10 **Abstract**

11 The combined impact of invasive species and climate change threatens natural systems worldwide,
12 often facilitating the expansion of harmful invasive species. It is imperative to understand the
13 mechanisms behind why species become invasive and widespread. Traditionally, it is thought that
14 invasive species have greater tolerances to a wider array of environmental conditions than natives. We
15 therefore tested the hypothesis that invasive species are more tolerant to the effects of short term
16 exposure to temperature and salinity stress. Using unifactorial experiments, we compared the
17 tolerances of two common fouling NE Atlantic ascidians, the native *Ciona intestinalis* and the
18 invasive *Styela clava*, to increased temperature and decreased salinity. We measured lethal and
19 behavioural responses affecting 50% of populations to give an indication of the tolerance limits for
20 temperature (LT_{50}) and salinity (EC_{50}), and respiration rate to give an indication of the change in
21 metabolic response. The invasive *S. clava* was more tolerant to increased stress ($LT_{50} = 29.5$ °C, EC_{50}
22 = 19.5) compared with *C. intestinalis* ($LT_{50} = 27.0$ °C, $EC_{50} = 22.7$), whereas both species displayed
23 similar metabolic responses observed through increased respiration rates. This study is among the first
24 to experimentally determine limits for temperature and hyposalinity stress for either species and
25 supports the hypothesis that the invader performs better under extreme conditions. Future
26 environmental changes caused by events such as heatwaves and climate change could push species to
27 the edge of their physiological limits, potentially facilitating competitive shifts between native and
28 invasive species.

29

30 **1. Introduction**

31 On a global scale the impact of invasive species is paramount, causing detrimental ecological impacts
32 to ecosystems and their native communities (Mack et al. 2000; Butchart et al. 2011). In combination
33 with climate change, the impacts of invasive species threaten biodiversity worldwide, potentially
34 causing wide ranging effects. These include: impacting native species abundances and distributions;
35 local extinctions; alteration of vital ecosystem functions and services; and significant economic
36 impacts (Pimentel et al. 2005; Halpern et al. 2008; Hellmann et al. 2008; Pejchar and Mooney 2009;
37 Butchart et al. 2011). Furthermore, these two drivers of change often interact with climate change
38 enhancing the spread of non-native species (Dukes and Mooney 1999; Hellmann et al. 2008).

39 Evidence supports the hypothesis that shipping and hull fouling is a major vector in transporting
40 marine species worldwide (Clarke Murray et al. 2012; Peters et al. 2017). What is less clear is the
41 mechanisms employed by invasive species to enable them to become so pervasive. Generally, for
42 invasive species perceived higher physiological tolerances to a range environmental conditions (e.g.
43 temperature, salinity, pollution levels) is thought to enable greater competitive ability over native
44 species, helping to facilitate successful settlement, establishment of populations, and further spread
45 (Lenz et al. 2011; Zerebecki and Sorte 2011; Lejeusne et al. 2014; Lagos et al. 2017).

46 Invasive species often cause serious detrimental impacts. Of the biofouling taxa, tunicates are a major
47 concern. They can cause smothering of aquaculture facilities and species, damage to structures,
48 increased drag on propellers resulting in reduced efficiencies, and significant cleaning costs (Aldred
49 and Clare 2014). For example, the highly invasive tunicate *Styela clava* presents a significant global
50 risk. Its introduction in the Gulf of St Lawrence, Canada, resulted in a 50% loss to shellfish
51 aquaculture industries (Colautti et al. 2006). In the present study we therefore address the tolerance of
52 *S. clava* in comparison to the NE Atlantic native tunicate *Ciona intestinalis*, which is also considered
53 invasive in other parts of the world and causes significant economic impacts (e.g. Colautti et al. 2006;
54 Therriault and Herborg 2008a). It is imperative that we understand the physiological mechanism
55 behind these species invasion success.

56 Recently *C. intestinalis* has undergone taxonomic re-evaluation. Formerly at least two cryptic species,
57 Types A and B, made up this species complex and are now known as *C. robusta* and *C. intestinalis*
58 respectively (Brunetti et al. 2015). *C. robusta* prefers warmer waters, is native to north-west Pacific
59 and is introduced worldwide including Europe. Conversely, *C. intestinalis* is considered a cold water
60 species native to north-western Europe, from northern Portugal to Norway (Bouchemousse et al.
61 2016a). This species is also considered invasive in China (Zhan et al. 2010) and the north-eastern
62 American coastline (Therriault and Herborg 2008b). However, recent genetic evidence suggests an
63 ampho-Atlantic native distribution (Bouchemousse et al. 2016a). Prior to taxonomic re-evaluation this
64 species was considered to tolerate temperatures exceeding 30 °C (Dybern 1965; Marin et al. 1987;
65 Carver et al. 2006); however the highest temperature tolerances were attributed to specimens found in
66 the Mediterranean where *C. robusta* is pervasive (Zhan et al. 2010). So virtually no information is
67 available on the tolerance of *C. intestinalis* to thermal stress. Similarly, previous data regarding the
68 salinity tolerance of this species should be carefully interpreted considering taxonomic re-evaluation.
69 Generally *C. intestinalis* is considered a euryhaline species and, among populations within this species
70 native range, it has been observed to tolerate salinities under 12 (Dybern 1967; Carver et al. 2006).

