neutron (absorbed) dose” (Valentin 2003) that does not include the contribution by photons released in the body by neutrons has been considered.

However, for accurate dosimetric studies, the gold standard is to be able to consider every dose component. To take into account the secondary photon dose in soft tissue mainly due to the 2.2 MeV photon from the $^1\text{H}(n,\gamma)^2\text{H}$ process, photon kerma factors in our algorithm are based on mass energy absorption coefficients (μ_{en}/ρ) data both from the NIST database and for the body parts for which these coefficients are not recorded, from the ICRU report 46, which are derived from Hubbell’s elemental data (Hubbell 1982). It has been reported that the difference between these two kerma sets produced no significant differences in dose calculations: the differences in photon kerma rate dose profiles were less than the statistical uncertainty in the difference between the profiles, which was 0.2% (Goorley et al. 2002).

To proceed with these photon dose calculations, two methods have been tested: an analytical correction method and the TLE method.

1.2.2.1 Analytical correction

Analogous to the kerma factor F_n and based on the Attix publication (Attix 2004), we define the radiative kerma factor R_γ as the energy given to γ -rays per unit mass of tissue and per unit fluence. The R_γ factor of thermal neutrons can be obtained from an equation similar to Eq 9, but replacing E_{tr} by E_{γ_i} (which corresponds to the γ -ray photon energy released in each i neutron capture) such as:

$$R_\gamma = 1.602 \times 10^{-6} m^{-1} \sum_i \sigma_i N_{t_i} E_{\gamma_i} \quad (12)$$

where σ_i is the neutron capture cross section for the i atom [$\text{cm}^2/(\text{target atom})$], N_{t_i} is the number of i target atoms in the irradiated sample, m is the sample mass [g], and E_{γ_i} is the γ -ray photon energy released in each neutron capture [MeV].

Given the body tissue composition and the differences in terms of neutron radiative capture cross section of the main target atoms contained in the body (Table 1), only the neutron cross section with H targets will be considered in the next steps of the analytical correction.

| Element | γ_{prompt} [MeV] | $\sigma_{capture}$ [barn] | $\Sigma_{capture}$ [cm^{-1}] | Atoms per g of muscle [g^{-1}] |
|---------|-------------------------|---------------------------|---|---|
| H | 2.2 | 0.3326 | 2.13×10^{-2} | 6.09×10^{22} |
| C | 1.3 | 0.0012 | 7.77×10^{-6} | 6.17×10^{21} |
| | 4.9 | 0.00262 | 1.70×10^{-5} | |
| N | 1.9 | 0.01458 | 2.31×10^{-5} | 1.506×10^{21} |
| O | 0.9 | 0.000175 | 5.13×10^{-6} | 2.79×10^{22} |

Table 1: Neutron capture cross section and prompt γ energies (International Atomic Energy Agency. 2007) in the case of skeletal muscle composition given by ICRU report 46 (ICRU 1992)

229 The R_γ factor of thermal neutrons will be thus obtained again from an equation similar to Eq 9, but replacing
 230 E_{tr} by $E_\gamma = 2.2$ MeV such as:

$$R_\gamma = 1.602 \times 10^{-6} \sigma N_t m^{-1} E_\gamma \quad (13)$$

231 where σ is the H interaction cross section [$\text{cm}^2/(\text{target atom})$], N_t is the number of H atoms in the irradiated
 232 sample, m is the sample mass [g], and E_γ is the γ -ray photon energy released in each neutron capture [MeV].
 233 From the simulation, the knowledge of the thermal neutron flux, as well as the knowledge of the quantity of H
 234 nuclei per gram of body material would thus allow a calculation of the contribution to the dose from the photons.
 235 A tabulation of this radiant energy per body material has been considered in this work in order to reduce the
 236 simulation time, since in such a configuration, the photons would not be longer tracked in the simulation. With
 237 such a method the deposited photon dose in a voxel of V volume will be equal to:

$$D_\gamma = R_\gamma \times \phi = R_\gamma \times \frac{L}{V} \quad (14)$$

238 1.2.2.2 TLE photon correction

239 The TLE method, as mentionned in 1.1.1, has been implemented in GATE for low energy photons. For
 240 the neutron dose calculation, the main contribution to the dose from photons is due to the 2.2 MeV photons
 241 from thermal neutron capture by hydrogen. The comparison between the μ_{en} and μ_{tr} (Attix 2004) for photon
 242 energies up to 3 MeV showed a difference between these two coefficients lower than 1% which comforts us in
 243 testing the performances of this TLE correction in our neutron dose calculation algorithm. The photon dose
 244 would thus be calculated as per Eq 4.

