Abstract

This paper deals with optimal input design for parameter estimation in a bounded-error context. Uncertain controlled nonlinear dynamical models, when the input can be parametrized by a finite number of parameters, are considered. The main contribution of this paper concerns criteria for obtaining optimal inputs in this context. Two input design criteria are proposed and analysed. They involve sensitivity functions. The first criterion requires the inversion of the Gram matrix of sensitivity functions. The second one does not require this inversion and is then applied for parameter estimation of a model taken from the aeronautical domain. The estimation results obtained using an optimal input are compared with those obtained with an input optimized in a more classical context (Gaussian measurement noise and parameters a priori known to belong to some boxes). These results highlight the potential of optimal input design in a bounded-error context.

Key words: Experiment design; Optimal input; Parameter estimation; State estimation; Continuous-time systems; Sensitivity functions; Nonlinear systems; Bounded noise; Interval analysis; Aerospace models.

1 Introduction

In this paper, we are interested in parameter estimation of models describing industrial systems. Such systems are often prone to uncertainties that complicate the modeling task. Usually, uncertainties are described as realizations of random variables with known distributions, which is difficult to justify in practice. In the presented work, perturbations are only assumed to be bounded with known bounds. Thus, the set-membership framework is considered. In this framework, the set of all parameters consistent with the model structure, the measurements and the bounds on the perturbations can be defined as the set estimate for the parameters. Various techniques are then available to characterize this set estimate (see for example [7] or [11]).

Set-membership estimation is an interesting alternative to classical least squares or maximum likelihood estimation. These methods have received a lot of attention in the last years, for example [10], [6], [21].

2 Problem formulation and notations

2.1 Notations

In what follows, boxes, i.e., cartesian products of intervals are denoted as \( [x] = [x, \overline{x}] \) (see [7]). This paper deals with optimal input design for estimating the unknown parameters of a nonlinear dynamical model described by the following form:

\[
\begin{align*}
\dot{x}(t, p, u) &= f(x(t, p, u), u(t), p), \\
y_m(t, p, u) &= h(x(t, p, u), p),
\end{align*}
\]

where \( x(t, p, u) \in \mathbb{R}^n \) and \( y_m(t, p, u) \in \mathbb{R}^h \) denote respectively the vectors of state variables and the model output. The initial conditions for \( x(.) \) at \( t = 0 \) are supposed to belong to an initial bounded box \( [x_0] \). \( u(t) \) represents the input, it is supposed to belong to an admissible set of inputs \( U_{ad} \) and the input is supposed to be composed of elementary functions. The vector \( p \in \mathbb{R}^p \) is the vector of parameters to be estimated, which is supposed to belong to an a priori box \( [p_0] \). The time \( t \) is assumed to belong to \( [0, t_{\max}] \).

The functions \( f \) and \( h \) are nonlinear functions.

\( f \) is supposed analytic on \( M \) for every \( p \in [p_0] \), where \( M \) is an open set of \( \mathbb{R}^m \) such that \( x(t, p, u) \in M \) for every \( p \in [p_0] \) and \( t \in [0, t_{\max}] \).

The model output at the sample time \( t_k \), with \( k \) from 1 to \( N \) is denoted \( y_{m}^k(p, u) = y_{m}(t_k, p, u) \). \( y_{m}^k(p, u) \) is a vector with components \( y_{m,i}^k(p, u) = y_{m,i}(t_k, p, u) \) for \( i = 1, ..., n_y \), \( k = 1, ..., N \).

Let \( y(t_k, u) \) be the vector of the measurements at the sample time \( t_k \). Suppose that there exists a “true” value of parameters \( p^* \) such we have:

\[
y(t_k, u) = y_m(t_k, p^*, u) + v(t_k), \quad k = 1, ..., N,
\]

where the measurement noise \( v(t_k) \) is supposed bounded by \( v(t_k) \text{ and } v(t_k) \) which are known as lower and upper bounds. Such bounds may, for instance, correspond to a bounded measurement noise or tolerance on sensors.

