**KEYWORDS:** Polymer nanocomposites, mechanical reinforcement, glass transition, segmental dynamics, interfacial layer

**ABSTRACT**

The addition of nanoparticles to a polymer matrix is a well-known process to improve mechanical properties of polymers. Many studies of the mechanical reinforcement in polymer nanocomposites (PNCs) focus on rubbery matrices; however, much less effort concentrates on factors controlling mechanical performance of the technologically important glassy PNCs. This paper presents a study of the effect of the polymer molecular weight (MW) on the overall mechanical properties of glassy PNCs with attractive interaction by using Brillouin light scattering. We found that the mechanical moduli (bulk and shear) have a non-monotonic dependence on MW that cannot be predicted by simple rule of mixtures. The moduli increase with increasing MW up to 100 kg/mol followed by a drop at higher MW. We demonstrate that the change in the mechanical properties of PNCs can be associated with the properties of the interfacial polymer layer. The latter depend on the interfacial chain packing and stretching, as well as polymer bridging that vary differently with MW of the polymer. These competing contributions lead to the observed non-monotonic variations of glassy PNC moduli with MW. Our work provides a simple, cost-effective, and efficient way to control the mechanical properties of glassy PNCs by tuning the polymer chain length. Our finding can be beneficial for rational design of PNCs with desired mechanical performance.

3  
4  
5  
6 Polymer nanocomposites (PNCs) have become a prominent area of current research and  
7  
8 development. Addition of hard nanoparticles to a polymer matrix leads to a significant  
9  
10 improvement of several macroscopic properties, such as electrical <sup>1</sup> or mechanical properties, <sup>2-3</sup>  
11  
12 as well as reduction in membrane aging. <sup>4</sup> This makes PNCs attractive for various applications,  
13  
14 including surface coating, electronics, and gas separation membranes. In industry, combinatorial  
15  
16 methods are often used to design PNCs. These methods do not always lead to the desired  
17  
18 properties, highlighting the importance of a fundamental understanding of the factors affecting  
19  
20 macroscopic properties in PNCs. Our fundamental knowledge is rather limited with many open  
21  
22 questions, and especially those related to the microscopic origin of the mechanical reinforcement  
23  
24 found for PNCs in rubbery and in glassy states.<sup>5-10</sup> Several mechanisms, such as particle jamming  
25  
26 <sup>11</sup> and the formation of bridges between NPs,<sup>8-9</sup> have been proposed to explain the increase in the  
27  
28 mechanical moduli in rubbery nanocomposites. However, much less is known about mechanical  
29  
30 enhancement in glassy PNCs due to the range of non-equilibrium states available for polymers,  
31  
32 and the limited number of experimental techniques to study viscoelastic, dynamic, and mechanical  
33  
34 properties of glassy polymers. Although the mechanical enhancement in a glassy PNC is large in  
35  
36 absolute values (a few GPa increase in modulus), the changes relative to the neat glassy polymer  
37  
38 are usually small (a few times),<sup>10, 12-14</sup> and difficult to measure. Originally, the mechanical  
39  
40 enhancement in the glassy PNCs is interpreted by the hydrodynamic effect of the hard  
41  
42 nanoparticles. <sup>15</sup> This effect is due to the deformation of the flow field around the particle. It has  
43  
44 been shown by Smallwood <sup>16</sup> and Guth <sup>17</sup> that the force field on the polymer surrounding the  
45  
46 particle can be mapped on the flow field, leading to the same relative increase in modulus as given  
47  
48 by Einstein <sup>18</sup> for viscosity, i.e.,  $1 + 2.5 \Phi$  at low volume fractions  $\Phi$ . However, recent mechanical  
49  
50 tests on glassy PNCs have clearly shown that mechanical reinforcement is stronger than predicted  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 by the hydrodynamic approach.<sup>10</sup> Besides, the dispersion state, i.e., the spatial arrangements of  
7  
8 the nanoparticles (NPs) within the matrix, has a strong impact on the mechanical performances.  
9  
10 Whereas the formation of a volume-spanning network of NPs, or NP aggregates might have  
11  
12 advantages in the melt state,<sup>19-23</sup> well-dispersed NPs are required to obtain optimal mechanical  
13  
14 properties below the glass-transition temperature,  $T_g$ .<sup>12, 24-25</sup> This indicates that different  
15  
16 mechanisms contribute to the reinforcement in glassy and rubbery PNCs.  
17  
18  
19  
20

21  
22 Recently, the concept of an interfacial polymer layer with a thickness of  $\sim 2 - 6$  nm around the  
23  
24 nanoparticles and enhanced moduli has been employed to explain the mechanical properties of  
25  
26 PNCs in both the rubbery and glassy states.<sup>9-10, 26</sup> For rubbery PNCs, a spatial dependence of the  
27  
28 viscoelastic modulus of the polymer chains has been proposed in relationship with the concept of  
29  
30  $T_g$ -gradient.<sup>7, 27</sup> In this approach, it is expected that the interfacial layer modulus will be about  $10^2$   
31  
32  $- 10^3$  times higher than that of the bulk rubbery polymer. This increase occurs because the adsorbed  
33  
34 polymer layer surrounding the nanoparticles displays an increased  $T_g$  in the case of attractive  
35  
36 polymer-filler interaction, and it might be in a glassy state even when the polymer matrix is still  
37  
38 in a rubbery state (above  $T_g$ ). This leads to a higher mechanical moduli (glassy) with respect to the  
39  
40 neat polymer (rubbery moduli). Enhancement of the interfacial layer modulus has later been  
41  
42 confirmed via a direct nanoscale probing of the mechanical properties of the layer with atomic  
43  
44 force microscopy (AFM), where an increase of approximately one order of magnitude was found  
45  
46 with respect to the neat rubbery polymer.<sup>28</sup> In glassy PNCs, AFM measurements have also  
47  
48 indicated the presence of an interfacial layer with higher modulus than the neat polymer,<sup>10, 29</sup> in  
49  
50 agreement with recent nanoindentation simulations<sup>30</sup>. However, the data on the magnitude of the  
51  
52 elastic response as well as the extent of the interphase are usually very scattered,<sup>30-31</sup> which make  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 quantitative determinations of the local interfacial layer properties a challenging task when using  
7  
8 AFM. Therefore, other methods capable of investigating the mechanical properties at the interface  
9  
10 are required in glassy PNCs.  
11  
12  
13