245 1.2.3 Total dose calculation

246 Finally, the total neutron dose D_{tot} deposited in a voxel, is calculated by the algorithms

- 247 • for the analytical correction such as:

$$D_{tot} = \sum_{k \in n} (D_k + D_{\gamma,k}) = \frac{1}{V} \sum_{k \in n} (F_{n,k} + R_{\gamma,k}) L_k \quad (15)$$

248 with, for a given neutron k , the neutron dose D_k , the γ dose $D_{\gamma,k}$, the kerma factor $F_{n,k}$, the radiative
 249 factor $R_{\gamma,k}$, and the distance L_k travelled by the neutron k in a volume element V .

- 250 • for the TLE correction such as:

$$D_{tot} = \sum_{k \in n} D_k + \sum_{l \in \gamma} D_{\gamma,l} = \frac{1}{V} \left(\sum_{k \in n} F_{n,k} L_k + \sum_{l \in \gamma} E_l \frac{\mu_{en,l}}{\rho} L_l \right) \quad (16)$$

251 with the neutron dose D_k of neutron k , the γ dose $D_{\gamma,l}$ of gamma l , L_k (resp. L_l) the distance travelled
 252 by the neutron k (resp. the gamma l) in a volume element V .

1.3 Simulation Test Cases

Different simulations have been performed in order to benchmark the nTLE algorithm against analog Monte Carlo simulations, in terms of dose calculation accuracy and variance reduction factor. Since the accuracy of the dose calculation by the algorithm had to be evaluated, a cut of 1 mm for γ and electrons was set: in each material, this value is transformed to an energy below which the continuous slowing down approximation is used. Furthermore, secondary particles below this energy are not produced, but the energy is deposited locally (Agostinelli et al. 2003). A cut of 0.1 mm was set for protons. To be able to fully compare the MC dose calculation and the nTLE dose calculation as well as the gain in terms of variance, simulations with an identical seed have been carried out.

Simulations have been carried out first in homogeneous cubic volumes to fully validate the dose calculation before proceeding with simulations on a heterogeneous phantom and voxelized phantom. Regarding the voxelisation of the volumes (simple volume or phantom), it is relevant to mention that since MC generation can use any resolution, both isotropic and anisotropic voxel size can be used by the method without any advantage given to one or other of voxel type. While any resolution can be used with the nTLE (using for example XCAT phantom (Segars et al. 2010)), the main concern would not be the shape of the voxel (isotropic or anisotropic) but its volume.

Moreover, since in high energy X-ray treatments we get mainly thermal neutrons (around 0.025 eV) and a fast neutron component (around 1 MeV), monoenergetic neutron beams of 0.025 eV and 1 MeV have been simulated to study the impact of the neutron energy on the dose calculation accuracy and on the variance reduction factor. The energy of 10 MeV has also been simulated to evaluate the performances of the algorithm at higher energies.

1.3.1 Simple homogeneous volume

The first step was to proceed with a benchmarking of the photon dose correction impact on the neutron dose calculation. Since the human body is mainly composed of soft tissues, the simulations were first carried out on simple cubic geometry configurations of muscle tissue. This allowed us to fully measure the algorithm's performance with the different photon dose corrections and its ability to give an accurate neutron dose calculation in comparison with the analog MC method. To do so, simulations were first carried out on cubes consisting of ICRU 44 skeletal muscle of various sizes with a density of $1.05 \text{ g}\cdot\text{cm}^{-3}$. The composition is given as per the ICRU report 46 composition in Table 2.

| Element | H | C | N | O | Na | P | S | Cl | K |
|-----------------------|------|------|-----|------|-----|-----|-----|-----|-----|
| Percent by weight [%] | 10.2 | 14.3 | 3.4 | 71.0 | 0.1 | 0.2 | 0.3 | 0.1 | 0.4 |

Table 2: Skeletal muscle composition given by ICRU report 46 (ICRU 1992)

Monoenergetic neutron sources (10^6 particles) with energies relevant in radiotherapy irradiated soft tissue targets. The tested energies were 0.025 eV, 0.1 MeV, 1 MeV and 10 MeV.