2.2 Parameter estimation in a bounded error context

In a bounded-error estimation context, one is interested in estimating the set \( \mathcal{P} \subset [p_0] \) of all parameters \( p \) consistent with the model structure and the bounds on the measurement noise. In order to obtain the most accurate estimates, we choose to minimize a cost function, for example the volume, of the set \( \mathcal{P} \) (or of an enclosure of \( \mathcal{P} \)). It may generally depend on the values of the input, the initial time, the sample times, among others. In this work, only the input is considered. Our aim is to design an input that minimizes the cost function. More formally, one has to find an input \( u^* \) such that:

\[
u^* = \arg \min_{u \in U_{ad}} \Phi(\mathcal{P}).
\]

Obtaining \( \mathcal{P} \) is difficult in practice. Nevertheless, there are efficient algorithm to obtain an outer-approximation \( [p] \) of \( \mathcal{P} \). The Problem (3) is thus relaxed as follows:

\[
u^* = \arg \min_{u \in U_{ad}} \Phi([p]),
\]

where \( [p] \) is an outer-approximation of \( \mathcal{P} \) obtained by a bounded-error estimation algorithm from interval analysis.

The next section briefly describes the tools from interval analysis used to perform the set-membership estimation.

3 Basic tools of interval analysis

Interval analysis provides tools for computing with sets which are described using outer-approximations formed by union of non-overlapping boxes. The following results are mainly taken from [7] and [14].

A real interval \( [u] = [\underline{u}, \overline{u}] \) is a closed and connected subset of \( \mathbb{R} \). The width of an interval \( [u] \) is defined by \( w([u]) = \overline{u} - \underline{u} \), and its midpoint by \( m([u]) = (\overline{u} + \underline{u})/2 \). An interval vector (or box) \( [x] \) is a vector with interval components and may equivalently be seen as a cartesian product.
of scalar intervals $[x] = [x_1] \times [x_2] \times \cdots \times [x_n]$. An interval matrix is a matrix with interval components. The set of $n \times m$ real interval matrices is denoted by $\mathbb{IR}^{n \times m}$. The width of an interval vector (or of an interval matrix) is the maximum of the widths of its interval components. The midpoint of an interval vector (resp. an interval matrix) is a vector (resp. a matrix) composed of the midpoints of its interval components.

Classical operations for interval vectors (resp. interval matrices) are direct extensions of the same operations for scalar vectors (resp. scalar matrices) [14].

The magnitude of an interval $[x]$, noted $||[x]||$ is given by the largest absolute value of $[x]$ that means the absolute value of the real with the largest value in $[x]$. The magnitude of an interval $[x]$, noted $mig([x])$ is the smallest absolute value of the elements of $[x]$ that means the absolute value of the real with the smallest value in $[x]$. In this work, the notions of magnitude and magnitude of an interval are extended to each component of an interval matrix. The corresponding matrices are respectively denoted $[A]$ and $mig([A])$. For example if $[x] = [-20, 10]$ then $||[x]|| = 20$ and $mig([x]) = 10$.

The determinant $\text{det}(\cdot)$ of a square interval matrix is defined as in the case of real square matrices except that the determinant of an interval matrix is an interval. A square interval matrix $[B]$ is regular if $0 \notin \text{det}([B])$. Let $[B]^{-1}$ the inverse interval matrix of $[B]$ which means the narrowest interval matrix enclosing the set of inverse matrices $\{B^{-1} / B \in [B]\}$. Considering the interval matrix $[L_i]$ whose entries are $[1, 1, 1] \in \mathbb{IR}^{n \times n}$ such that $[B]^{-1} [B] \subset [L_i]$. An interval matrix $[A]$ is said to be positive definite if each $A \in [A]$ is positive definite (in the classical sense). Positive definiteness of symmetric interval matrix is closely related to regularity. A symmetric interval matrix is positive definite if and only if it is regular and contains at least one positive definite matrix [22].

For an interval vector $[z]$ with components $[z_i]$, the real $||[z]||$ is given by $||[z]|| = \max_i |[z_i]|$.

The Frobenius norm for an interval matrix $[A]$ is denoted by $||[A]||_F$ and $||[A]||_F = \sqrt{\text{tr}([A]^T[A])] = \sqrt{\sum_{i,j} |[a_{ij}]|^2}$ where $\text{tr}([B])$ is the trace of the interval matrix $[B]$.

4 Criteria for optimal input

4.1 Problem formulation

In this section, we exhibit criteria involving the input $u$ to be used, to minimize the volume of $[p]$ for an appropriate choice for $u$. In [11], the authors have used a centered inclusion function at $m \in \mathbb{IR}^{n_u}$ for the model output. The use of sensitivity functions leads to reduce more quickly the size of outer approximations of the sets of interest. Thus we start from this idea which leads to obtain an explicit expression of $[p] - m$.