14  
15 Brillouin light scattering (BLS) is a non-destructive optical technique based on the inelastic  
16  
17 scattering of visible light by thermal acoustic phonons, which can be used in both glassy and  
18  
19 rubbery PNCs.<sup>32</sup> It allows accessing the velocity of sound in the system and therefore the elastic  
20  
21 properties (longitudinal and shear moduli) in the Gigahertz frequency range related to microscopic  
22  
23 length scales. Note that dynamic mechanical analysis or tensile tests provide macroscopic  
24  
25 properties, and are more sensitive to secondary relaxations, sample quality, and defects. Several  
26  
27 BLS studies have provided evidence of mechanical reinforcement in glassy PNCs.<sup>10, 32-34</sup> It was  
28  
29 found that both the shear and bulk moduli increase with particle loading, and that this increase  
30  
31 cannot be explained by a two-phase model<sup>35</sup> assuming NPs dispersed in a homogeneous matrix.

60  
10.<sup>26</sup> This discrepancy is a clear indication of an additional mechanism for reinforcement other than  
the hydrodynamic effect, and it has been associated with the presence of an interphase with higher  
modulus in the vicinity of the nanoparticles. The interfacial layer moduli were found to be about  
2 times higher than that of the matrix using the interfacial layer model (ILM)<sup>36</sup> approach developed  
for multi-component systems. On the other hand, other BLS studies have reported opposite  
evolutions of the PNC elastic properties depending on the process conditions (solvent choice and  
annealing),<sup>33</sup> or on the NP-polymer interaction using different types of surface modification, like  
silanization<sup>37</sup> and chain grafting<sup>38-39</sup>. In particular, recently it has been found that a PNC with  
grafted polymer chains displays lower moduli in the interfacial layer than in the case of PNC filled  
with bare NPs, while still having a higher  $T_g$  and stronger suppression of the segmental dynamics.

1  
2  
3  
4  
5  
6 <sup>39</sup> Such a counter-intuitive behavior suggests a competition between different effects, namely  
7  
8 frustration in chain packing (density) and chain conformation (stretching) in the interfacial layer.  
9  
10 These effects can be varied by the polymer grafting density, and a low grafting density resulted in  
11  
12 a reduction of density and of the mechanical properties of the grafted PNCs. All these observations  
13  
14 highlight the prevalent role played by both the structural organization and dynamics of the  
15  
16 interfacial layer. In this context, the chain length or polymer molecular weight (MW) is an  
17  
18 important parameter. In PNCs with attractive interactions, both theoretical <sup>40</sup> and experimental <sup>41</sup>  
19  
20 studies have suggested that the chains form a physically adsorbed layer at the NP interface with  
21  
22 an average thickness proportional to the polymer radius of gyration. Such a bound layer gives rise  
23  
24 to a dynamic interfacial layer with different segmental dynamics <sup>26</sup> and also different mechanical  
25  
26 properties than the bulk, as discussed above. Whereas one of our recent works report on the  
27  
28 unexpected MW-dependence of the interfacial layer thickness, which slightly decreases with  
29  
30 increasing chain length, <sup>42</sup> the evolution of elastic properties of the interfacial layer with MW has  
31  
32 never been studied to the best of our knowledge. Such studies of microscopic parameters  
33  
34 controlling macroscopic mechanical properties in glassy PNCs are highly desirable for both  
35  
36 fundamental research and practical applications.  
37  
38  
39  
40  
41  
42  
43

44 This paper focuses on studies of the polymer molecular weight effect on the mechanical (bulk and  
45  
46 shear moduli) and dynamic properties of PNCs in the glassy state. We study a model  
47  
48 nanocomposite system based on poly(2-vinylpyridine) (P2VP) with a fixed loading of silica  
49  
50 nanoparticles ( $\approx 40$  wt%), by combining Brillouin light scattering (BLS), small-angle X-ray  
51  
52 scattering (SAXS), broadband dielectric spectroscopy (BDS), and temperature-modulated  
53  
54 differential scanning calorimetry (TMDSC). We deliberately choose a high filler content to  
55  
56  
57  
58  
59  
60

2  
3  
4  
5  
6 achieve maximum enhancement of mechanical properties, while still maintaining reasonable  
7  
8 processability of the film, which is important for practical applications. Our analysis reveals that  
9  
10 the chain length has a strong influence on the resulting mechanical reinforcements in PNCs below  
11  
12  $T_g$ . PNCs with low MW exhibit a stronger enhancement of mechanical properties compared to the  
13  
14 PNCs with high MWs. We ascribe the observed difference in mechanical reinforcement to an  
15  
16 increase in chain packing frustration in the interfacial layer with increase in MW. Our results  
17  
18 demonstrate that the PNC's mechanical moduli can be effectively tuned by changing only the chain  
19  
20 length, and that depending on molecular weight they can be either increased or decreased.  
21  
22

24  
25

## 26 **Materials and Methods**

27  
28 **Materials.** Poly(2-vinylpyridine) with different weight-average molecular weights (MW = 9.1,  
29  
30 35.9, 101.1, 216, and 404 kg/mol and polydispersity index below 1.2) were purchased from  
31  
32 Scientific Polymer Products Inc., and used as received. The silica nanoparticles (SiO<sub>2</sub> NPs) were  
33  
34 synthesized by a modified Stöber method<sup>43</sup> in ethanol with the final NP concentration of 16 mg/ml.  
35  
36 They were characterized by SAXS in ethanol at 0.7 vol% dilution. The scattered intensity revealed  
37  
38 a log-normal size distribution ( $R_0 = 9.7$  nm,  $\sigma = 17\%$ ), leading to an average nanoparticle radius  
39  
40 of 9.85 nm.  
41  
42  
43