1.3.2 Voxelised cases

1.3.2.1 Heterogeneous volume

Simulations with monoenergetic neutron beams impinging upon a simple voxelised volume were used to evaluate the nTLE performances of dose calculation accuracy and variance reduction. Given the fact that mean voxel resolution is of the order of a few mm^3 in the computational phantom models, simulations on a voxelised (1 mm^3 voxels) cylindrical soft tissue volume (diameter of 33 cm) were made. Eight inserts (diameter of 3 cm) of Griffith lung tissue $0.26 \text{ g}\cdot\text{cm}^{-3}$ (ICRU 1992), and eight inserts of cortical bone, $1.920 \text{ g}\cdot\text{cm}^{-3}$ (ICRU 1992), were added to test the performances of the nTLE algorithm in terms of the dose calculation in an heterogeneous volume. Monoenergetic planar neutron sources of 0.025 eV, 1 MeV and 10 MeV irradiated the cylindrical volume. To ensure an homogeneous irradiation of the volume, the cylinder was rotated around its long axe.

Figure 2: Transverse section of the cylindrical geometry with its heterogeneities

1.3.2.2 ICRP phantom

In order to assess the potential of the nTLE method to produce dose distributions in realistic cases and to evaluate the gain in variance reduction, two simulations were performed using a voxelized ICRP phantom (publication 110) (ICRP 2009) as input to define the geometry and composition of the volume in which the dose deposition would be evaluated (Figure 3). The voxel size was $2.1 \text{ mm} \times 2.1 \text{ mm} \times 8 \text{ mm}$ for a total voxel volume of about 35.3 mm^3 . A typical neutron spectrum measured in a treatment room (Chu et al. 2011) irradiated the pelvis area of the phantom. The object was rotated around an axis perpendicular to the beam direction in order to produce a homogeneous irradiation. About 3×10^{10} particles were incident on the phantom in order to have a statistical uncertainty lower than 1% with the analog MC dose calculation to accurately assess our algorithm dose calculation performances.

1.3.2.3 Comparison parameters for benchmarking against analog MC

Dose ratio To check the dose calculation accuracy of the nTLE against the MC method, dose ratio maps ($r_{Analog/nTLE}$) have been generated such as:

$$r_{Analog/nTLE} = \frac{D_{Analog}}{D_{nTLE}} \quad (17)$$

Figure 3: ICRP phantom slice densities

307 **Statistical uncertainty** To measure the differences in regards to the statistical uncertainties for the same
 308 simulation parameters, dose maps representing the uncertainty ratios ($r_{Analog/nTLE}$) at the three simulated
 309 energies have been generated such as:

$$r_{Analog/nTLE} = \frac{\sigma_{Analog}}{\sigma_{nTLE}} \quad (18)$$

310 with σ_{Analog} the statistical uncertainty of the analog MC dose calculation and σ_{nTLE} the statistical uncertainty
 311 of the nTLE algorithm.

312 Then, the estimation of the number of events N_t required to get a statistical error of about σ_t is (Mittone
 313 et al. 2013):

$$N_t = \left(\frac{\sigma_i}{\sigma_t} \right)^2 N_i \quad (19)$$

314 with σ_i and σ_t the standard deviations, N_i and N_t number of simulated events.

315 The ratio N_t/N_i can be easily related to the gain in computing time. However these values have to be cor-
 316 rected considering the fact that the nTLE algorithm requires about 10% more computation time in comparison
 317 to the MC with the same simulation seed. These ratios are given by Figures 6 and 8.

