Abstract
Inaccurate positioning or modified shape of speech articulators due to intraoral surgery can induce persistent speech disorders. The literature emphasises the importance of the link between speech perception and production, and in particular of auditory and proprioceptive feedback, both for language acquisition and maintenance. Some theories postulate the existence of speech internal models – or representations – coding the relations between the articulatory movements, their proprioception and their acoustic outcome. Therefore, we hypothesise that part of articulatory disorders may be ascribed to some degradation of the efficiency of the sensory channels, especially the proprioceptive ones, or an erroneous speaker’s internal representation. Since many studies have revealed that subjects are somehow able of articulatory awareness and of tongue reading, using the vision of articulators can be assumed to enhance sensory feedback channels and constitute a promising perspective for the remediation of articulation disorders. In the article, we describe a clinical study on the efficiency of speech therapy based on the visualization of tongue movements captured by ultrasound imaging for the rehabilitation of patients who underwent intraoral surgery subsequent to tongue cancer. We explored two rehabilitation paradigms: visual illustration, which consists in providing the patient with pre-recorded ultrasound image sequences showing the target tongue movement, and visual feedback, that is the visualization in real-time by the patient of his/her own tongue. Based on a cohort of 10 patients, we demonstrate the benefit of complementing the illustration paradigm with visual feedback.

Keywords
Speech therapy, tongue ultrasound imaging, biofeedback, articulation disorder, assistive technologies.
1 Introduction

Speech perception and production mechanisms are concurrently developed during the language acquisition process and remain closely related in its maintenance. Various studies demonstrate how critical the perception of others and of oneself is for language acquisition and maintenance (e.g. Joseph S Perkell (2012) or Turgeon, Prémont et al. (2015) for auditory perception, and Mills (1987) for visual perception). Joseph S. Perkell, Guenther et al. (2000) develop a theory of the segmental component of motor control which considers that the programming of the articulatory movements to reach auditory targets (i.e. phonemes or segments) relies on an internal model. This model, also called efferent copy, predicts the acoustic consequences of articulatory movements and adjusts the motor commands to minimize the discrepancy between the prediction and both the auditory feedback and somatosensory feedback.

The link between perception and production, that is to say the perceptuo-motor nature of speech as described by Schwartz, Basirat et al. (2012), is made explicit in various studies that propose internal models of speech representation. For instance, Treille, Vilain et al. (2016) suggest that the visual processing of audible but not visible movements (such as tongue movements) induces ‘motor and visual mental simulation of the perceived actions to facilitate their recognition’.

Numerous studies have highlighted and quantified the contribution of the vision of visible articulators (such as lips, jaw, face, tongue tip, teeth) to the perception of speech (e.g. Erber (1975), Sumby & Pollack (1954), Benoît & Le Goff (1998); see Badin, Tarabalka et al. (2010) for a review). Interestingly, Badin et al. (2010) demonstrate that, in addition to the well documented lip reading ability, humans possess a tongue reading ability as well, i.e. they are able to use the vision of tongue inside the oral cavity for the recognition of phonemes in adverse (e.g. noisy) conditions.

This theoretical and experimental work has demonstrated the links between speech production and perception, as well as the ‘naïve’ capacities to exploit visual information from an inside articulator whose natural representation, almost exclusively based on proprioception, remains partial. This framework served as the starting point for several studies focusing on the interest of an articulatory visual representation that would help the rehabilitation of speech disorders. Indeed, speech disorders may be attributed to a deterioration of the efficiency of the sensory channels, especially the proprioceptive one, necessary for the acquisition or maintenance of speech production capabilities, or to a lack of internal representations of the speaker. These deficiencies may be related to deafness, motor disability, developmental disorders or orofacial surgery. Using the vision of articulators as a complement of sensory feedback may thus offer an interesting opportunity for the rehabilitation of speech disorders.