71 By contrast *S. clava* is native to the north-west Pacific but has spread worldwide including to Europe,
72 North America and Australasia (Lützen 1999; Davis and Davis 2008). Within these locations its
73 settlement is known to result in significant economic impacts to aquaculture; in Canada alone this was
74 estimated between CA\$ 34–88 million per year (Colautti et al. 2006). Within Europe it was first
75 recorded in 1953 (designated as *Styela mammiculata*) in the Lynher Estuary, Plymouth, UK (Carlisle
76 1954). It then started expanding across north-western Europe during the following decades (Lützen
77 1999) and was first recorded in the Mediterranean by the mid 2000's (Davis and Davis 2008). Major
78 vectors of this spread can be attributed to human mediated transport on ship hulls and within ballast
79 water whereas natural dispersion is responsible for spread to neighbouring sites only (Davis et al.
80 2007). Experimental and observational studies of specimens located outside of this species native
81 range show that *S. clava* settles in locations experiencing temperatures ranging from -2 °C to in excess
82 of 23 °C (Buizer 1980; Davis and Davis 2008). However, there is limited evidence to suggest its

83 maximum tolerance. In addition, these studies have also indicated a preference for warm waters,
84 showing that for successful reproduction and settlement of this species ambient water temperatures
85 must exceed 16 °C for several days (Davis et al. 2007). This species also has limited osmoregulation
86 capabilities, preferring salinities above 20 (Davis et al. 2007; Davis and Davis 2008). However it has
87 been known to survive lower salinities by closing siphons for prolonged periods (Sims 1984; Lützen
88 1999).

89 Understanding the tolerance of species to environmental conditions is key to understanding their
90 potential spread. Regarding the two species of interest here, while they are common in urbanised
91 habitats, often dominating fouling communities (Lambert and Lambert 1998; Gittenberger and Van
92 Der Stelt 2011), their tolerance to temperatures and salinities is not widely understood, particularly
93 with regard to the metabolic impacts of these stressors. Furthermore, the recent taxonomic re-
94 evaluation of *C. intestinalis* calls to question previous evidence of tolerance for this species. We
95 therefore conducted a series of short term (24 hour) experiments examining the impact of increased
96 temperatures and decreased salinities on *S. clava* and *C. intestinalis*, evaluating survival and
97 metabolic response in terms of respiration. These were used to determine upper temperature and lower
98 salinity tolerance limits. These limits are known to be strongly correlated with the range of conditions
99 a species would be expected to be able to tolerate under natural conditions (Zerebecki and Sorte 2011;
100 Kelley 2014); therefore, these upper limits give an indication of the capacity of these species to be
101 able to survive extreme conditions. We hypothesised that the invasive *S. clava* would display a greater
102 tolerance to short term hyposalinity and increased temperature in comparison to the native *C.*
103 *intestinalis*, both in terms of survival and metabolic response.

104 **2. Methodology**

105 **2.1 Collection and maintenance of organisms**

106 *Ciona intestinalis* and *Styela clava* were collected from the Château Marina in Brest, France
107 (48°22'44"N, 4°29'21"W) in June 2017. Seawater temperature was continually monitored at 3
108 locations within the marina using HOBO (UA-002-64) data loggers, deployed between the 26 March

109 – 4 October 2017 and attached to floating structures (Supplementary material). Individuals were
110 found in high abundances attached to artificial substrates (pontoons, ropes, metal pillars). Species
111 were collected from under pontoons by SCUBA diving, carefully scraping and removing adults from
112 structures located within the centre of the marina. Organisms were subsequently transported to the
113 Roscoff Biological Station in seawater where they were cleaned of epiphytes and epibionts and placed
114 overnight in running ambient temperature seawater aquariums. Specimens were then transferred into
115 controlled temperature tanks with renewed seawater inflow for long term storage. Based upon water
116 conditions from which they were taken and temperatures appropriate to maintain live animals,
117 specimens were kept at 16 °C. Every two days specimens were fed a 1:2 (by cell count) mixture of the
118 algae *Chaetoceros gracilis* (IFREMER strain from Argenton) and *Isochrysis galbana* (Tahitian strain
119 from Roscoff Culture Collection) totalling approximately 4×10^8 cells L⁻¹. All specimens were
120 acclimated to these conditions for at least 72 hours prior to experimentation.

