HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
INTRODUCTION

Glycosaminoglycans (GAGs) are linear anionic periodic polysaccharides. They bind to their protein targets in the extracellular matrix, and so participate in many cell-signaling processes. As such, they are very promising targets for the design of novel functional biomaterials for regenerative medicine.

Experimental methods (X-ray, NMR) to solve the structure of GAG-protein complexes are impaired by GAG flexibility and high negative charge density that makes it difficult to obtain pure homogenous samples. Therefore, it often requires computational docking methods. But GAGs are also too flexible for (semi-)rigid docking, and too large for fully flexible docking.

Fragment-based docking permits to deal with the high number of degrees of freedom of the ligand. However, most current methods are limited to small ligands and well delineated binding sites. We have recently extended such approach to flexible linear polymers docked on the whole protein surface.

We chose 3mer as fragment length in order to conciliate binding specificity (enough contacts per frag.) and a low number of flexible bonds. GAG having a periodicity in [A-B)n, we dock two types of trimers: A-B-A and B-A-B.

METHODS

Inputs

The binding region can be predicted by fast rigid docking of GAG fragments and selection of the most contacting residues, or by electrostatic potential calculations, with good precision.

Flexible Docking

- AutoDock
- Glycam06
- All atoms representation, implicit solvent
- Grid centered on the COM of the bound ligand
- 1000 poses for each fragment type
- Rigid receptor (bound), fully flexible ligand

Refinement

The assembled chains are clustered (0.5A) and the overlapping parts of the compatible poses are averaged. This results in incorrect monomer geometries, which is corrected by reassigning each monomer by the closest one in a structural library, extracted from all initial docking poses.

CONCLUSION

We developed a new method to model protein-bound GAGs with high accuracy, on a coarsely known binding site on the protein. The approach proved effective to select correct fragment poses at the surface of the protein, and to model GAG up to a degree of polymersation dp7 with an accuracy of 3.0 Å RMSD, with more than 10% correct models.

Perspectives

- We considered the binding region as coarsely known. We will extend the method to cases where the binding region could not be predicted with sufficient confidence. We could either repeat the AD docking with a large number of grids, or use another docking engine for exhaustive sampling.
- For this second option, we will implement a saccharide coarse-grained representation in the ATTRACT docking program.
- We considered the protein as rigid. We intend to model also the protein flexibility, by representing parts of the surface in several conformations, that will have to match with neighbor conformations in the chain assembly.
- Finally, we will apply the method to the docking of intrinsically disordered proteins (IDPs).