1.1 Articulatory visual illustration and feedback

In this article we distinguish two articulatory visualisation paradigms. The first one, called ‘articulatory visual illustration’, aims to provide the patient with an intuitive visualisation of a targeted lingual movement, recorded on a reference speaker (typically someone with no speech disorders such as the speech therapist). Through various collaborations between engineers, researchers and speech-language pathologists (SLPs) various software applications have emerged. These applications are based either on stylized movements such as Diadolab (Menin-Sicard, Sicard et al. (2016)), ‘The vocal tract in action’ (Canault, 2010), or on real articulatory data such as Massaro & Light (2004), Engwall (2008), Fagel & Madany (2008), Badin et al. (2010) or Hueber (2013). Chen, Johnson et al. (2016) review the literature on the contribution

\[1\] This software can be tested at http://anatomie3d.univ-lyon1.fr/webapp/website/website.html?id=3346735&pageId=223201
of these visual illustration techniques in various populations: hearing-impaired people with cochlear implants, children with stigmatisation or adults with aphasia. In each case, visual illustration seems to accelerate the learning process. It also appears to be easily assimilated by the patient who manages to associate what (s)he sees on the screen - which stands in the articulatory internal space of another speaker - with his/her own articulation.

In contrast, the second paradigm, called ‘articulatory visual feedback’, aims to provide the patient with a visual representation of his/her own tongue movements, in his/her own articulatory space and with his/her own morphology. The goal is to help him/her better understand and correct his/her gestures, in particular by providing him/her with his/her own complementary visual articulatory information, along with the practitioner's instructions. The two main techniques actually used for visual biofeedback in speech therapy are electropalatography (EPG)\(^2\) and ultrasound imaging (US).

EPG has been used for three decades as biofeedback in speech therapy (see Gibbon (2013) for an exhaustive review). All studies conclude to some positive effects of EPG, though most of them do not involve control subjects and statistical evaluation. Drawbacks of EPG are the need to build a customized palate for each patient as well as the invasiveness of the palate and connecting wires.

Ultrasound imaging is a very interesting technique to observe tongue movements during speech production in real time, as it is harmless and minimally invasive for speakers (e.g. Epstein (2005) and recently Jonathan L. Preston, Holliman-Lopez et al. (2018)). The reader is referred to Stone (2005) for a complete description of the use of ultrasound imaging in phonetic research, experimental setup, analysis techniques, etc. More than three decades ago, Shawker & Sonies (1985) suggested to use ultrasound images of the tongue for the rehabilitation of English /ɹ/ for a nine year old patient. Since this first case study, English /ɹ/ rehabilitation with ultrasound remains a widely studied topic (Adler-Bock, Bernhardt et al. (2007), Jonathan L Preston & Leaman (2014), Byun, Hitchcock et al. (2014), Cavin (2015), Jonathan L Preston, McAllister et al. (2018)). Modha, Bernhardt et al. (2008), Jonathan L Preston, Brick et al. (2013), Joanne Cleland, James M. Scobbie et al. (2015), Jonathan L Preston, Maas et al. (2016) or Cleland, Scobbie et al. (2017) studied the use of ultrasound in speech sound disorders or apraxia of speech. Studies have also been conducted in cases such as severe hearing impairment (Adler-Bock et al. (2007), Bernhardt, Gick et al. (2003) or Gallagher (2013)), Down syndrome (Fawcett, Bacsfalvi et al. (2008)), cleft palate (Roxburgh, Cleland et al. (2016)), acquired apraxia of speech post stroke (Jonathan L Preston & Leaman (2014), Acher, Fabre et al. (2016) and Haldin, Acher et al. (2017)) or partial glossectomy (Blyth, McCabe et al. (2016)).

In summary, the literature on ultrasound visual feedback reflects a great diversity of experimental designs. Thus, depending on speech disorders and studies, various protocols regarding number, duration and/or content of sessions, or number and age of participants, have been set up. Importantly, most studies have been conducted in English-speaking countries. Moreover, the performance was mostly evaluated through speech assessments although acoustic (audio recordings) or articulatory (contours segmentation of images) analyses sometimes supplement these reports (Joanne Cleland, James M Scobbie et al. (2015)). Besides,\(^3\)

---

\(^2\) As the feedback or illustration used in the present study are of an articulatory nature only, the term « articulatory » will not be specified in the rest of the article.

\(^3\) Electromagnetic articulography (EMA) has also been used by Katz & McNeil (2010) and Mental, Carey et al. (2017) but remains too invasive and not convenient enough to be concretely used in a clinical environment.
the experimental designs differed from one study to another: while Bernhardt, Bacsfalvi et al. (2008) alternated traditional rehabilitation and ultrasound visual feedback, Roxburgh et al. (2016) proposed a comparative study between the ultrasound visual feedback and the illustration by an articulatory talking head, whereas Cleland, McCron et al. (2013) and Bacsfalvi, Bernhardt et al. (2007) aimed to compare two main visual feedback devices, EPG and ultrasound. As a matter of fact, the recent study by Jonathan L Preston et al. (2018), aiming to compare two types of ultrasound biofeedback, is the only one that led to a statistical analysis of the outcomes. Finally, Blyth et al. (2016) led the only study of ultrasound biofeedback for two glossectomized patients.