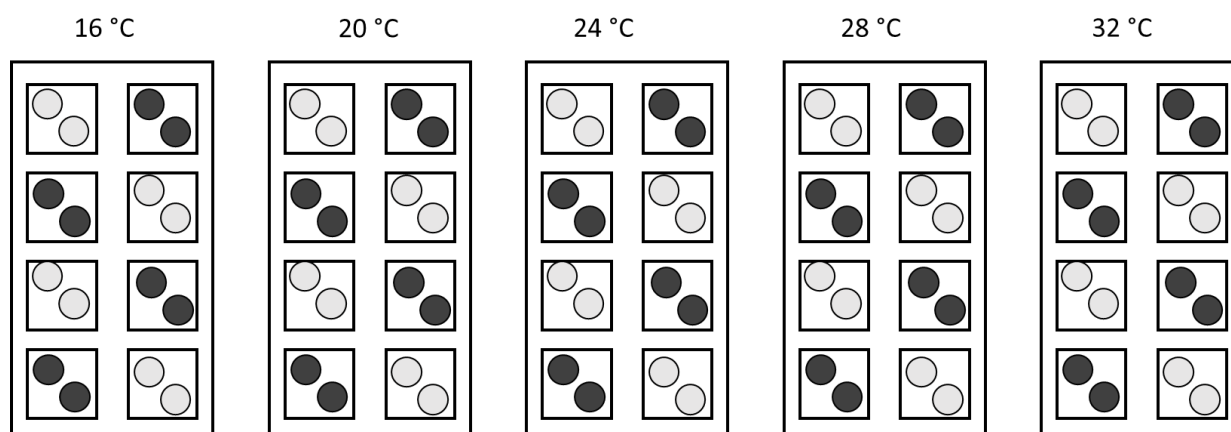

121 **2.2 Experimental setup**

122 The same experimental procedure was used for both the temperature and salinity experiments. During
123 each experiment, experimental units (EU's) consisted of 2 individuals of a single species placed in a
124 1.8 L tank supplied with constant aeration. In total each experiment used 40 EU's – 2 species x 5
125 treatments (levels of salinity or temperature) x 4 replicates for each treatment-species combination.
126 This equated to 4 EU's per treatment per species which were spread among 5 large temperature-
127 controlled aquaria (Figure 1); the heaters used maintained temperature ± 0.5 °C from the target.

128 After 24 hours each EU was assessed for mortality based upon the number of live and dead
129 individuals within the tank (n = 4 EU's per treatment per species). In addition, 1 individual was
130 removed from each EU to measure respiration. Hence 4 individuals were used per treatment per
131 species for respiration (n = 4). Specimens used in the respiration measurements were selected based
132 upon their visual size: approximately 5-8 cm for *C. intestinalis* and 8-11 cm for *S. clava*. To
133 determine mortality 3 criteria were assessed: contraction (siphon or body), colour change, and loss of
134 response to gentle touching of the siphons.

135 2.3 Temperature experiment

136 Temperature treatments were as follows: 16 (control: stock tank temperature), 20, 24, 28 and 32 °C.
 137 Desired temperatures were achieved by raising the water temperature within the 5 large temperature-
 138 controlled aquaria (Figure 1). After placing individuals within tanks and starting from 16 °C,
 139 temperatures were raised by 1 °C every 15 minutes. Once the desired temperature was reached tanks
 140 were left for 24 hours.

141

142 **Figure 1:** Experimental setup of the temperature experiment. Each experimental unit (EU; small square) contains 2
 143 individual specimens of the same species (circles; *Ciona intestinalis* = light grey, *Styela clava* = dark grey). EUs are placed
 144 inside larger temperature-controlled tanks (large rectangle) filled with freshwater to homogenise and maintain the
 145 temperature within each EU over the 24 hour experimental duration.

146 To assess respiration acrylic incubation chambers (600 ml) were utilised using methods from Noisette
 147 et al. (2016). Each chamber was filled with seawater that was equilibrated to the same temperature
 148 used in the corresponding treatment. One individual from each EU was taken and placed in a single
 149 chamber (n = 4 per treatment per species). A magnetic stirrer was placed within each chamber and the
 150 chambers were positioned on a waterproof stirring plate. The plate was kept underwater in an
 151 additional temperature-controlled aquarium, equilibrated to the corresponding treatment temperature.
 152 The stirring plate allowed 6 chambers to be incubated simultaneously. In addition, 6 control chambers
 153 were used for each temperature to correct for fluxes due to microbial activity within the seawater in
 154 each of the treatments. Using a fibre-optics system and reactive oxygen spots on the chambers
 155 (FIBOX 3, PreSens, Regensburg, Germany), oxygen was measured at the start and end of an
 156 incubation period which lasted for 30 minutes. Respiration (R; in $\mu\text{mol O}_2 \text{ g}^{-1} \text{ DW hr}^{-1}$) was calculated
 157 using the following equation:

$$R = \frac{\Delta O_2 \times V}{\Delta t \times DW}$$

158 where ΔO_2 (in $\mu\text{mol O}_2 \text{L}^{-1}$) is the difference in oxygen concentration between the start and end of the
159 incubation, V is the measured volume of each chamber minus the volume of the specimen, Δt is the
160 incubation time (hours), and DW is the dry weight (g) of the specimen and obtained by placing
161 specimens in a drying oven for 48 hours at 60°C .

162 **2.4 Salinity experiment**

163 To obtain the desired salinities distilled water was added to seawater and checked using a Fisher
164 Scientific™ Traceable™ salinometer. Salinity treatments were as follows: 35 (control: natural
165 seawater), 28, 24, 21 and 17. The lower values were chosen based upon the ranges of salinity
166 tolerance observed in other studies (Shumway 1978; Carver et al. 2006; Clarke and Therriault 2007;
167 Davis et al. 2007) and on pilot studies where mortalities occurred between salinities of 14-21. Each
168 EU contained 2 individuals which were placed directly from natural seawater into altered salinity
169 water. EU's were randomly dispersed amongst the 5 large temperature-controlled aquaria to prevent
170 fluctuations in temperature over the experimental duration.