318 2 Results

319 2.1 Simple homogeneous volume

320 Figure 4 presents the differences of dose calculation by the different methods. The stars, squares, circles
 321 and triangles respectively represent the dose calculated with the analog MC method, algorithm without photon
 322 correction, algorithm with analytical photon correction (1.2.2.1) and with TLE photon correction (1.2.2.2). It
 323 clearly appears from these figures, that the photon dose calculation has to be taken into account in order to not
 324 underestimate the neutron deposited dose, while on the other hand the TLE photon correction allows a better
 325 photon dose calculation. Indeed for almost all the configurations, maximal dose calculational differences are
 326 lower than 3% compared to the MC calculation except for the 1 mm³ case with incident neutrons of 10 MeV
 327 where we get a 40% dose overestimation by the algorithm. This overestimation is due to the fact that with
 328 10 MeV neutrons, protons up to 10 MeV will be produced: these protons have a range of around 1 mm in the
 329 soft tissues which produces an unsatisfied CPE condition which in turn leads to a dose overestimation by the

algorithm. For the other tested volume sizes, since CPE is fulfilled, this overestimation no longer occurs with the TLE photon correction.

At thermal neutron energy, the analytical correction shows two divergences compared to the MC method. It shows an overestimation of the dose when used in both the 1 mm^3 and 1 cm^3 volumes for the thermal neutron energy. This overestimation is due to the fact that with this correction, neutrons with energies lower than or equal to 0.025 eV are considered to be systematically captured by the H nuclei of the target, leading to a systematical local dose deposition from the generated 2.2 MeV photons as per Eq 15. When a larger volume is considered, the analytical correction leads to an underestimation of the dose (30%). The analysis of the generated photon spectrum inside the target excluding the capture generated photons showed that this difference is due to other photons interactions processes that are not taken into account by the analytical correction such as bremsstrahlung effects, pair creation and Compton scattered photons.

Given these observations, the TLE photon correction has been chosen over the analytical correction for the rest of our work.