Despite their great diversity, all these studies converge towards the same conclusion: the use of ultrasound seems to have a therapeutic benefit in speech rehabilitation as it enhances the positive impact of speech therapy, especially in the early stages (e.g. Blyth et al. (2016), Jonathan L Preston et al. (2018)). This contribution, yet, remains subtle and difficult to measure. It is therefore necessary to conduct larger studies focused on specific disorders to hope to gather convincing arguments.

This is the main motivation of the present study which focusses on speech disorders occurring after oral surgery.

1.2 Speech disorders related to oral surgery with partial glossectomy

When a cancerous lesion appears on the tongue, it can be removed by a surgical procedure called partial glossectomy, which can be extended to the mouth floor and/or the mandible. If the resected specimen is too large and the functional outcomes are expected to be too severe, the surgeon may be required to replace the resected specimen by a flap made from a patient’s piece of muscle, bone and/or skin. These surgical gestures are often supplemented by chemoradiotherapy (CRT) which severely alters the remaining tissues and the patients’ quality of life (QoL). Because of the intraoral resection and the CRT adjuvant treatment, patients may often experience difficulties in both eating (since tongue in involved in oral preparation, propulsion and swallowing of the bolus) and communicating (as tongue is deeply involved in speech production). The vocal tract has been modified in terms of shape and volume, strength and sensibility of the remaining tissues, as well as in amplitude and velocity of their movements. Subsequently, speech is often affected by a loss of tone, precision and speed, which can alter the production of certain phonemes as described by Perrier, Savariaux et al. (1999). Acher, Perrier et al. (2014) report possible alterations in French patients after partial glossectomy. Thus, consonants involving tongue movements in the point and the manner of articulation, i.e. alveolar, post-alveolar and velar consonants, are naturally affected by these anatomical changes. For instance, a significant noise can be noticeable during the holding phase of these obstruent consonants. Speech therapy is then necessary to help the patient to accurately produce speech and master his/her new articulatory space.

1.3 Goal of the present study

The purpose of the present study was thus to evaluate - in a clinical environment - the efficiency of visual tongue illustration and/or feedback in speech rehabilitation after intra-oral surgery including partial glossectomy. For this purpose, ten patients who have undergone intra-oral surgery have been included in this study over a period of two years (2016 - 2018). They followed speech therapy sessions based either on visual illustration or on a combination of visual illustration and feedback, as detailed in Section 2.1, and were regularly assessed.
2 Materials and methods
This study was carried out at the Rocheplane rehabilitation centre in Saint Martin d’Hères, France, with the agreement of the ethical committee Lyon Sud Est II (69HCL15_0736). This rehabilitation centre receives patients when they are discharged from the hospital after their surgery and provides them with intensive speech and swallowing therapy.

Three SLPs were involved in this project. Two of them (MGR and BG) were alternatively responsible for the patients’ rehabilitation, according to their schedules, whereas two of them (MGR and OC) were in charge of monitoring the patients’ progress.

2.1 Therapy sessions
This study aimed to compare the progress achieved with two speech rehabilitation protocols.

Two protocols were followed alternatively. In the protocol providing visual illustration only (IL protocol), the patient visualized the target/gesture produced by a reference speaker but relied only on his/her acoustic and somatosensory feedback to understand why his/her gesture was wrong and how (s)he should correct it. In the protocol providing both visual illustration and feedback (FB+I protocol), the addition of a real time visual feedback of his/her own gesture is expected to fasten the recalibration process.

Thirty minutes therapy sessions were conducted once or twice a day, weekend excluded. The patients were divided in two cohorts (FI and IF). The patients of the FI cohort followed a first series (S1) of 10 therapy sessions with the FB+I protocol, and then a second series (S2) of 10 sessions with the IL protocol. The order of the series in the IF cohort was reversed. A speech assessment was performed by the SLP at baseline, prior to the first series (at time T0) and then at the end of each series S1 and S2 (times T1 and T2). Speech therapy sessions were usually conducted at a mean frequency of about 5 sessions per week (2 to 10 depending on patient overall condition, but constant for each patient, cf. Table 1). Patients were assigned to the FI or IF cohorts using stratified random sampling based on their T0 assessment scores in order to obtain similar means for both cohorts.