171 This experiment was independent from the temperature experiment and used different apparatus for
172 calculating oxygen concentration. The experimental setup follows the methodology used in the
173 temperature experiment, the differences being the chambers used for incubation and the device used
174 to measure oxygen within the water. The equation for calculating respiration remains the same. In this
175 experiment, incubations were conducted within hermetically sealed glass chambers of two sizes (200
176 ml and 500 ml). Due to the smaller *C. intestinalis* used in this experiment, a smaller size of incubation
177 chamber (200 ml) was necessary to allow an appreciable change in oxygen to be able to calculate
178 respiration accurately. This chamber was too small for *S. clava* which was therefore incubated in the
179 larger (500 ml) chamber. Oxygen was measured using an oxygen probe (Hach-Lange LDO101) prior

180 to sealing the chambers (incubation start) and following the incubation (approximately 30 minutes), at
181 which point the seal was broken and the oxygen measured immediately.

182 **2.5 Data analysis**

183 Mortality data were used to calculate the temperature that was lethal to 50% of the population (LT_{50}).
184 For the salinity experiments, at the range used, a behavioural response was observed rather than a
185 mortal response; the effective concentration (EC_{50}) was therefore calculated and defined as the
186 salinity at which 50% of individuals displayed a response. Binomial regression models using the
187 probit link function were used to model the response and to produce mortality curves. Using these
188 models, the LT_{50} and EC_{50} and corresponding confidence intervals were calculated. All analyses were
189 completed using the statistical programme R, version 3.22 (R Core team 2015) and visualised using
190 the ggplot2 package (Wickham, 2009).

191 Two-factor ANOVA was used to analyse the respiration data, which, depending on the experiment,
192 used either the temperature or salinity and species as fixed factors. To facilitate a balanced statistical
193 design in the temperature experiment, the highest temperatures (28 and 32 °C) were not included in
194 the analysis due to high mortality. To explore interaction terms and explore the impact of temperature
195 on individual species (thus incorporating excluded data for higher temperatures where data were
196 available), single factor ANOVA and Tukey's HSD *posteriori* comparisons (where appropriate) were
197 performed for each species. Residuals of the model were checked for normality and homogeneity of
198 variances; the salinity data set was log transformed to meet normality and homogeneity of variances
199 criteria.

200 **3. Results**

201 **3.1 Temperature experiment**

202 After 24 hours increased temperatures had a significant effect on the mortality of both *Ciona*
203 *intestinalis* and *Styela clava* (Figure 2A); in both species 100% mortality occurred within the highest
204 temperature treatment (32 °C). There was a small difference in the modelled LT_{50} values observed in

205 both species. The invasive *S. clava* displayed higher tolerance to increased temperatures ($LT_{50} = 29.5$
 206 $^{\circ}C$; $CI = 27.1-31.9$) than the native *C. intestinalis* ($LT_{50} = 27.0$ $^{\circ}C$; $CI = 25.5-28.5$).