44 **Preparation of polymer nanocomposites.** The polymer and nanoparticles were mixed in ethanol  
45  
46 with proportions calculated to obtain a nominal silica content of 26 vol% in the final PNCs. Solvent  
47  
48 was evaporated during stirring at room temperature before further drying under vacuum at 403 K  
49  
50 for 48 hours in Teflon dishes. The real silica fractions in nanocomposites were obtained by  
51  
52 thermogravimetric analysis (TGA, Q50, TA Instruments, 20 K/min, under air) from the weight  
53  
54 loss between 403 K and 1073 K. The silica volume fraction,  $\Phi_{NP}$ , was determined by mass  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 conservation using the density of the neat polymers measured by pycnometry and the silica density,  
7  
8  $\rho_{\text{NP}} = 2.406 \text{ g}\cdot\text{cm}^{-3}$ .<sup>10</sup> Differences in the obtained  $\Phi_{\text{NP}}$  with respect to the expected values are due  
9  
10 to pipetting errors and precision of the weighting, and do not exceed 5%. The glass-transition  
11  
12 temperature,  $T_g$ , was determined using temperature-modulated differential scanning calorimetry  
13  
14 (Q2000, TA Instruments). Samples of about 10 mg were sealed in aluminum Tzero pans and  
15  
16 annealed at 433 K for 20 min. Then, they were measured at an average 2 K/min rate with  
17  
18 temperature modulation amplitude and period of  $\pm 0.5$  K and 60 s, respectively.  $T_g$  was defined as  
19  
20 the inflexion point temperature in the reversible heat flow upon heating.  
21  
22

23  
24 **Small-angle X-ray scattering (SAXS)** experiments were performed with an in-house setup of the  
25  
26 Laboratoire Charles Coulomb, “Réseau X et gamma”, University of Montpellier, France. A high  
27  
28 brightness low power X-ray tube, coupled with aspheric multilayer optics (GeniX<sup>3D</sup> from Xenocs)  
29  
30 was employed. It delivers an ultralow divergent beam (0.5 mrad). Scatterless slits were used to  
31  
32 give a clean 0.6 mm beam diameter with a flux of 35 Mphotons/s at the sample. We worked in a  
33  
34 transmission configuration and scattered intensity was measured by a 2D “Pilatus” pixel detector,  
35  
36 at a distance of 1900 mm from the sample. The scattering of the neat polymers,  $I_{\text{Neat}}$ , has been  
37  
38 measured independently in order to subtract the matrix contribution,  $(1-\Phi_{\text{NP}}) I_{\text{Neat}}$ , for each PNC  
39  
40 sample.  
41  
42

43  
44 **Broadband dielectric spectroscopy (BDS).** Dielectric spectra were measured using disk-shaped  
45  
46 samples with a diameter of 20 mm. All samples have been hot pressed (423 K) to reach a typical  
47  
48 thickness of 0.15 mm, prior to drying under vacuum at 393 K for 3 days. Thin films were then  
49  
50 placed between gold plated electrodes forming a capacitor. For pure matrices, a ring of Teflon  
51  
52 (inner diameter of 16 mm, thickness 0.14 mm) was used as a spacer to prevent possible short-  
53  
54 circuits due to polymer flow. A broadband high-resolution dielectric spectrometer (Novocontrol  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 Alpha) was used to measure the complex dielectric permittivity,  $\epsilon^*(\omega) = \epsilon'(\omega) - i \epsilon''(\omega)$ , in the  
7  
8 frequency range from  $10^{-2}$  to  $10^7$  Hz ( $\omega = 2\pi f$ ). Before measurement each sample was annealed  
9  
10 for 1 h at 433 K in the BDS cryostat (under nitrogen atmosphere). Then isothermal frequency  
11  
12 measurements have been performed from 433 K down to 103 K, with temperature stability better  
13  
14 than 0.1 K. Then, the spectra were measured again at 293 K and 433 K in order to check the  
15  
16 reproducibility of our measurements. Accurate estimates of the volume fraction of the interfacial  
17  
18 layer require accurate measurements of the dielectric spectra in absolute values. To achieve that,  
19  
20 and to get rid of possible artefacts coming from (i) different surface states of the samples and (ii)  
21  
22 thickness variation due to temperature change, the complex permittivities have been normalized  
23  
24 using spectra measured at the lowest measurable temperature,  $T = 103$  K. The real part of the  
25  
26 permittivity at such a low temperature corresponds to the dielectric constant,  $\epsilon_{\infty}$ , which relates to  
27  
28 the refractive index. Considering that the latter depends on the molecular weight of the polymer  
29  
30 only at small values (typically below a few thousand),<sup>44</sup> we used an MW-independent value of  $\epsilon_{\infty}$ .  
31  
32 In practice, the  $\epsilon'(103 \text{ K})$  for the neat polymers have been rescaled to 3.05 using measurements on  
33  
34 the 36k-matrix. For PNCs,  $\epsilon_{\infty}$  was calculated using a two-component model<sup>45</sup> that included silica  
35  
36 volume fraction, as well as taking  $\epsilon_{\infty} = 3.05$  and  $3.9$ <sup>42</sup> for the polymer and silica permittivity  
37  
38 values, respectively (see SI for details). PNC data at 103 K were rescaled to this theoretical value,  
39  
40 and then the permittivity data at all other temperatures were rescaled by the same value estimated  
41  
42 at  $T = 103$  K.  
43  
44  
45  
46  
47  
48

49 **Density measurements.** All samples were dried in the oven for at least 12 hours at 393 K before  
50  
51 density measurement. Density was measured at room temperature on Pycnometer AccuPyc II 1340  
52  
53 in helium. Each sample was measured at least seven times and the average value is presented in  
54  
55 Table 1. The standard deviation was found to be on the order of 1%.  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 **Brillouin light scattering (BLS).** Bubble-free polymer nanocomposite disks with a diameter of  
7  
8 10 mm and a thickness of 1 mm were first prepared and sandwiched by two sapphire glass windows  
9  
10 at 393 K and stored at this temperature in an oven under vacuum. The temperature was then  
11  
12 decreased to ambient very slowly using a cooling rate of about 0.2 K/min. All BLS measurements  
13  
14 were conducted in a symmetric scattering geometry at a 90 degree scattering angle using a solid  
15  
16 state laser (Verdi,  $\lambda_{\text{laser}} = 532 \text{ nm}$ ).<sup>39</sup> The power of the incident laser beam was  $\sim 5 \text{ mW}$ . The  
17  
18 advantage of the symmetric scattering geometry is the compensation of the refractive index,<sup>46</sup>  
19  
20 which provides an estimate of the sound velocity from the Brillouin peak frequency without  
21  
22 knowledge of the materials refractive index. Both VV and VH polarizations were utilized to  
23  
24 capture the longitudinal (VV and VH) and transverse modes (VH). All the measurements were  
25  
26 performed at room temperature with mirror distances in the tandem Fabry-Pérot interferometer  
27  
28 fixed to 7 mm for VV and 15 mm for VH polarizations, which covers the frequency range between  
29  
30 2 GHz and 21 GHz with a resolution of 0.04 GHz. The experimental error bar for the longitudinal  
31  
32 ( $V_L$ ) and transverse ( $V_T$ ) sound velocities did not exceed 0.2%.