2.2 Patients
Twelve adult patients were initially included in the study: eight males and four females. One male left before the end of the study whereas one female experienced problems of concentration during the T1 assessment and did not read the right words; their scores are thus not reported nor analysed in this study. Finally, ten patients (seven males and three females) were retained (average age of 59.4 years for the FI cohort and 58.6 years for the IF cohort). Details of surgery and treatment for each patient are presented in Table 1. The patients included in this study did not report any speech disorder or speech therapy prior to surgery. Note that all of them were explained the protocol and signed an informed consent before being included in the study, as described in the protocol allowed by the ethical committee.
2.3 Experimental setup

2.3.1 Visual illustration software

The Ultraspeech-player software (Hueber (2013)) was used in this study for visual tongue illustration. This software is dedicated to the visualization of high-speed ultrasound and video sequences of the tongue and lips, recorded synchronously with the speech audio signal, using the Ultraspeech software (Hueber, Chollet et al. (2008)). The software aims to display natural tongue movements acquired on a reference speaker, for different kinds of sequences (isolated vowels, VCV, swallowing, etc.), as illustrated in Figure 1 (top). Ultraspeech-player embeds a mechanism of real-time processing of audio and video streams, allowing the user to control the speed of the illustrated articulatory gesture, and that of the associated sound signal, in order to better observe it. The use of articulatory data acquired on a real speaker allows to restore realistic coarticulatory patterns. This software is free to download at http://www.ultraspeech.com.

For the present study, a new database was recorded and added to Ultraspeech-player⁴. One of the SLTs involved in the study was instructed to pronounce all the training sequences used

---

⁴ This database will be made publicly available if the paper is accepted.
during the therapy (see 2.4 for more details). Her tongue movements were recorded at 60fps using the Telemed Echoblaster system configured with a typical parameter set for tongue imaging (e.g. 7cm depth, with all image post-processing techniques such as frame averaging or speckle reduction disabled), with a 3-5MHz microconvex probe, maintained fixed with respect to the speaker’s head (and below the chin) thanks to a slightly modified version of the helmet developed by Articulate Instrument⁵. Lip movements were also recorded (but not used in the therapy session) at 60fps (640×480 pixels) using an industrial CMOS camera (ImagingSource DFM22BUC03ML). The acoustic speech signal was acquired at 44.1kHz / 32bits with the low-latency (ASIO compatible) RME Fireface soundcard and a cardioid AKG C-1000S microphone. All recordings were performed in a semi-anechoic room using the Ultraspeech 1.3 recording software.

One possible issue with ultrasound tongue images is the difficulty for the patient to make sense of them. Actually, the tongue is displayed out of any spatial context since the palate, teeth and pharynx are not visible in ultrasound images. In order to make the image more intuitive, the ultrasound image was supplemented with a schematic contour of the oral cavity (in red on Figure 1). This contour was extracted from a static MRI scan available for a female speaker. A set of transformations (rotation, shift, scaling) was then manually estimated to register the ultrasound image with the MRI contours. Using a ‘trial and error’ approach, the coarse-grained location of tongue-palate contacts for alveolar and velar stops was empirically checked, as well as the position of the tongue for some front and back vowels (note that the goal was not to register perfectly the two modalities together, which is a research problem on its own, but simply to make the ultrasound tongue image easier to interpret).

![Figure 1](image_url)

**Figure 1.** Top: illustration of the control interface and midsagittal ultrasound image display with sketchy vocal tract outline provided by Ultraspeech-player and used in the IL protocol. Bottom: illustration of the double interface, including the real time display of the speaker’s tongue by Ultraspeech-biofeedback, used in the FB+I protocol.

⁵ [http://www.articulateinstruments.com/]
2.3.2 Visual feedback hardware and software

The same ultrasound system was used during the therapy sessions as a biofeedback tool. However, the probe stabilization helmet was not used since it may have been too uncomfortable in case of post-surgery facial oedemas. The probe was thus hold manually by the SLT, as patients had a partial loss of sensitivity in the region below the chin and tongue, and were not able to maintain the ultrasound probe in the adequate position.