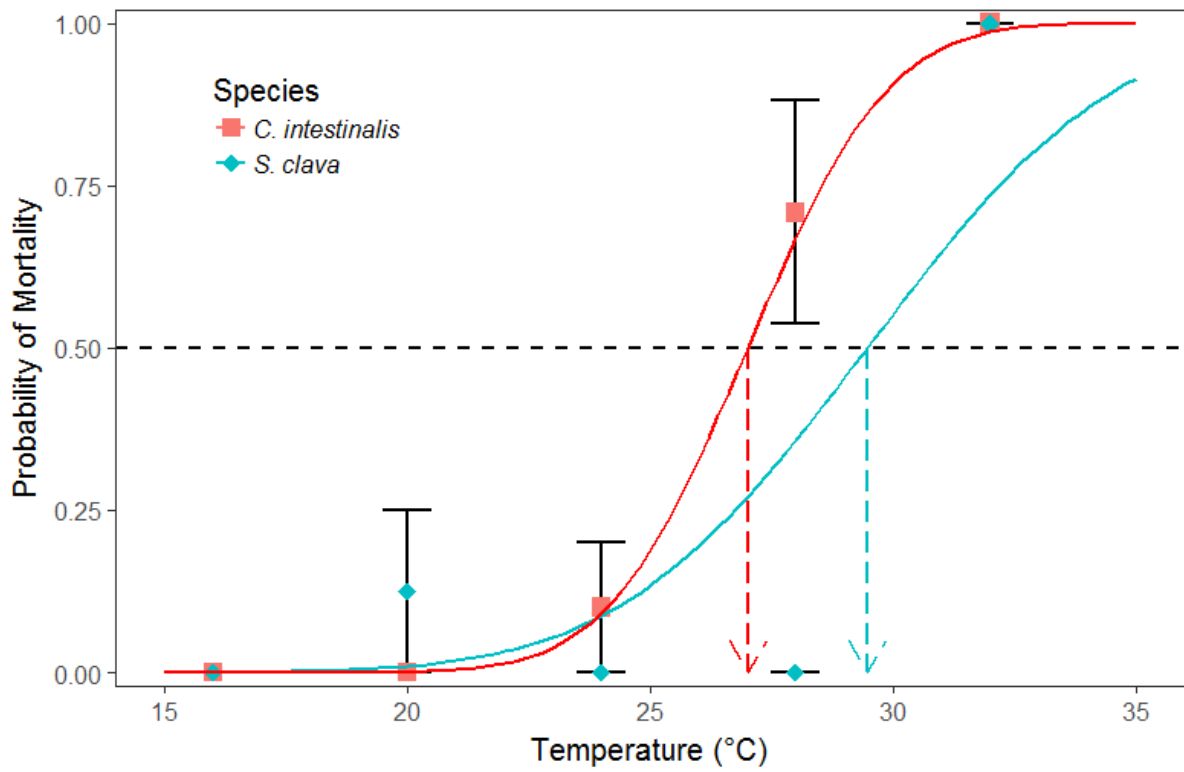

207 In the analysis of respiration (Table 1), there was no significant interaction term between species and
 208 temperature treatments indicating respiration in both species was affected similarly by increased
 209 temperatures. Overall respiration was significantly lower in *S. clava* compared to *C. intestinalis*.
 210 Temperatures above 16 $^{\circ}C$ resulted in the highest respiration for both species (Figure 2B). There was
 211 100% mortality at 32 $^{\circ}C$, and only 1 surviving *C. intestinalis* at 28 $^{\circ}C$ on which respiration could be
 212 measured, therefore only the first 3 temperature treatments were considered in the two factor ANOVA
 213 (Table 1). Increased temperatures resulted in significantly higher respiration in comparison to the
 214 16 $^{\circ}C$ temperature treatment. There were no differences between the measured respiration at 20 $^{\circ}C$ and
 215 24 $^{\circ}C$ for *C. intestinalis*, nor at 28 $^{\circ}C$ in *S. clava* (Figure 2B).

216 Table 1: Two-factor ANOVA examining the effects of temperature (A) and salinity (B) on two species of ascidian – the
 217 native *Ciona intestinalis* and the invasive *Styela clava* – using species and the stressor (either temperature or salinity) as
 218 fixed factors. Effects of temperature were examined at 3 levels (16, 20 and 24 $^{\circ}C$) and salinity at 5 levels (17, 21, 24, 28 and
 219 35). Bold type indicates a significant effect at $p < 0.05$; $n = 4$ for all treatments.

A) Temperature	Factor	df	MS	F	p
	Temperature	2	636.1	27.13	<0.001
	Species	1	126.9	5.41	0.031

220

A

221
222

B

223

224 Figure 2: – A) Mean probability of mortality (±SE) and B) respiration (µmol O₂ g⁻¹ dry weight h⁻¹) of *Ciona intestinalis* and225 *Styela clava* exposed to increased temperatures for 24 hours (n = 4). Mortality curves (A) were produced using Probit

226 analysis and indicate the probability of a species mortality at a given temperature; 50% mortality is indicated for each

227 species (LT₅₀). For respiration (B), bars represent mean respiration (±SE) and circles are individual data points, as within the

228 ANOVA there were significant main effects, letters indicate significant differences within the temperature factor only, as
229 determined by posteriori analyses (28 °C was not included in the analysis due to lack of replication).

230 **3.2 Salinity experiment**

231 There was a minimal effect of lowered salinities on mortality at the ranges tested. Only 2 specimens
232 were clearly identified as dead, meeting all 3 criteria of mortality as defined in the methodology.

233 There was, however, a behavioural response whereby specimens no longer responded to touching
234 their siphons. In addition to being unresponsive, the siphons of *S. clava* specimens were continually
235 open (not contracted), whereas in *C. intestinalis* specimens were extremely contracted. Therefore, in
236 the following analysis, this behavioural response has been modelled, calculating the effective salinity
237 impacting 50 % of the population (EC_{50}).

238 Both species displayed a tolerance to decreased salinities, however after 24 hours all individuals in the
239 lowest salinity treatment displayed the described behavioural response (Figure 3A). *S. clava* displayed
240 the greatest tolerance to decreased salinity with an EC_{50} of 19.5 (CI = 17.3-21.6) whereas *C.*
241 *intestinalis* displayed an EC_{50} of 22.7 (CI = 21.6-23.8).

242 Within the two factor model analysing the impacts of salinity on respiration (Table 1), there was no
243 significant interaction term, while the main effects were significant. Within the salinity experiment
244 there was a large difference in respiration rates observed between the two species. Similarly to the
245 temperature experiment, overall higher respiration by body mass was observed in *C. intestinalis*.

246 Salinity had a significant effect on both species (Table 1) whereby respiration rate was lower in
247 natural seawater (salinity 35) in comparison to salinities less than 28 (Figure 3B).

248
249

250

251 Figure 3: A) Mean probability of the loss of response (\pm SE) and B) respiration ($\mu\text{mol O}_2 \text{ g}^{-1}$ dry
 252 weight h^{-1}) of *Ciona intestinalis* and *Styela clava* exposed to decreased salinities for 24 hours ($n = 4$).
 253 Response curves (A) were produced using Probit analysis and indicate the probability of a species

254 losing responsiveness to stimuli at a given salinity; 50% of the populations response loss is indicated
255 for each species (EC_{50}). For respiration (B), bars represent mean respiration ($\pm SE$) and circles are
256 individual data points, as within the ANOVA there were significant main effects, letters indicate
257 significant differences within the salinity factor, as determined by posteriori analyses.