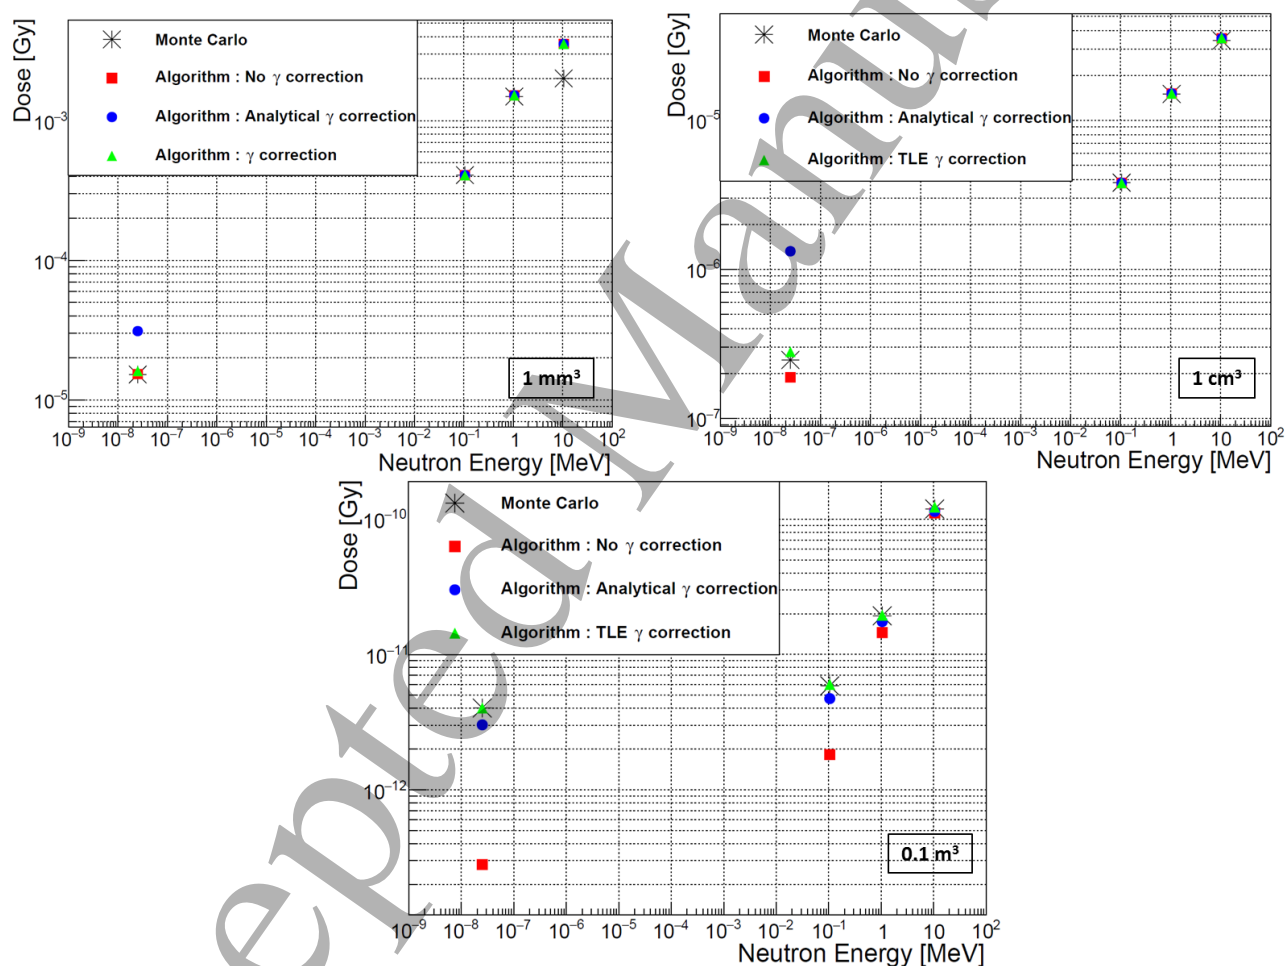

Figure 4: Comparison of dose calculation by the nTLE algorithm with the different photon dose corrections vs the MC dose calculation in different skeletal muscle cubical volumes

2.2 Voxelised heterogeneous volume case

2.2.1 Dose calculation

The dose ratio for the different simulated neutron energies are represented in Figure 5. At thermal energies, the mean dose differences between the nTLE and the analog MC over the whole volume is about 3%. However the dose difference can reach a maximum of 25% for a few voxels especially in the lung area. For the 1 MeV irradiation, the mean difference is about 1% except in the central lung inserts. For the 10 MeV neutron energy, the mean difference is lower than 1% in the whole volume except at the boundaries of the different materials. These differences are linked to the range of the secondary charged particles responsible for the dose deposition, the voxel size and the local dose approximation made by the nTLE algorithm.