In order to ensure a consistent display between illustration and feedback, a new software was developed, called Ultraspeech-biofeedback. It allows to superimpose in real-time the same schematic contour delimiting the oral cavity mentioned in section 2.3.2 on the ultrasound image (see Figure 1, bottom). Just before the first session for each new patient, the SLT took a minute to adjust the display to the intraoral morphology of the patient using the trial-and-error procedure mentioned above and stored the settings in a preset file which was reloaded at each following session and possibly updated.

2.4 Rehabilitation material

For the first half of the therapy sessions, the patients were instructed to perform Oral Motor Exercises (OME) including lips, mouth, cheeks and tongue range of movements. For the second part of the sessions, articulation of selected phonemes involving tongue (/t/, /k/, /kt/, /kl/, /st/, /sk/, /ʃ/ and /tl/) was trained using previously recorded words and sentences as described in Section 2.3.1.

2.5 Speech assessment tools

Speech assessment was carried out to evaluate patients’ progress by means of tests extracted from the French BECD test battery (Auzou & Rolland-Monnoury (2006)). Inspired by the Frenchay Dysarthria Assessment (Enderby (1983)), it assesses the degree of dysarthria with different approaches. In the present study, three tests addressing isolated phonemes and words / sentences / conversation were used:

- ‘Phonetic Intelligibility test’ (TPI): the patient is instructed to read from cards a list of 52 words randomly chosen from 13 groups of four words. In each group, one word differs from the three others by one or two phonetic features (for instance ‘début’ [deby], ‘dëbute’ [debyt], ‘des bouts’ [debu], ‘dëbote’ [debut]). The SLP selects the closest word to what (s)he hears (without seeing it) from a list of four words. In each of the 13 series, the phonetic feature errors are scored on between 0 and 8 (since two features may simultaneously be erroneous for each of the four words, e.g. [deby] vs. [debut] in the previous example). Note that the three random lists (for T0, T1 and T2) were the same for all patients.

- ‘Intelligibility test’ (Intell): it is made of three parts, based on a set of words, a set of sentences and a spontaneous conversation. The patient is instructed to read twelve words and twelve sentences randomly picked in a pile of cards. The SLP reports what (s)he hears, without seeing it, and compares it with the expected content. Finally, the patient has a short conversation with the SLP. A global score between 0 and 8 is attributed by the SLP for each part.

- ‘Phonetic Analysis test’ (PhAn): the patient is instructed to repeat a list of 33 isolated phonemes, 37 words including simple phonemes and 25 words with complex phonemes

---

This software will be made publicly available if the paper is accepted.

Girod-Roux et al. Rehabilitation of speech disorders based on ultrasound visual feedback
pronounced by the SLP. The SLP scores the altered phonemes for each production (33 isolated, 88 simple and 30 complex phonemes), leading to a total of 151 scores on 0-1.

The rehabilitation program is conducted by two SLPs who alternatively educate the patients. Initially, all assessments were performed at T0, T1 and T2 by only one of them (MGR) for the sake of evaluation homogeneity. However, as this evaluation was not blinded, a blind SLP (OC) was asked to rate all the patients again, based on the audio records, with the same protocol.

3 Results

In order to evaluate statistically the results of each test, it is needed to model the relation between the response variable, i.e. the score obtained by the patient, and several explanatory variables as well as their interactions, i.e. cohort (qualitative variable, 2 categories, FI and IF) and time (qualitative variable, 3 categories, T0, T1 and T2).

The score variables are integer values between 0 and 8 for TPI and between 0 and 8 for Intell, and can thus be considered as ordered categorical variables. Besides, as each patient was tested three times, the patient variable (10 participants) is considered a random effect for the test with repeated data. We have therefore employed ordinal regression with random effects for the TPI and Intell tests, using the clmm procedure of the R package (R Development Core Team (2008)) based on Tutz & Hennevogl (1996).

Then, it was checked whether the models adjusted the data correctly, i.e. if the empirical probabilities (i.e. relative frequency) were close to the probabilities estimated by the model and if they were within the range of 95% prediction. Finally, four contrasts have been estimated by means of the lsmeans procedure of the R package. For each test, the following comparative contrasts have been evaluated (note that ‘FI or IF(Ti–Tj)’ denotes the difference in scores in the FI or IF cohort between times Ti and Tj):

\[
\text{FI}_{\text{IF}}\text{S1} = \text{FI}(T0–T1) \text{ vs. } \text{IF}(T0–T1): \text{difference in progress achieved after the first series S1, i.e. difference between FI cohort (FB+I sessions) and IF cohort (IL sessions) after the first series;}
\]