258 **4. Discussion**

259 In experiments examining the tolerance of two common fouling species to increased temperatures and
260 decreased salinities, the invasive *Styela clava* and the native *Ciona intestinalis* both displayed high
261 tolerances to short term (24 hours) exposure. Comparatively, while in both species the respiration
262 rates responded similarly to the altered salinities or temperatures, *S. clava* displayed tolerances greater
263 than that of *C. intestinalis* in terms of displaying mortal (LT_{50}) and behavioural responses (EC_{50}). This
264 is in agreement with other studies stating invasive species have a wider tolerance range which, among
265 other responses, impact survival and respiration (Lenz et al. 2011; Zerebecki and Sorte 2011;
266 Lejeusne et al. 2014). Worldwide both species are commonly found fouling urbanised habitats such as
267 marinas and are considered invasive species (Davis and Davis 2008; Zhan et al. 2010). As such,
268 human-induced dispersal and climate change influencing temperature and salinities have the potential
269 to influence worldwide distribution patterns and range expansions of these species (De Rivera et al.
270 2011; Rius et al. 2014). This study offers empirical evidence of the versatility of these ascidians,
271 particularly regarding *S. clava* which is a highly prolific invader. This species was shown to tolerate a
272 wide range of environmental conditions, therefore facilitating its spread and the threat of future
273 invasion success.

274 **4.1 Thermal tolerance**

275 In the mortality analysis, the invasive *S. clava* was able to tolerate and survive at higher temperatures
276 than the European Atlantic native *C. intestinalis* ($LT_{50} = 29.5$ °C and 27 °C respectively). In terms of
277 the respiratory response, both species were affected similarly by increased temperature. This
278 complements previous experimental studies documenting that invasive species temperature tolerances
279 are greater than those of comparative native species (Zerebecki and Sorte 2011; Kelley 2014;

280 Lejeusne et al. 2014). Furthermore, we empirically show upper temperature limits to acute thermal
281 stress (LT_{50}), providing information on each species thermal niche. Higher upper thermal tolerance
282 limits are known to be a strong indicator of the eurythermality of a species (Kelley 2014). When
283 assessing multiple species, these upper limits can therefore give a good indication of comparative
284 tolerances of species, thus relating to how species would cope with environmental changes in the
285 wild. Based on geographic ranges, *C. intestinalis* is documented to be found in temperatures ranging
286 from subzero to up to 24 °C (Dybern 1965; Carver et al. 2006; Vercaemer et al. 2011). However, the
287 recent taxonomic separation of *C. intestinalis* (previously *C. intestinalis* type B) from its congener *C.*
288 *robusta* (type A) calls to question tolerance experiments conducted prior to its separation. By
289 comparison, previous monitoring has shown that *S. clava* typically establishes invasive populations in
290 locations where temperatures range from subzero to in excess of 23 °C (Buizer 1980; Davis and Davis
291 2008), however there is less information on a maximum temperature for this species. In an example of
292 known populations where sea surface temperatures have exceeded these limits, Davis and Davis
293 (2010) noted that in Sète, French Mediterranean, extreme summer temperatures reached 29.1 °C in
294 2006. While this is only slightly lower than the LT_{50} we observed here, the survival of this population
295 in Sète was originally theorised to be due to refuge habitats at lower (and cooler: 26.6 °C) depths
296 (Davis and Davis 2010). We show that *S. clava* could survive these extreme events, at least for the
297 short term.

298 The IPCC predicts that climate change is expected to increase global temperatures worldwide by
299 between 1-3.7 °C by the end of the century (IPCC 2013) and increase the severity of summer
300 heatwaves by up 2 °C in the coming decades (Meehl 2004; Perkins-Kirkpatrick and Gibson 2017).
301 Extreme summer temperatures have already been shown to significantly impact subtidal communities
302 (Lejeusne et al. 2010; Sorte et al. 2010; Smale et al. 2015). With increasing severity, the observed
303 effects will become more pronounced. At present, in the Château Marina in Brest, France, we
304 observed maximum summer water temperatures of 21 °C and the summer averages approximately 18
305 °C (Supplementary material). Future increases in temperature will likely impact fouling communities

306 and could potentially impact invasive and native species differently based upon their respective
307 tolerances (Sorte et al. 2010; Smale et al. 2015).

308 With respect *S. clava* and *C. intestinalis*, it is likely that temperatures up to or exceeding the LT_{50} for
309 both species could be detected within Europe by the end of the 21st century. This could have
310 significant impacts on the range of *S. clava*, causing it to become an even more ubiquitous invader in
311 European waters and worldwide. Already we are seeing this species moving further north (e.g. Cook
312 et al. 2013) but there is potential for it to spread to new locations around the Iberian Peninsula and the
313 Mediterranean (Davis and Davis 2010; Çinar 2016). While ocean warming could facilitate the spread
314 of *S. clava*, the native *C. intestinalis* is a cold water species and its hypothetical range expansion due
315 to climate change would be more limited. At present *C. intestinalis* is dominant within Brittany where
316 this species occurs in syntopy with *C. robusta*. It is known that warmer summers in these locations
317 tend to facilitate increased settlement of the invasive *C. robusta* (Bouchemousse et al. 2016b) and
318 monitoring suggests *C. intestinalis* has a much lower thermal maxima and is less tolerant to thermal
319 changes than *C. robusta* (see Bouchemousse et al. 2016a, b). With respect to climate change,
320 increased temperatures could impact physiological mechanisms and result in higher mortality in *C.*
321 *intestinalis*, thus decreasing its competitive ability over *C. robusta* and resulting in a competitive shift
322 between the two species. Given that the tolerance of native species tends to be lower than
323 taxonomically similar invasive species (Lenz et al. 2011; Lejeusne et al. 2014), other species will
324 likely be impacted similarly to increased temperatures and result in significant community shifts.