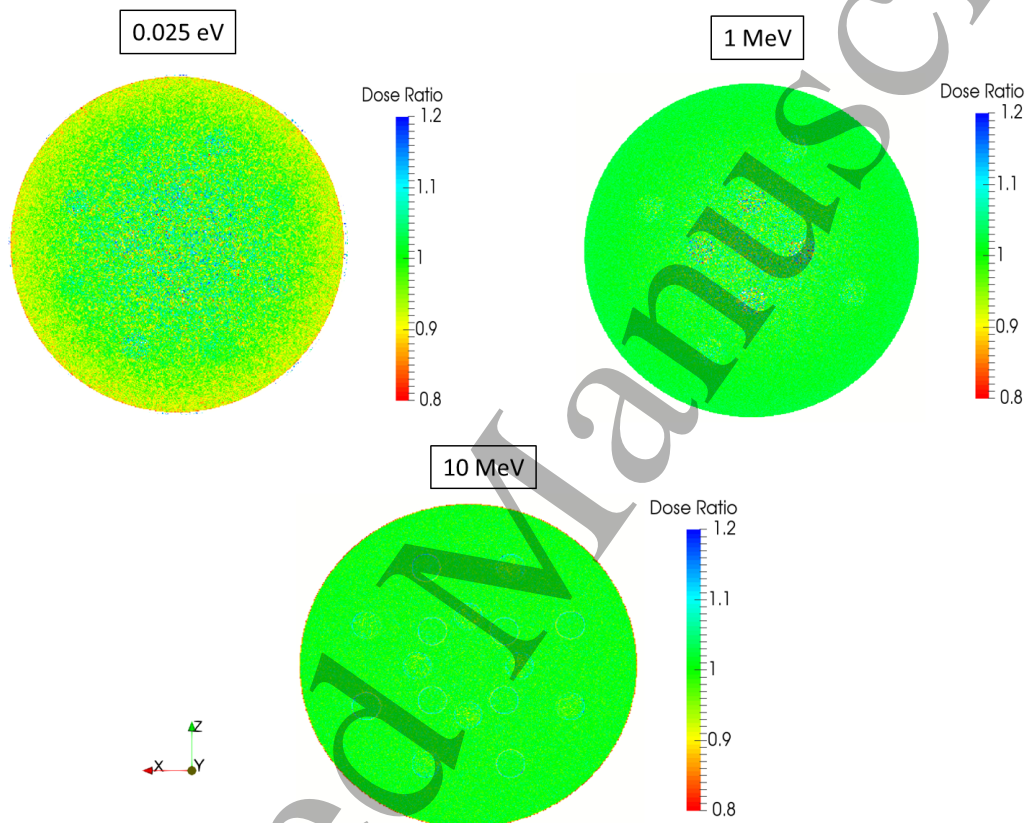

Figure 5: Dose ratio (analog over nTLE) for the different simulated neutron energies.

2.2.2 Statistical uncertainty

The uncertainty ratios for the different simulated neutron energies are represented in Figure 6. These ratios show that a factor of 4 to 20 can be obtained depending on the energies of the incident particles and the materials. The nTLE dose algorithm allows thus an increase of the calculation speed up to 400 times compared to the *DoseActor* of GATE. To be able to fully evaluate the gain in the phantom, an uncertainty ratio profile (Figure 7) has been plotted for each energy across a line in the middle of the slice crossing two lung inserts. It appears clearly that the speed gain is affected both by neutron energy and medium composition.

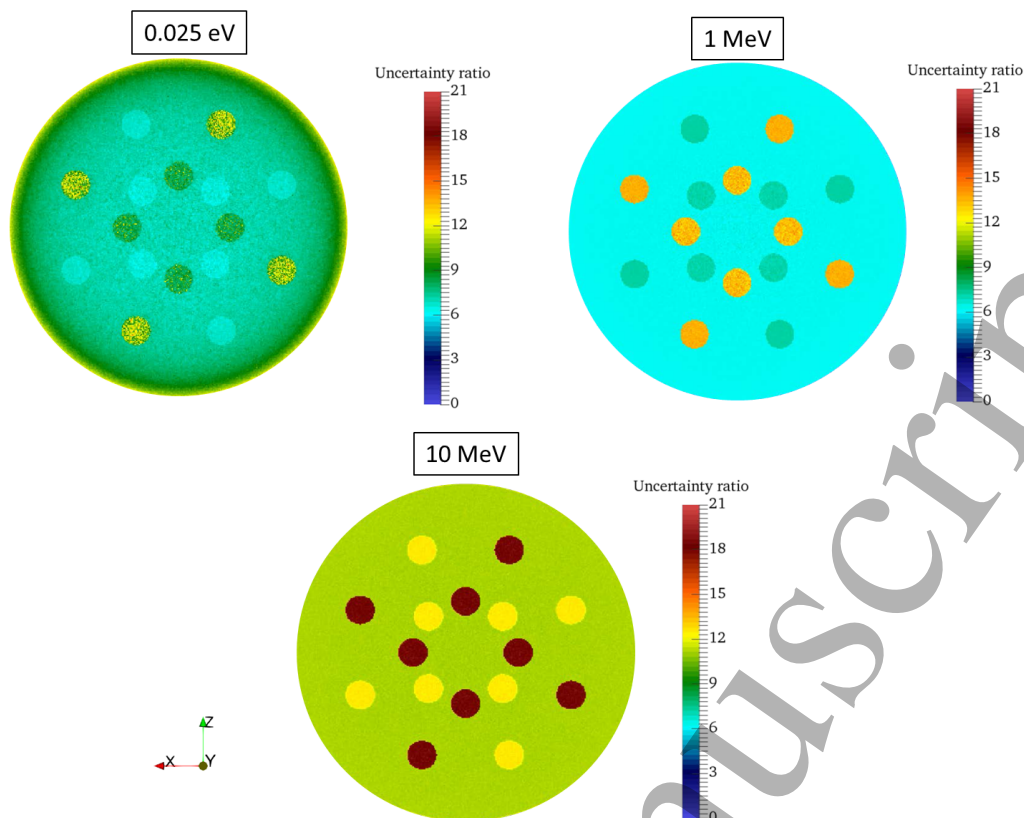

Figure 6: Uncertainty ratios (analog over nTLE) for the different simulated neutron energies.