\[
\text{FI}_{\text{IF}}\text{S2} = \text{FI}(T1–T2) \text{ vs. } \text{IF}(T1–T2): \text{difference in progress achieved after the second series S2, i.e. difference between FI cohort (FB+I protocol) and IF cohort (IL sessions) after the second series S2;}
\]

\[
\text{FI}_{\text{IF}} = \frac{1}{2} [\text{FI}(T0–T1) + \text{IF}(T1–T2)] \text{ vs. } \frac{1}{2} [\text{FI}(T1–T2) + \text{IF}(T0–T1)]: \text{difference in progress between FB+I protocol and IL sessions averaged over series S1 and S2.}
\]

For test PhAn, the score variable is the sum of the scores obtained for each of the 151 assessed phonemes, divided by 151. This, consequently, takes a nearly continuous value between 0 and 1. The patient variable is again considered as a random effect. For this type of scores, beta regression with random effects has been employed using the glmmadmb procedure of the R package glmmADMB. The four contrasts were estimated with the glht procedure of the R multcomp package based on Hothorn, Bretz et al. (2008). The whole analysis has been performed for both raters (MGR and OC) separately.

The analysis was first applied, for the three tests, to the scores of the ten patients by the two raters: no difference was found significant at p=0.05. This means that it is impossible to claim that any patient significantly benefited better from the FB+I sessions than from the IL sessions.

A cohort analysis was then performed for each cohort of patients (FI and IF), for each test (TPI, Intell, PhAn) and each SLP (MGR, OC). The first result is that none of the differences were significant for the Intell test. This was not unexpected for two reasons: as the number of words in the list was small, the SLP tended to un-volitionally learn them and eventually to answer in
a forced choice way; moreover, each score level grouped several possible errors, which reduced the chance to observe small progress. No detailed results are thus reported for this test which appeared to be less relevant as expected. The results for the other two tests (TPI and PhAn) are reported in Table 2.

The first important observation is that, for the TPI, the FB+I sessions are significantly more efficient than the IL sessions, on average over both S1 and S2 series, for both raters. This is a positive indication that patients’ overall progress tends to be better with the FB+I sessions than with the IL sessions. A similar observation can be made from the results of the S2 series, though the difference related to rater MGR has a p-value slightly above 0.05. More surprising are the results for the S1 series, where only rater OC finds that the IL sessions were significantly more efficient than FB+I sessions, though the difference remains small. Finally, Table 2 shows that the PhAn test does not lead to any significant differences, except for rater MGR in session S1.

Table 2. Cohort score progress averages and standard deviations (SD); p-values of their comparisons (significant differences are marked in bold). The ‘S1 + S2’ columns correspond to the merging of the FB+I scores and of the IL scores from S1 and S2.

### 4 Discussion, conclusion and perspectives

Our literature review showed the importance of multiple sensory feedback channels in motor actions such as speech, including speech in glossectomized speakers. These multiple channels help maintain or correct internal models of coherent speech production and perception. We presented two paradigms of articulatory visual representation (for the rehabilitation of articulatory disorders) that were expected to improve the patients’ speech ability by providing them with additional information on the defective phonemes: ‘illustration’ and ‘articulatory visual feedback’. Based on the 10 glossectomized patients included in the present study, taking care to counterbalance the order and treatment conditions to avoid possible bias, the results of this research support the idea that the use of articulatory visual feedback significantly improves speech outcomes.

Baseline (T0) and tests (T1 and T2) have only assessed non-treated words (which included treated and non-treated phonemes) in order to observe generalization in conversational speech. The present study tends to show that speech was significantly improved in both cohorts with the use of US biofeedback. Indeed, in the early stage of the rehabilitation (2-3 first weeks) and especially within the S2 series, both cohorts show better speech outcomes (p<0.05) at the TPI test with the combination of US visual feedback and illustration, than with the illustration only.

Regarding S1 series and according to rater OC, results seem to be in favour of the illustration only. At this point, we have not found any interpretation. One hypothesis is that this rater was less accustomed to glossectomized speech than the other rater MGR.