Considering $[p]$ such that $[p] \subset [p_0]$, $m \in [p]$ and a mean value form for $y_m(t_k, [p], u)$, $[p]$ has to satisfy:

$$y_m^k(m, u) + \sum_{j=1}^{n_p} (([p_j] - m_j) \left[ \frac{\partial y_m^k}{\partial p_j} \right] ([p], u) \subseteq [y^k],$$

where $[y^k] = [y(t_k, u)]$. Then:

$$\sum_{j=1}^{n_p} ([p_j] - m_j) \left[ \frac{\partial y_m^k}{\partial p_j} \right] ([p], u) \subseteq [y^k] - y_m^k(m, u).$$

Denoting $[S^k]$ the row vector whose entries are:

$$[S^k_j] = \left[ \frac{\partial y_m^k}{\partial p_j} \right] ([p], u), \quad [S^k_j] \in \mathbb{IR}^{1 \times n_p}, \quad j = 1, \ldots, n_p.$$

The interval matrix $[S^k] \in \mathbb{IR}^{n_y \times n_p}$ is built with the $n_y$ rows $[S^k]$ and $[v^k] = [y^k] - y_m^k(m, u)$.

In the following, the interval matrix $[S^k]^T[S^k]$ is assumed to be positive definite and we note $(S^k)^T[S^k] = [I^k]$. One has to find $u$ such that $||[p] - m||$ is as small as possible. By noting $[v^k] = [v(t_k)]$, (5) becomes:

$$[S^k]([p] - m) \subseteq [v^k].$$

From (6), we obtain $[S^k]^T[S^k]([p] - m) \subseteq [S^k]^T[v^k]$, then by using $(S^k)^{-1}$ the following inclusion is obtained:

$$[I^k]([p] - m) \subseteq ([S^k]^T[S^k])^{-1}[S^k]^T[v^k].$$

The following proposition gives two upper bounds for $[I^k]([p] - m)$.

Proposition 4.1 For all $k \in \{1, \ldots, N\}$

$$||[I^k]([p] - m)||^2 \leq ||([S^k]^T[S^k])^{-1}[S^k]^T||_{[v^k]}^2, \quad \text{and}$$

$$||[I^k]([p] - m)||^2 \leq ||\text{tr}([I^k]((S^k)^T[S^k])^{-1}||_{[v^k]}^2$$

with $[v^k] = [v^k]$.

Proof:

Let $[A] = ([S^k]^T[S^k])^{-1}[S^k]^T$ and $[a_{ij}]$ be the entries of $[A]$:

$$[I^k]([p] - m) \subseteq [A][v^k],$$

and:

$$||[I^k]([p] - m)||^2 \leq ||[A][v^k]||^2 \leq \left( \max_{1 \leq i \leq n_u |[a_{ij}]||[v^k]|^2 \right).$$

Since $\left( \sum_{j=1}^{n_p} |[a_{ij}]||[v^k]|^2 \right)^2 \leq \sum_{j=1}^{n_p} |[a_{ij}]|^2 \sum_{j=1}^{n_p} |[v^k]|^2$.

One obtains:

$$\max_i \left( \sum_{j=1}^{n_p} |[a_{ij}]||[v^k]|^2 \right)^2 \leq \max_i \sum_{j=1}^{n_p} |[a_{ij}]|^2 ||[v^k]|^2, \leq \left( \frac{||[A]|}{F} \right)||[v^k]|^2.$$
Then $||A||^2_p = |\text{tr}([F^k][S_k^T(S_k)^{-1}])|$ because $\text{tr}([A][A]^T) = \text{tr}([A]^T[A])$ and:

$$[A][A]^T = ([S_k^T(S_k)^{-1}][S_k^T][S_k](S_k)^{-1}],$$

$$= [F^k][S_k^T(S_k)^{-1}].$$

This leads to Proposition 4.1.

An upper bound of $|\text{tr}([F^k][S_k^T(S_k)^{-1}])|$, depending on $|\text{tr}([S_k^T(S_k)^{-1}])|$, is given in Proposition 4.2.

**Proposition 4.2** For all $k \in \{1, ..., N\}$

$$|\text{tr}([F^k][S_k^T(S_k)^{-1}])| \leq \lambda_{\text{max}}(||I_e||) |\text{tr}([S_k^T(S_k)^{-1}])|,$$

where $\lambda_{\text{max}}(||I_e||) = 1 + n_p \epsilon$ is the maximum eigenvalue of $||I_e||$.