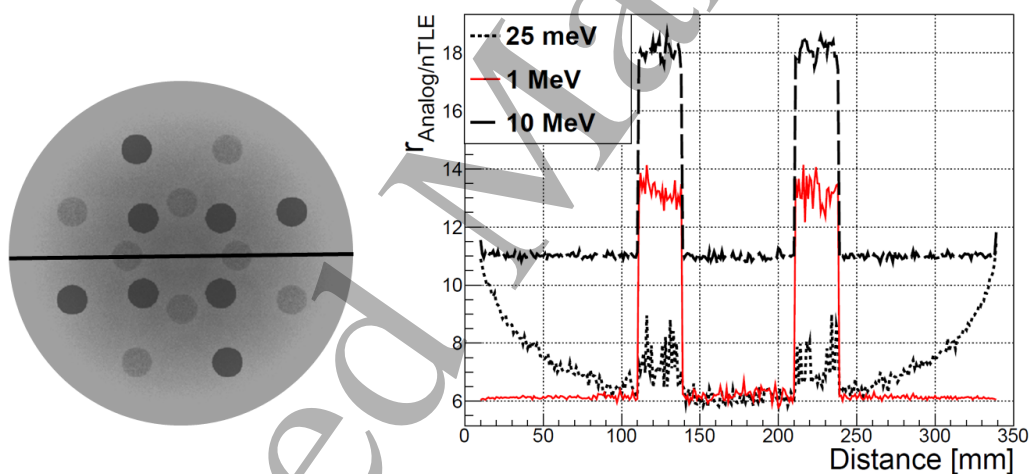

Figure 7: Uncertainty ratio profiles (analog over nTLE) for the different simulated neutron energies along the black line.

2.3 Voxelised ICRP phantom

2.3.1 Dose calculation

The left side of Figure 8 represents the dose ratio map. The mean dose ratio between the analog MC and the nTLE of the slice is 0.998 (0.992 in the central area). These results show a very good agreement of the nTLE algorithm with the MC method for dose calculation in a realistic radiotherapy case.

2.3.2 Statistical uncertainty

Results in terms of statistical uncertainty ratios are shown on Figure 8. For a realistic neutron spectrum in a radiotherapy room (mean energy around 1 MeV) and a voxel volume of 35.3 mm^3 the mean simulation time

Figure 8: Left: Dose ratio (analog over nTLE) ; Right: Uncertainty ratio (analog over nTLE) for the pelvis of a voxelised ICRP phantom irradiated with a realistic neutron spectrum.

gets accelerated by a factor from about 15 to 40 depending mainly on tissue compositions. This factor appears to be much lower than the one found with the heterogeneous phantom (voxel size = 1 mm^3) at the energy of 1 MeV. This is due to the fact that the acceleration factor is inversely proportional to the voxel size.