Intra-patient analysis has not been conducted as only cohort analysis led to statistically significant results, and as inter-rater agreement was low. The analysis of the TPI-test shows that all patients improved their speech during the study (from T0 to T2), except patient FI-008; this patient had been particularly more affected by chemoradiation, leading to a lot more pain, fatigue and lack of motivation, than the other patients. Moreover, according to both raters, the speech quality decreased for one patient (patient IF-004) within the first series (IL); this can be
explained by the occurrence of intercurrent medical events (in this case, a flap alteration). Furthermore, a qualitative analysis of the errors in the TPI shows that errors on aperture for vowels and place of articulation for consonants benefited from the use of the US visual feedback. Lastly, previous single-case studies of biofeedback intervention, including the latest of Jonathan L Preston et al. (2018) reported the existence of non-responders, which could be the case of patient FI-007: according to rater OC, this patient produced more errors at T1 assessment after the US visual feedback sessions.

Finally, the patients of this study have informally reported benefits – at least for the first sessions – of the US real-time feedback: they felt that the feedback helped them better imagine their tongue position, movement or shape – of whose they were not aware due to their naïve condition and their lack of tongue sensitivity following surgery. During the therapy sessions, the SLPs hold the probe under the patients’ chin. Indeed, participants were unable to adequately maintain the probe due to the lack of sensitivity in the chin’s area. This is consistent with Jonathan L. Preston et al. (2018)’s study of the undesired effects in ultrasound speech therapy, where 21% of the responses were related to the difficulties in positioning the probe, which was found uncomfortable or annoying. In agreement with Roxburgh, Scobie et al. (2015), both SLPs also reported that the US biofeedback enabled them to provide positive reinforcement to their patient on their skills.

Note that, since the 10 subjects of the study were patients following intensive therapy and complementary treatment after surgery (chemotherapy and/or radiation), the frequency of the therapy sessions had to be modulated and adapted to the participants (overall condition, medical complication, pain, fatigue, medical consultation appointment, chemoradiation sessions, public holidays, etc.). Thus, even if they all have followed the study design (10 sessions of each protocol I and F), they did not have the same number of sessions per week (mean = 5 sessions / week, range = 2–10 sessions / week): this modulation could have had an impact on the results. Moreover, the heterogeneity of the cohort in terms of tumour stage, type of the surgery, need for chemoradiation, number of remaining teeth, etc., may also have a potential influence on the results, for instance by increasing the dispersion of the scores.

Another possible bias may arise from the heterogeneity of the therapist contribution to the rehabilitation and assessment tasks. Indeed, two SLPs were in charge of the patients’ rehabilitation with or without US visual feedback, depending on their work load and schedule, though only one of them was in charge of the assessment, for the sake of homogeneity. A third blind-SLP was in charge of the reassessment of the 10 patients based on the audio records, so that the inter-rater reliability could be evaluated. The results show various degrees of agreement between the two raters, consistent with the findings of Roxburgh et al. (2016) who reported a statistically weak agreement between the scores of 22 phonetically-trained listeners for the same patients.

Regarding the assessment material, Woisard, Espesser et al. (2013) showed that the standard BECD test battery (Auzou & Rolland-Monnoury (2006)) suffers from limitation, in particular due to its use of real words: the raters are more likely to restore distorted sequences for real words, which may induce them to under- or over-estimate the errors, depending on phonemes. In the future, it could be more efficient to use the new intelligibility test proposed by Ghio, Lalain et al. (2018), based on the pronunciation of pseudo-words that neutralizes unwanted lexical and learning effects of items by the raters. However, such a test would not allow therapists to assess speech in its functional dimension of communication.

To conclude, the present study is, to the best of our knowledge, the first cohort study demonstrating the effectiveness of ultrasound visual feedback jointly used with illustration for rehabilitating glossectomized patients.
The generalisability of these results is however subject to certain limitations. For instance, the sample size remains limited and should be increased in future studies (a multicentre trial could be an efficient way to recruit more patients while maintaining strict inclusion criteria). The speech assessment method could also be improved, for instance by relying on intelligibility tests recently proposed in the literature (e.g. Ghio et al. (2018)); it could also involve a more extended set of raters (though Roxburgh et al. (2016) have shown that the agreement remains low). In addition, future work could also exploit recent technological development aiming at improving the displayed ultrasound tongue image. Indeed, such image may remain difficult to interpret for some patient since the tongue is displayed out of any spatial context (the palate, teeth and pharynx are not visible in an ultrasound image of the vocal tract). Fabre, Hueber et al. (2017), have recently proposed a machine learning-based method for animating automatically and in real-time the 3D tongue model of an articulatory talking head from ultrasound images. Validating this technique in a clinical context is part of our roadmap.