## 41 **Results and Discussion**

42  
43 Table 1 presents the characterization results of neat P2VP and silica-filled P2VP nanocomposites  
44  
45 (similar loadings) with different polymer molecular weights from 9 to 404 kg/mol. The  $T_g$  of the  
46  
47 PNCs is found to increase by  $\sim 1.5 - 5 \text{ K}$  relative to the pure matrices (see SI for an illustration of  
48  
49 the trend in  $T_g$  and density).

**Table 1.** Characteristics of P2VP matrices and PNCs: sample name, silica concentration from TGA, glass-transition temperature from TMDSC and BDS, longitudinal ( $V_L$ ) and transverse ( $V_T$ ) sound velocities from BLS, bulk (K) and shear (G) moduli.

SAXS was used to analyze the nanoparticle dispersion in PNCs, where the scattered intensities were compared to form factor scattering (Figure 1a). All spectra show a well-defined repulsive interaction peak at intermediate  $q$ , corresponding to a dominant distance in the nanoparticle dispersion. The observed differences at low  $q$  may result from slight differences in the interactions and large-scale distribution of the filler particles in the matrix. It may for instance be caused by impurities. The local structure on the length scale of interest, i.e. the first layers of neighbors between particles as evidenced by the structure factor peak, turns out to be only marginally affected. The position of the peak,  $q_{NP}$ , is related to the typical center-to-center interparticle distance,  $d = 2\pi/q_{NP}$ , from which the average surface-to-surface interparticle spacing can be obtained,  $IPS = d - 2R_{NP}$ . The IPS values estimated from SAXS are reported in Figure 1b as  $2R_g/IPS$ , where  $R_g$  is the radius of gyration of the chain. They are in agreement with the theoretical estimates for IPS based on either a cubic or random<sup>47</sup> packing of nanoparticles in the sample, and

the NP volume fraction (Table 1). This result clearly indicates that nanoparticles are uniformly distributed in all PNCs studied here. The final organization of the nanoparticles in the PNC is set during the drying process when only part of the solvent has evaporated.<sup>48</sup> This step leads to a strong increase of the matrix viscosity inducing the freezing of the NP dispersion. As previously observed,<sup>49</sup> the choice of the polymer solvent (here ethanol) is crucial as it controls the formation of an adsorbed polymer layer onto the nanoparticles in suspension. Such a bound layer, whose thickness was found to be of the order of the polymer  $R_g$  in similar P2VP-silica PNCs,<sup>50</sup> provides steric stabilization and prevents NP agglomeration that would result from opposite forces like depletion attraction. We emphasize that it is not possible to describe the apparent PNC structure factor using only polydisperse hard-spheres interactions, which indicates the existence of additional repulsive long-range interactions between nanoparticles. The latter are most probably of electrostatic origin resulting from the presence of stabilizing charges on the silica surface.<sup>48</sup>

**Figure 1.** a) Reduced representation of the scattered intensity for a series of P2VP/silica nanocomposites with different molecular weights from 9 to 404 kg/mol and same silica content ( $\Phi_{NP} \approx 26$  vol%). The NP form factor normalized to PNC scattering is represented by a continuous line. b) Ratio of P2VP chain size ( $2R_g$ ) and different estimations of the interparticle spacing as a function of molecular weight.

5  
6  
7 Figure 2 presents the BLS spectra with the longitudinal modes (LM) in the main figure, and  
8 transverse modes (TM) in the inset, for selected nanocomposites at similar loadings and a pure  
9 polymer matrix for comparison. The BLS data of all measured samples (PNCs and neat polymers)  
10 are presented in the SI. A clear shift towards high frequency is observed for both the LM and TM  
11 of PNCs, indicating a more rigid medium with higher modulus relative to the neat polymer. To  
12 extract the longitudinal and transverse sound frequencies, we fit our data to the damped harmonic  
13 oscillator model, where we determined frequency of the peak positions ( $\nu_{L,T}$ ). Using the  
14 frequencies of the BLS peaks, we estimate the longitudinal and transverse sound velocities (Table  
15 1) using the linear dispersion relationship for acoustic modes:  $V_{L,T} = 2\pi\nu_{L,T} / Q$ , where  
16  $Q = 2\pi\sqrt{2} / \lambda_{laser}$  (this equation is valid for symmetric scattering at  $90^\circ$ ). The shear ( $G = \rho V_T^2$ )  
17 and longitudinal moduli ( $M = \rho V_L^2$ ) are used to calculate the bulk modulus ( $K = M - 4/3G$ ) by  
18 using the mass density measured by pycnometry.<sup>51</sup> The obtained densities and microscopic  
19 mechanical moduli for the PNCs and neat polymers are reported in Table 1, and Figure 3a presents  
20 the evolution of the PNC moduli  $K_{PNC}$  and  $G_{PNC}$  with the polymer molecular weight.

**Figure 2.** A representative plot of the longitudinal mode (LM) from Brillouin light scattering of neat P2VP (MW = 404 kg/mol) and selected P2VP/silica nanocomposites (PNCs,  $\Phi_{NP} \approx 26$  vol%) with MW = 9, 36, and 404 kg/mol. Inset: transverse mode (TM).

**Figure 3.** a) Bulk ( $K$ ) and shear ( $G$ ) moduli of P2VP/silica nanocomposites with different molecular weights. b) Normalization of the PNC moduli on the corresponding moduli of pure polymers with the same MW.