325 While the survival data relate to thermal maxima, a functional stress response can be observed for
326 both species at lower temperatures. This directly relates to the tolerance of a species and its potential
327 to become an invader outside of its native range. For both species, the rates of respiration increased
328 when temperatures exceeded 20 °C, where it reached its maximum. At temperatures above 20 °C,
329 there were zero or negligible increases in respiration rate. Similar results were observed by Ai-Li et al.
330 (2008) and Kang et al. (2015) who confirm this relationship is consistent among size classes of *S.*
331 *clava*. Similar results have also been observed on other physiological responses in *C. intestinalis*. For
332 example in populations from Denmark, Petersen and Riisgård (1992) discovered that filtration rates

333 began to decline above 21 °C, whereas at lower temperatures, a linear relationship between filtration
334 rate and increasing temperature was observed. This suggests thermal stress was occurring above these
335 temperatures and complements the present study where a metabolic response is observed and peaks at
336 20 °C. At higher temperatures, there were no further significant changes in respiration rate however
337 given that there was high mortality in our treatments above 24 °C, it is reasonable to suggest
338 temperature is causing a significant stress response, at least for *C. intestinalis*.

339 In this study, no further increases in metabolic response over 20 °C indicates a reduction in
340 temperature-dependency of the metabolism (i.e. at higher temperatures metabolism is not impacted by
341 increasing temperature). While this could be interpreted as an indication that the animal is stressed,
342 measurement of multiple physiological mechanisms should be regarded to fully consider an
343 organism's ability to survive or grow (e.g. scope for growth model: Warren and Davis 1967; Newell
344 and Branch 1980). In other studies of temperature effects on various physiological mechanisms
345 employed by *S. clava*, temperatures above 24 °C have resulted in declines of feeding and excretion
346 rates, and temperatures of 28 °C have been shown to cause declining function and scope for growth
347 (Jiang et al. 2008; Kang et al. 2015). However, even within this temperature range, *S. clava* has been
348 shown to be well adapted, with the capacity to maximise its physiological response according to
349 temperature to meet energy demands (Jiang et al. 2008). The higher tolerance displayed by *S. clava*
350 and other invasive species is perhaps one of the most significant features that allow them to spread
351 and establish worldwide.

352 **4.2 Hyposalinity tolerance**

353 Our results correspond with the tolerances observed within natural ranges of both species. *C.*
354 *intestinalis* is a euryhaline species, reportedly within its native habitat tolerating salinities ranging
355 from 12–40 (Dybern 1967; Carver et al. 2006; Therriault and Herborg 2008b). By contrast the
356 invasive *S. clava* is rarely found below salinities of 20 (Lützen 1999; Davis et al. 2007; Davis and
357 Davis 2008). However, this species has been known to survive short durations when subjected to
358 salinities below 20, purportedly surviving for several days by closing siphons (Sims 1984; Lützen
359 1999). Similar behavioural responses have been observed in *C. intestinalis* which, in addition, has

360 been shown to cease respiring during times of lowered salinity (Shumway 1978). This behavioural
361 response of closing siphons is, perhaps, related to avoidance mechanisms similar to those employed
362 by other species, such as bivalves closing shell valves (e.g. Davenport 1977) or burrowing behaviour
363 in polychaetes (e.g. Shumway and Davenport 1977). This mechanism was not employed within our
364 experiments for either species, however for both species cessation of response to siphonal stimuli did
365 occur, indicating a severe stress response to decreased salinity. In mortality studies on tunicates, this
366 lack of response is often recorded as an endpoint (Sims 1984; Peck et al. 2009; Zerebecki and Sorte
367 2011; Jofré Madariaga et al. 2014) however, as seen in this study, the lack of a response does not
368 indicate death or cessation of respiration. Other factors should be taken into consideration to assess
369 mortality or fitness of an individual, especially under salinity stress.