Proof:

For each $k \in 1, ..., N$ there exists $\epsilon_k$ such that $[F^k] \subset [I_e]$, $[F^k][S_k^T(S_k)^{-1}] \subset [I_e][S_k^T(S_k)^{-1}]$. Let $\epsilon = \max_{k \in \{1, ..., N\}} \epsilon_k$ then $[I_e] \subset [I]$. Let $[C] = ([S_k^T(S_k)^{-1}]$, the following inequalities are obtained:

$$|\text{tr}([F^k][C])| \leq |\text{tr}([I_e][C])| \leq |\text{tr}([I][C])| \leq \lambda_{\text{max}}(||I_e||)|\text{tr}([C])|,$$

because the matrices $||I_e||$ and $||C||$ are symmetric matrices. This leads to the announced result.

Then $||[F^k][p - m]||$ depends on $|\text{tr}([S_k^T(S_k)^{-1}])|$. Previous Propositions 4.1 and 4.2 lead to for all $k \in \{1, ..., N\}$:

$$||[F^k][p - m]||^2 \leq \lambda_{\text{max}}(||I_e||) |\text{tr}([S_k^T(S_k)^{-1}])| ||v_k||^2,$$

which gives a possible criterion $J_1$ for optimal input. It may be defined as follows:

$$J_1(u) = \sum_k |\text{tr}([S_k^T(S_k)^{-1}])|.$$

Then this leads to the following definitions.

**Definition 4.1** The criterion $J_1$ is called the set-membership-A-optimality criterion.

This criterion consists in considering the largest absolute value of $|\text{tr}([S_k^T(S_k)^{-1}])|$. 

**Definition 4.2** An input $u^*$ is said to be set-membership-A-optimal when:

$$u^* = \arg \min_{u \in \mathcal{U}_{ad}} J_1(u).$$

In order to avoid the inverse matrix computation $([S_k^T(S_k)^{-1}])$, the following criterion is proposed:

$$J_2(u) = \sum_k \text{mig} \left( |\text{tr}([S_k^T(S_k)^{-1}])| \right).$$

This criterion consists in considering the smallest absolute value of $|\text{tr}([S_k^T(S_k)^{-1}])|$. 

**Definition 4.3** The criterion $J_2$ is called the set-membership-T-optimality criterion.

**Definition 4.4** An input $u^*$ is said to be set-membership-T-optimal when:

$$u^* = \arg \max_{u \in \mathcal{U}_{ad}} J_2(u).$$

In this case it is necessary to verify the invertibility of the matrix $[S_k^T(S_k)^{-1}]$ by verifying that $0 \notin \text{det}([S_k^T(S_k)^{-1}])$.

**Remark 4.1** If the matrix $[S_k^T(S_k)^{-1}]$ is not invertible, possible solutions are available: the reduction of the a priori domain of the parameters, a sensitivity analysis to limit the number of influential parameters or the elimination of inputs leading to singular matrices. If these attempts fail, another criterion must be chosen: the MIGMAG criterion based on interval sensitivity analysis [12] or another based on the interval determinants of the gram matrix of sensitivities are available [13].

Next section is devoted to optimal input design and parameter estimation of the case study.

## 5 Application

### 5.1 A model from aerospace

Consider a model describing the longitudinal motion of a glider [4]. This model has no undermodelling:

$$\dot{\Phi} = -g \sin(\dot{\theta}) - \frac{1}{2m} \rho S V^2 (C^\alpha_x + C_{\alpha m} \tilde{\alpha} + C_{\alpha m} \tilde{\alpha} m),$$

$$\alpha = \frac{2}{m V^2 + \rho S V^2 C_{\alpha m}} \left( m V g + m g \cos(\dot{\theta}) - \frac{1}{2} \rho S V^2 C_{\alpha m} \right),$$

$$\dot{q} = \frac{1}{2B} \rho S V^2 \left( \frac{C_{\alpha m}}{m m_{\alpha}} + C_{\alpha m} \tilde{\alpha} + C_{\alpha m} q V \right)$$

$$+ \frac{1}{2} \rho S V^2 C_{\alpha m} \left( m V g + m g \cos(\dot{\theta}) \right)$$

$$- \frac{1}{2} \rho S V^2 C_{\alpha m} \left( m m_{\alpha} \tilde{m} \right),$$

$$\dot{\theta} = q, \quad \tilde{m} = m_{\alpha} - \tilde{m}_{\alpha}, \quad \alpha = \alpha - \alpha_0,$$

in which $C_{\alpha m} = C_{\alpha m} + C_{\alpha m} \tilde{\alpha} + C_{\alpha m} \tilde{\alpha} m + C_{\alpha m} \tilde{\alpha} m$ and $\dot{\theta} = \theta - \alpha$.