Both PNC moduli exhibit a non-monotonic dependence on MW (Fig. 3): initial increase with MW up to 100 kg/mol, followed by a decrease for higher MWs. To understand these data, we normalized them to the mechanical moduli of the neat polymers (Figure 3b). The non-monotonic trend remains, and it cannot be ascribed to nanoparticle aggregation, which was excluded by the SAXS results. To gain deeper insight into the mechanism of this non-monotonic behavior, a detailed analysis of the mechanical properties in the interfacial polymer layer surrounding the nanoparticles is required. The presence of an interfacial layer caused by the physical adsorption of

1  
2  
3  
4  
5  
6 the polymer on the NP surface in P2VP-silica nanocomposites has been confirmed in previous  
7  
8 studies reported in literature.<sup>39, 52-53</sup> To determine the individual contribution of this layer to the  
9  
10 mechanical properties of PNCs, we use the interfacial layer model (ILM) approach developed to  
11  
12 describe both mechanical and dielectric properties of heterogeneous systems.<sup>36, 54</sup> Previous BLS  
13  
14 studies on P2VP<sup>39</sup> and poly(vinyl acetate) (PVAc)<sup>10</sup> nanocomposites at different silica loadings  
15  
16 have demonstrated that ILM provides a much more accurate description of the mechanical  
17  
18 properties of PNCs than other existing models. The validity of ILM was also confirmed by a finite  
19  
20 element analysis in ref<sup>10</sup>. In order to apply the ILM model to the BLS data, it is first required to  
21  
22 determine the volume fraction of the interfacial region, which can be independently obtained using  
23  
24 broadband dielectric spectroscopy as detailed in the following part.  
25  
26  
27  
28  
29

30  
31 Comparisons between the dielectric loss spectra of selected nanocomposites and their  
32  
33 corresponding pure matrices are shown in Figure 4. Comparisons for all other MWs are presented  
34  
35 in SI. The PNC spectra display a shift of the main relaxation peak associated with the segmental  
36  
37 ( $\alpha$ -) relaxation towards low frequencies, a reduction of its amplitude, and a significant broadening  
38  
39 in the peak shape. The low-frequency broadening of the  $\alpha$ -relaxation reveals the interfacial layer  
40  
41 contribution, which has slower segmental dynamics than that of the bulk, as previously observed  
42  
43 in nanocomposites with attractive polymer-filler interaction.<sup>26, 55-56</sup>

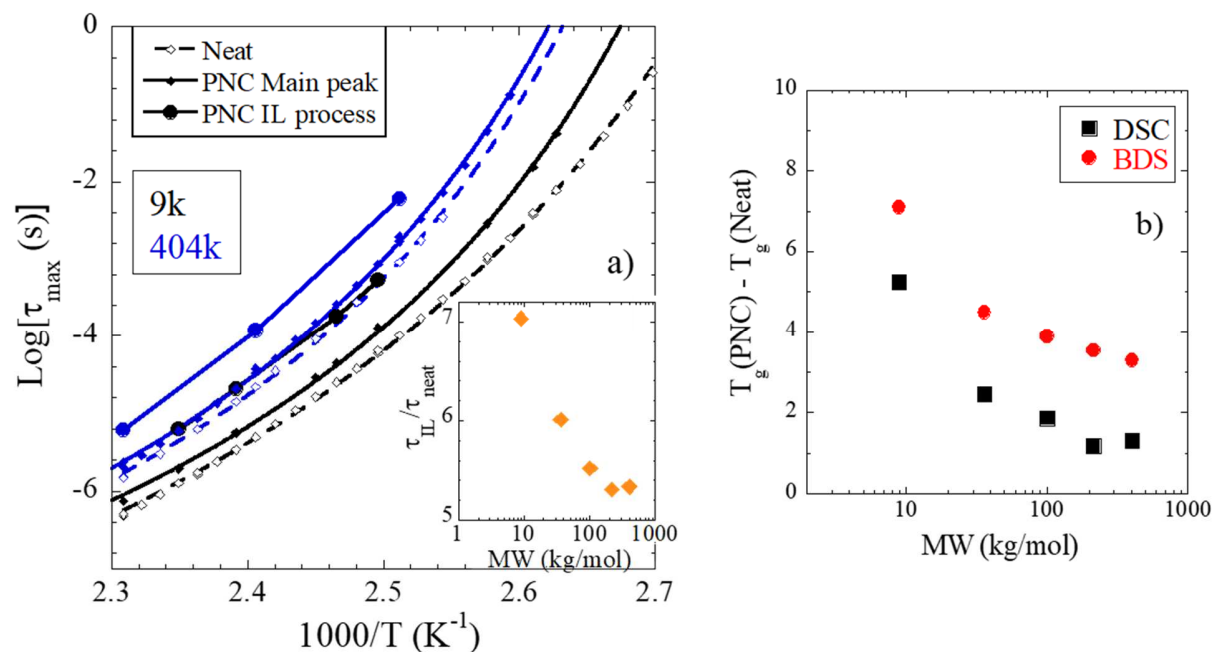

**Figure 4.** Comparison of the dielectric loss spectra,  $\epsilon''(\omega)$ , of the pure polymer matrix (empty circles) and PNC (plain circles) with MW = 9 kg/mol (a) and 404 kg/mol (b) both at  $1.1T_g$  ( $T_g$  of the nanocomposite). The response from the interfacial layer process (red line) is shown for the nanocomposite samples. Arrows indicate the time scale  $\tau_{\max}=1/(2\pi f_{\max})$  of this process. The dotted line for the PNC-9k in (a) presents a fit of the apparent peak maximum by a single HN function.

To describe the dielectric response of the interfacial layer, we use ILM.<sup>54</sup> In this model, we approximate the dielectric function of the interfacial layer by a (symmetric) Cole-Cole function, whereas the polymer bulk contribution was described by a Havriliak–Negami (HN) function<sup>57</sup> having the same spectral shape parameters and time scale as the dielectric function of the neat polymer. We emphasize that the ILM does not simply add these two contributions, but has a more complex form that explicitly takes into account interference terms in the dielectric response of heterogeneous systems (see ref<sup>55</sup> for details). The ILM analysis clearly separates the interfacial layer and bulk-like polymer contributions to the dielectric spectra (see, e.g., data for PNC-9k, and