370 To our knowledge, only 2 previous studies have researched the effects of lowered salinities on the
371 respiration of the two target species (ISI web of science search, accessed March 2018, using keyword
372 combinations of: salinity|respiration|oxygen consumption – no further results were found when the
373 search was expanded to include other ascidians). Of these, both studies present results contradictory to
374 our own. Where we identified an increase in respiration due to the effects of lowered salinity,
375 Shumway (1978) and Ai-Li et al. (2008) show decreasing salinities caused reductions in the
376 respiration of *C. intestinalis* and *S. clava* respectively. However, these studies focus on shorter
377 duration exposures than the results we present (6 hours and 2 hours respectively compared with our
378 24 hour exposure). Longer term subjection to lowered salinities could facilitate acclimation and a
379 response related to longer term exposure. Kinne (1966) proposed 4 categories describing the varied
380 physiological responses of organisms when exposed to changes in salinity, stating that metabolic rates
381 will either be “(1) increased by subnormal salinities, and/or reduced in supranormal salinities, (2)
382 increased both in sub- and supranormal salinities, (3) reduced both in sub- and supranormal salinities,
383 (4) essentially unaffected.” Within this study, our results correspond with categories 1 and 2
384 describing increases in metabolic response caused by subnormal salinities. This is a response typical
385 of other euryhaline species (e.g. Kinne 1966; Roast et al. 1999; Ern et al. 2014). To compensate for
386 increased stress, regulatory mechanisms (such as osmoregulation) come at a significant energetic cost

387 (Rivera-Ingraham and Lignot 2017). In turn, this can lead to an elevated oxygen demand and
388 increased respiration rates (Rivera-Ingraham and Lignot 2017).

389 Previous experimental evidence suggests that impacts caused by decreased salinities would be lower
390 for invasive species (Lenz et al. 2011). While *S. clava* had a lower respiration rate than *C. intestinalis*
391 at all salinities, surprisingly we found limited evidence to suggest that, within the range tested,
392 hyposalinity had a greater negative impact on *C. intestinalis*. Furthermore, given that previous
393 evidence suggests the salinity tolerance range of *C. intestinalis* to be greater than *S. clava* (Dybern
394 1967; Lützen 1999; Carver et al. 2006; Davis et al. 2007), it is interesting to note that a behavioural
395 response (unresponsive to stimuli) was observed in *C. intestinalis* at higher salinities (lower stress).
396 Within this study we did not measure recovery, ultimately this could be a determining factor when
397 analysing the tolerance limits of either species.

398 Tolerance ranges can often vary among populations of the same species. Within the Baltic Sea,
399 Dybern (1967) noted the high tolerance of *C. intestinalis* to low salinities of 11 in regions that are
400 regularly subjected to these regimes. Similarly, Lützen (1999) noted that populations of *S. clava*
401 within Danish fjords are able to survive regular periodic drops below salinities of 20, tolerating
402 salinities documented to be lethal elsewhere. The individuals collected in this study were taken from a
403 marina which was in close proximity to the Penfeld River in Brest. This could facilitate regular
404 exposure to low salinities, especially after strong rainfall. Over generations, species have the ability to
405 adapt to new locations and conditions through natural selection and adaptive evolution (Colautti and
406 Lau 2015). This adaptive ability seen in invasive species makes them particularly problematic within
407 the marine environment. To fully appreciate the impact of invasive species, studies need to be
408 conducted on the resistance of species to environmental pressures within and among their native and
409 invasive ranges.

410 **5. Conclusion**

411 We found that the invasive *Styela clava* displayed greater tolerance compared with *Ciona intestinalis*
412 to both increased temperatures and to decreased salinities, however limited differences in metabolic

413 response between the two species were observed. This study is among the first to experimentally
414 suggest upper limits on survival and metabolic response for either species to these common
415 environmental stressors. This was due to limited prior experimental evidence for the newly
416 taxonomically re-evaluated *C. intestinalis* and the invasive *S. clava*. As such this study offers insights
417 into the mechanisms behind the successful ability shown in these species to become invasive
418 worldwide. Human mediated dispersal of organisms is likely to select for the most tolerant, fast
419 growing and adaptive species. These species must be able to survive transport and subsequently
420 become established within an area to truly become invasive. Future threats from climate change will
421 only exacerbate the spread of invasive species. The wide tolerance ranges displayed here by *S. clava*
422 are typical of invasive species worldwide, and as such, these factors must be taken into consideration
423 to understand how and where species invasions are likely to occur.

424 **Supplemental material**

425 Table S1: Continuous water temperature data from 26/04/2017 – 03/10/2017, logged using HOBO
426 data loggers recording temperature every 15 minutes and permanently fixed to floating structures
427 from 3 locations within Château Marina, Brest, France.

428 **Acknowledgements**

429 We are undoubtedly grateful to the Harbour Authority of the Château Marina in Brest for their
430 authorisation in collection. We would like also to thank Jérôme Coudret and Mathieu Camusat for
431 help with field collection, and Sophie Martin for help with the respiration measurements and analysis.
432 We are also grateful to the ‘Service Mer et Observation’ and to the ‘Centre de Ressources en Biologie
433 Marine’ of the Roscoff Biological Station which provided technical support for diving and algae
434 culture respectively. This work was partly funded by the Region Bretagne under the SAD postdoctoral
435 program ‘Bzh-ITun’ and the Conseil Departemental of Finistere postdoctoral program, both to JK (PI:
436 CL).

437 **Compliance with ethical standards**

438 Funding: This work was partly funded by grants from the Region Bretagne under the SAD
439 postdoctoral program ‘Bzh-ITun’ and the Conseil Departemental of Finistere postdoctoral program,
440 both to Joseph Kenworthy (Principal Investigator: Christophe Lejeusne).

441 Conflict of interest: The authors declare no conflicts of interest.

442 Ethical approval: All applicable international, national, and/or institutional guidelines for the care and
443 use of animals were followed