3 Discussion

The main goal of this work was to develop an efficient tool for neutron dose calculation in radiotherapy. The results of cylindrical phantom with the monoenergetic neutron beams allowed us to evaluate the performances of our algorithm and the origin of possible inaccuracies on dose calculation. When considering the thermal neutron beam with a voxelisation of 1 mm^3 , the comparison of the nTLE dose calculation to the MC method showed an average difference of 7% in the peripheral area of the phantom. This difference is due to the local dose approximation made in the nTLE method. At the thermal energy, neutrons captured by the H nuclei will generate photons of 2.2 MeV that will lead to the production of secondary electrons with energies up to 2 MeV. The range of these electrons is 1 cm in soft tissue and 4 cm in the lung. In a 1 mm^3 voxelised volume, in the first layers of the volume the generated electrons are too energetic to deposit their dose locally in the voxel which leads to an overestimation of the dose by the nTLE in the concerned voxel, the charged particle equilibrium not being fulfilled. However, deeper in the phantom layers (central area of the phantom), charged particle equilibrium becomes established which leads to a better dose calculation by the algorithm, with a mean difference close to 1% with the analog MC. For energies of 1 MeV, this peripheral dose overestimation does not appear, since at these energies, the energy is mainly deposited through scattered protons which have a range in tissue of less than 1 mm. However, once these neutrons get thermalised and captured by H, photons and electrons will be generated which explains the overestimation of the dose in the lung tissue in the middle of the phantom, due to the range of the secondary electrons in such a tissue. At this energy the mean difference in the dose calculation between the dose actor and the nTLE is estimated to be about 1% except for the pulmonary region, where the non fulfillment of the CPE condition leads to a maximal difference of 20% in comparison with the analog MC. When we evaluate the performances of the nTLE at a higher energy such as 10 MeV, the dose ratio map shows an accuracy with a mean dose difference of 1% with the analog MC except at the voxel

392 delimiting the interface of two different materials.

393 When a typical neutron energy spectrum in radiotherapy irradiated the pelvis region of an ICRP phantom,
394 the mean discrepancy between the analog MC and the nTLE is less than 1% (mean dose ratio of 0.998 over the
395 slice). This is explained on one hand by the fact that in a radiotherapy treatment the main component of the
396 spectrum are neutrons with a mean energy of 1 MeV while on the other hand, the ICRP phantom voxel size is
397 40 times bigger than the cylindrical phantom voxel size. In such a case the local dose deposition approximation
398 made by the algorithm will be more valid and fulfilled. These results highlight both the fact that the nTLE
399 allows us to have a good performance in terms of neutron dose calculation and the fact that it is feasible to use
400 it in radiotherapy applications.

401 Regarding the variance reduction factor, it appears that it is mainly affected by the neutron energy, the
402 material composition and the voxel size of the phantom. For neutron beams of 25 meV, 1 MeV and 10 MeV,
403 the mean gain of computing time in muscle tissue is respectively about 60, 30 and 120 with voxels of 1 mm³.
404 At 1 MeV, with a similar voxel size, depending on the considered material, the mean gain of computing time is
405 respectively about 200, 30 and 50 for the lung muscle and bone material. For a given voxel size, the cylindrical
406 phantom simulation case allowed us to determine the fact that the gain will be increased by two factors: the
407 mean free path of the particles and the density of the medium. Indeed, the longer the mean free path of the
408 particle, the greater will be the gain, since with the nTLE approach we consider a continuous energy deposition
409 in all the voxels crossed by the particle. The density of the medium will also have an impact on the gain as
410 shown in Figures 6 and 7, where it clearly appears that the gain is in each case higher in the lung tissue due
411 to its lower density in comparison with the bone and skeletal muscle. The change in the voxel size which is
412 illustrated by the dose calculation in the pelvis of the phantom, shows a mean drop in the gain by a factor of
413 3, which indicates that the variance reduction factor will be higher when fine spatial resolutions are considered.
414 Thanks to the nTLE, the mean gain obtained for dose calculations in the voxelised ICRP phantom is 25 times
415 greater than the analog MC.

416 4 Conclusion

417 The neutron TLE algorithm (nTLE) developed in GATE has proven to be a precise and efficient tool for
418 neutron dose calculation in radiotherapy. By reducing the mean calculation time by a factor 25 for a typical
419 radiotherapy neutron spectrum on a computational phantom, the nTLE could be part of a future MC peripheral
420 dose computation framework, dealing with neutron dose calculation, in order to systematically and accurately
421 evaluate the neutron component generated through the different treatment parameters. The comprehensive
422 study of its performances will allow its optimal use, especially when it comes to making the right compromise
423 between the voxel size and acceleration factor. Thanks to this tool, the out-of-field neutron dose absorbed
424 by the radiosensitive organs of a patient will be much easier to track and evaluate. While the present paper
425 has focussed on high energy X-ray radiotherapy, the method developed could be used for other radiotherapy
426 treatment involving neutrons (protontherapy, neutron capture therapy, hadrontherapy) when the sampling of
427 the geometry does not compromise the CPE and local dose deposition approximations.