1  
2  
3  
4  
5  
6 PNC-404K in Figure 4). This analysis provides estimates of the characteristic relaxation time in  
7  
8 the interfacial layer (using the peak position) and the volume fraction of the interfacial layer from  
9  
10 the decrease in the amplitude of the bulk-like contribution. Figure 5a presents the temperature  
11  
12 dependence of the relaxation times of the interfacial layer in PNCs with two MWs,  $\tau_{IL}$ , and of the  
13  
14 corresponding pure matrices,  $\tau_{neat}$ . One can see that the interfacial layer process is significantly  
15  
16 slower than the dynamics of the bulk polymer and, more importantly, that the amplitude of this  
17  
18 slowing down depends on the polymer molecular weight. The evolution of the segmental dynamics  
19  
20 of the interfacial layer relative to the bulk,  $\tau_{IL}/\tau_{neat}$ , as a function of molecular weight is shown in  
21  
22 the inset of Figure 5a for a selected temperature,  $T = 1.1 T_g$  ( $T_g$  of PNC). We chose this temperature  
23  
24 because it is the closest temperature to  $T_g$  where the interfacial layer relaxation process is still  
25  
26 within the experimental frequency window of BDS. Interestingly, stronger slowing down of the  
27  
28 interfacial dynamics is obtained for the lower molecular weight, and then it decreases  
29  
30 monotonously. The interfacial dynamics for PNC-9k is seven times slower comparing to the neat  
31  
32 polymer, while it is only five times slower in PNC-404k. Such results agree with our earlier results  
33  
34 on MW dependence in PVAc/silica nanocomposites.<sup>42</sup> To verify that our results are not related to  
35  
36 any non-equilibrium issues, we annealed the highest MW PNC (where we expect the longest  
37  
38 equilibration times) at  $T_g + 50$  K for an additional 15 days, which corresponds to about  $10^{12} \tau_\alpha$ .  
39  
40 Such an extremely long annealing did not produce any detectable changes in the segmental  
41  
42 relaxation spectra (Fig. S5), indicating that the samples are either at equilibrium or are trapped in  
43  
44 a very deep metastable state and are as close to equilibrium as experimentally possible. This was  
45  
46 also confirmed by measuring spectra twice at two selected temperatures using different path-ways  
47  
48 (see Materials and Methods section and details in SI). The spectra perfectly overlap demonstrating  
49  
50 that our BDS results are independent of the cooling protocol. Finally, one may note that a strong

9

10  
11  
12 To evaluate the overall segmental dynamics in nanocomposites, the apparent peak maximum in  
13 the dielectric spectra is fitted with a single HN function over a restricted frequency range (Figure  
14 4a), i.e., without any decomposition on interfacial layer and bulk contributions in this case. The  
15 corresponding time scales are included in Figure 5a. At high temperatures, the segmental  
16 relaxation times of the bulk polymer and the main PNC process tend to converge for both MWs.  
17 As the temperature approaches  $T_g$  ( $\tau_\alpha = 100$  s), the slowing down of the main peak in the PNC  
18 relative to the pure matrix is stronger in PNC-9k than in PNC-404k. Such an observation indicates  
19 that the behavior of the  $T_g$ -shift strongly depends on the molecular weight in these PNCs. The  
20 dynamic glass-transition temperature can be determined by fitting the temperature dependence of  
21 the segmental relaxation times (main process for PNCs) to the Vogel-Fulcher-Tammann (VFT)  
22 equation (Figure 5a), and extrapolating to the temperature at which  $\tau_\alpha = 100$  s. The obtained values  
23 are in good agreement with the calorimetric  $T_g$  (see Table 1 and Figure 5b). For the lowest  
24 molecular weight, the difference in  $T_g$  between the nanocomposite and the neat polymer is the  
25 highest (5.3 K by TMDSC), and this difference decreases with the increase of molecular weight.  
26 It reaches the value of only 1.4 K for MW = 404 kg/mol. This result further confirms that the  
27 dynamics of the interfacial layer process has a larger slowing down in low-MW PNCs comparing  
28 to high-MW ones.

**Figure 5. a)** Temperature dependence of the interfacial segmental relaxation times,  $\tau_{IL}$  (filled circles), for P2VP/silica nanocomposites with MW = 404 kg/mol (blue) and 9 kg/mol (black), averaged PNC dynamics (filled diamonds), and bulk-like dynamics,  $\tau_{neat}$  (empty diamonds), with their fits by the Vogel-Fulcher-Tammann equation. Inset: Ratio of  $\tau_{IL}$  to  $\tau_{neat}$  corresponding to the interfacial layer slowing down at 1.1Tg. **b)** Change in  $T_g$  of PNCs with respect to corresponding neat polymers as a function of MW.

We now turn to the interfacial layer volume fraction,  $\Phi_{IL}$ , obtained from the ILM analysis. One can see in Figure 6 that the interfacial layer fraction with slowed-down dynamics does not show any significant MW dependence, and takes an average value of 47 vol%. It means that there is only about 27 vol% of bulk-like polymer left in the interstitial space between nanoparticles, which gives rise to a bulk dielectric signal in all PNCs (another 26 vol% is occupied by silica). The estimation of the interfacial layer thickness from  $\Phi_{IL}$  is straightforward using simple geometric considerations with a cubic arrangement of nanoparticles, and taking into account the overlapping volume between surrounding interfacial layers (see SI for details). We find an average thickness

of about 4.3 nm (Figure 6). It means that, in P2VP-silica PNCs, both the silica loading (see ref <sup>52</sup>) and MW do not play a significant role on the interfacial layer thickness.

**Figure 6.** Volume fraction and estimated thickness of interfacial layer surrounding the silica nanoparticles in P2VP nanocomposites with similar loadings ( $\Phi_{NP} \approx 26$  vol%) and different MWs. Lines show the average values.

Using the so obtained volume fraction, it is then possible to apply the ILM model and calculate the bulk and shear moduli of the interfacial layer from the BLS results (Table 1 and Figure 3). ILM predicts the elastic response of the nanocomposites as <sup>36</sup>

$$K_{PNC} = \frac{K_{NP} \Phi_{NP} + K_{IL} \Phi_{IL} R + K_{Neat} \Phi_{Neat} S}{\Phi_{NP} + \Phi_{IL} R + \Phi_{Neat} S} \quad (1)$$

$$\text{with } S = \frac{(3K_{NP} + 4G_{NP})(3K_{IL} + 4G_{Neat}) - 12d(K_{IL} - K_{NP})(G_{IL} - G_{Neat})}{\Phi_{NP} + \Phi_{IL} R + \Phi_{Neat} S}, \quad R = \frac{3K_{NP} + 4G_{IL}}{3K_{IL} + 4G_{IL}} \quad \text{and} \quad d = \frac{\Phi_{NP}}{\Phi_{NP} + \Phi_{IL}}$$

$\Phi_{IL} + \Phi_{NP} + \Phi_{Neat} = 1$ , where  $\Phi$  is the volume fraction and the sub-indices Neat, NP, IL, and PNC stand for pure polymer (bulk), silica nanoparticles, interfacial layer, and nanocomposite, respectively.  $K_{IL}$  is the bulk modulus and  $G_{IL}$  the shear modulus of the interfacial layer. Further

1  
 2  
 3  
 4  
 5  
 6 details on the ILM calculation can be found in refs <sup>10,36</sup>. In eq 1, the bulk and shear moduli of the  
 7  
 8 nanoparticles are fixed to  $K_{NP} = 35.12$  GPa and  $G_{NP} = 30.06$  GPa, which are calculated by assuming  
 9  
 10 the sound velocity of the NP is the same as in fused silica. <sup>60</sup> For all PNC samples, we use the  
 11  
 12 average value of  $\Phi_{IL}$  (47 vol%, see Figure 6), which was obtained at a selected temperature  $T =$   
 13  
 14  $1.1T_g$  ( $T_g$  of PNC) as the closest to the glassy state in our experiments. The mechanical properties  
 15  
 16 of the interfacial layer calculated using eq 1 are presented in Figure 7a. The results reveal a  
 17  
 18 significant increase in the glassy moduli of interfacial layer in the case of PNC-9k and PNC-36k,  
 19  
 20 while a much weaker increase in shear modulus and even a drop in the bulk modulus are observed  
 21  
 22 for the interfacial layer in PNC-216k and PNC-404k.

**Figure 7. a)** Bulk modulus,  $K_{IL}$ , and shear modulus,  $G_{IL}$ , of interfacial layer in P2VP/silica nanocomposites ( $\Phi_{NP} \approx 26$  vol%) from ILM calculations using  $\Phi_{IL} = 47$  vol%. **b)** Ratio of the mechanical moduli of interfacial layer to the moduli of the corresponding matrix (neat).

The differences observed between the interfacial layer moduli for PNCs with different molecular weights are likely the result of the difference in polymer rearrangement in the interface promoted by different MW of the matrix. Here, molecular features like chain packing, stretching of the polymer near the NP surface,<sup>42</sup> and polymer bridging play an important role. For instance, any difference in chain packing is expected to induce some changes in macroscopic density. To confirm this conjecture, we estimate the average density of the polymer matrix,  $\rho_{\text{Matrix}}^{\text{PNC}}$ , in the PNCs (Figure 8). The ratio of this quantity to the density of the neat polymer of same mass is shown in Figure 8a, where a clear evolution with molecular weight can be seen. The relative average density of the matrix in PNC is slightly higher than one for PNC-9k, as expected due to the attractive polymer-filler interaction, but then it decreases below one for higher molecular weights. This confirms that packing of the chains in nanocomposites depends strongly on the chain length. A similar evolution of  $\rho_{\text{matrix}}^{\text{PNC}} / \rho_{\text{Neat}}$  with MW was reported and discussed in ref<sup>42</sup> for PVAc/silica PNCs, suggesting some general behavior of PNCs with attractive interactions.

**Figure 8.** a) Ratio between average density of the matrix in P2VP/silica nanocomposite,  $\rho_{\text{matrix}}^{\text{PNC}}$ , and density of the pure polymer,  $\rho_{\text{Neat}}$ , for different molecular weights.  $\rho_{\text{matrix}}^{\text{PNC}} = \frac{\rho_{\text{PNC}} - \rho_{\text{NP}} \Phi_{\text{NP}}}{1 - \Phi_{\text{NP}}}$ , where  $\rho_{\text{PNC}}$  and  $\rho_{\text{NP}}$  are the densities of PNC and silica NPs, respectively. b) Sketch of the chains confined between nanoparticles for low and high MW cases.

1  
2  
3  
4  
5  
6 The density evolution can explain the decrease in mechanical properties of higher-MW PNCs,  
7  
8 which is especially pronounced for PNC-216k and PNC-404k (Figure 7). The main idea here is  
9  
10 that polymer chains adsorbed onto the silica NPs can experience different conformations, which  
11  
12 are affected by many parameters, including MW and IPS. According to theory and simulations,  
13  
14 adsorbed chains can form loops, trains, and tails near the NP surface.<sup>40, 61</sup> When the distance  
15  
16 between NP surfaces becomes smaller than the size of the chain ( $\sim 2 R_g$ ), large polymer loops in  
17  
18 high-MW PNCs are strongly confined between nanoparticles.<sup>26, 42</sup> This effect induces strong  
19  
20 repulsive chain-chain interactions in the interfacial region, where the loops repel each other,  
21  
22 leading to loose polymer packing and a lower density than in the bulk. However, in the case of  
23  
24 low-MW PNCs, the chains are able to pack better because of their small size and the significant  
25  
26 amount of free (non-adsorbed) chains. They may therefore arrange their conformation leading to  
27  
28 a dense packing. This is in agreement with the evolution of the interfacial layer properties, which  
29  
30 displays a stronger slowing down at low MW (inset of Figure 5a), while the volume fraction of  
31  
32 interphase does not vary much (Figure 6). This behavior means that the dynamical changes  
33  
34 observed in Figure 5 are not a function of how much polymer is impacted at the interface, but the  
35  
36 result of different packing in the interfacial region. Since the density directly correlates with  
37  
38 mechanical properties, the decrease in density ultimately leads to a decrease in mechanical moduli.  
39  
40 However, density and chain packing alone are not sufficient to explain the maximum in bulk and  
41  
42 shear moduli of interfacial layer obtained for PNC-36k. In this nanocomposite, the density is lower  
43  
44 than the density of the pure polymer, while mechanical properties are maximal. Such behavior  
45  
46 suggests the presence of other mechanisms of mechanical enhancement.

4  
5  
6 Bridging<sup>62</sup> of polymer chains between nanoparticles has been reported in literature for PNCs in  
7  
8 glassy<sup>10</sup> and rubbery<sup>8-9, 63</sup> states. This mechanism is actively used in particle flocculation.<sup>64</sup> We  
9  
10 believe that in our case, bridging is promoted by the high concentration of nanoparticles since the  
11  
12 interparticle spacing is equal or smaller than  $2 R_g$  of the polymer (Figure 1b). If polymer chains  
13  
14 are adsorbed simultaneously on more than one particle, it can be expected that IPS displays a  
15  
16 broader distribution, whereas absence of bridging may induce purely repulsive interactions leading  
17  
18 to a narrower distribution of the interparticle distances. It is interesting to note that in PNC-9k,  
19  
20 where the IPS is about  $2 R_g$  of the polymer, the distribution of IPS deduced from the width of the  
21  
22 repulsive interaction peak in SAXS is indeed narrower than in all other MWs (Figure 1a). This  
23  
24 may suggest that bridging is unlikely for the low-MW PNC. The interaction peak becomes broader  
25  
26 already in PNC-36k, and the most probable interparticle distance slightly decreases with increase  
27  
28 of MW (IPS = 6.4 and 5.3 nm for MW = 36 and 404 kg/mol, respectively). This suggests initiation  
29  
30 and possible progression of the bridges with decrease in IPS, as predicted by De Gennes for the  
31  
32 case of flat surfaces.<sup>9, 62</sup> Chain bridging between nanoparticles, on one hand, leads to an  
33  
34 improvement of the mechanical properties;<sup>10</sup> on the other hand, it facilitates a significant  
35  
36 frustration in chain packing (see Figure 8b) that causes the drop in density and reduction of  
37  
38 mechanical properties. Thus, the combined evolution of density and bridging may explain the non-  
39  
40 monotonic behavior of mechanical properties with MW.  
41  
42  
43  
44  
45  
46  
47

48  
49 Another possible mechanism of mechanical enhancement is related to chain stretching in the  
50  
51 interfacial layer. This effect has been proposed in theoretical works,<sup>61, 65-66</sup> where it was  
52  
53 demonstrated that polymer adsorbed onto a solid wall will adopt a stretched conformation. It was  
54  
55 also demonstrated experimentally for polymer brushes covalently grafted on a flat surface<sup>67</sup> or  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 grafted on spherical nanoparticles.<sup>68-69</sup> However, the degree of stretching for nanocomposites  
7  
8 varies with the chain length. For instance, using self-consistent field theory calculations in PNCs,  
9  
10 it was shown that stretching decreases with the MW increase.<sup>70</sup> Furthermore, it has also been  
11  
12 shown that chain stretching leads to enhancement of mechanical properties (along the stretching  
13  
14 direction).<sup>71-72</sup> In our case, this would mean that short and intermediate chains are stretched  
15  
16 stronger than longer chains, which might be the reason for improvement in mechanical properties  
17  
18 in these PNCs. Unfortunately, we do not have any experimental measure of chain stretching to  
19  
20 support this idea, and it is difficult to evaluate whether stretching, bridging, or some other effects  
21  
22 dominate the enhancement of mechanical properties. However, the presented experimental results  
23  
24 revealed the existence of optimal conditions for achieving mechanical reinforcement that are  
25  
26 realized in PNC-36k in our case.  
27  
28  
29  
30  
31

32  
33 Although we do not have any direct evidence of chain stretching and bridging in PNCs (more  
34  
35 theoretical and experimental studies are on the way to address these points), some indirect evidence  
36  
37 exists in our studies. We found that the interfacial layer bulk modulus and shear modulus have a  
38  
39 different behavior. The interfacial layer modulus  $G_{IL}$  is always above the shear modulus of the  
40  
41 neat polymers (Figure 7b), while the bulk modulus  $K_{IL}$  is below that of the neat polymer at high  
42  
43 MW. In general, bulk modulus relates to the inverse of material's compressibility and is more  
44  
45 sensitive to the density, while shear modulus is a deformation that is more sensitive to the  
46  
47 anisotropic conformation of the polymer chains and hence more affected by chain stretching and  
48  
49 bridging. Furthermore, we also found that the segmental dynamics of the interfacial layer are  
50  
51 slower than the bulk segmental dynamics in all PNCs, but the observed slowing down is more  
52  
53 pronounced at low MW. This finding is in line with theoretical works predicting a slowing down  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4  
5  
6 of segmental dynamics<sup>70, 73</sup> in systems with more stretched polymer chains. Slowing down of the  
7  
8 dynamics in our nanocomposites has a different magnitude with MW, further highlighting a  
9  
10 complex interplay of chain stretching, packing (density), and bridging.  
11  
12  
13  
14

## 15 **Conclusions**

16  
17 In summary, we presented measurements of mechanical properties in glassy P2VP/silica  
18  
19 nanocomposites with different molecular weights and a single high NP loading ( $\approx 26$  vol%). Our  
20  
21 results suggest that mechanical properties are strongly influenced by the MW of the polymer and  
22  
23 represent a complex interplay between chain packing, stretching, and bridging, which are acting  
24  
25 in opposite directions. Strong enhancement in the glassy mechanical properties is achieved at low  
26  
27 MW, with the maximum for PNC-36k, while further increase in MW results in a decrease of the  
28  
29 mechanical properties enhancement. Such a non-monotonic dependence results from a complex  
30  
31 interplay between chain packing and stretching in the interfacial polymer layer and formation of  
32  
33 inter-particle bridges. Using ILM, and the independently estimated thickness of the interfacial  
34  
35 layer, we estimated the glassy mechanical moduli in the interfacial region surrounding  
36  
37 nanoparticles. The interfacial region occupies about 64 %vol of the polymer matrix in the studied  
38  
39 PNCs. The mechanical moduli of the interfacial layer exhibit strong enhancement at low MW that  
40  
41 decreases at larger MW due to frustration in packing of chains strongly confined between  
42  
43 nanoparticles. In particular, the bulk modulus in the interfacial layer of high-MW PNCs appears  
44  
45 to be even lower than in the neat polymer. Our results also reveal that the slowing down of PNC  
46  
47 segmental dynamics and the shift in PNC  $T_g$  decrease with polymer MW, suggesting a common  
48  
49 structural origin controlling glassy moduli and structural relaxation in nanocomposites. We  
50  
51