The projection of the general equations of motion onto the aerodynamic reference frame of the aircraft and the linearization of aerodynamic coefficients give the previous system. In these equations, the state vector $x$ is given by $(V, \alpha, \theta, \dot{\theta})^T$, the observation $y_m$ is full (i.e., $y_m = x$), the input $u$ is $\tilde{m}$ given in degree ($\tilde{m}$ represents the initial condition). The variable $V (m/s)$ denotes the speed of the aircraft, $\alpha (\text{deg})$ the angle of attack, $\alpha_0$ the trim value of $\alpha$, $\theta (\text{deg})$ the pitch angle, $q (\text{deg/s})$ the pitch rate. The
other constants represent $\delta_m$, the elevator deflection angle, $p$ the air density, $g$ the acceleration of gravity, $l$ a reference length and $S$ the area of a reference surface. $B$ represents a moment of inertia. The parameters to be estimated are $\mathbf{p} = (C_{c\alpha}, C_{c\alpha}, C_{m\alpha}, C_{m\delta}, C_{m\theta})^T$, which are assumed to be uncertain. The initial conditions are supposed to belong to $[28.48, 28.52]$ for $V$, $[6.2682, 6.7265]$ for $\alpha$, $[-0.2292, 0.2292]$ for $q$ and $[2.2002, 2.6585]$ for $\theta$. The prior domain for the parameters is given by $[p_0] = [1.71, 1.89] \times [4.75, 5.25] \times [-5.25, -4.75] \times [-23.1, -20.9]$. The measurement noise (2) is supposed to be bounded by $[-0.0447, 0.0447]$ for $V$ and $[-0.2521, 0.2521]$ for $\alpha$, $q$ and $\theta$. The measurements have been simulated by using the parameters equal to $\mathbf{p}^* = [1.85, -5, -22]^T$. The test duration is fixed at one second. The stop criterion for the algorithm SIVIA (Set Inversion Via Interval Analysis) [8] used in the estimation parameter process is $\varepsilon = [0.01, 0.05, 0.05, 0.1]^T$ that means that the stop threshold for the first parameter is 0.01, the second and third are 0.05 and the last one is 0.1. The package VNODE-LP ([17], [18]) has been used to calculate the solutions of (12) and the sensitivities.

5.2 Optimal input

In this application, the admissible input has been limited to full amplitude square waves only. In fact, analytic works for similar problems demonstrate that inputs similar to square waves were superior to sinusoidal inputs for parameter estimation [2]. In our application, the test time is divided into discrete steps called stages. The inputs tested by our procedure are given by:

$$u(t) = u_0 + \sum_{i=1}^{s} (a_i\varepsilon_i - a_{i-1}\varepsilon_{i-1})H(t - \tau_{i-1}), \quad \varepsilon_0 = 0,$$

where $u_0$ is an input trim value (given by $\delta_{m0}$) and $H$ is the Heaviside function. The variables $\tau_i$ are the switching times with $\tau_0$ the initial test time. Indeed, the variables $a_i$ are chosen to be equal to the square wave positive amplitude [16]. The given variables $\tau_i$ satisfy $\tau_0 < \tau_1 < \ldots < \tau_{r-1}$ and $\varepsilon_i \in \{-1, 0, 1\}$ for $i = 1, \ldots, r$. This step gives the optimal number of square waves $r$ and the optimal values of $\varepsilon_i$ (with fixed time and fixed amplitude) to be realized. The variables $\tau_i$ are not optimized during this step. In order to obtain an optimal input, the set-membership-T-optimality criterion $J_2$ is considered.

The criterion $J_2$ has been maximized for different total numbers of stages $r$. The values are given in Table 1. The variable $T$ represents the computing time (in seconds). The fourth column of this Table represents the optimal value of $u(t)$ on each stage, for the value of $r$ given in the first column. The time length of each stage is linked to the number of stages; the test time being fixed at one second. For example, if the test time is divided in four stages: each stage duration is fixed at 0.25 seconds. The total number of sample times is $N = 10$. Through this Table, we show that the optimal number of stages is five. With an other total number of sample times $N = 120$, we obtain the same optimal number of stages and the same optimal input with five stages but the computing time is multiplicated by approximatively 4. Therefore, in the next section, we use $N = 10$ points to estimate the parameters of interest.

**Remark 5.1** The proposed approach can be applied to a large class of dynamical systems; particularly when the input is piecewise continuous, parametrized by a finite number of parameters including a number of stages. It can be applied, for example, in the aeronautical domain, in marine systems [3], in pharmakokinetics [12]. In the methodology described in [15] concerning aircraft parameter estimation experiments, the maximum number of stages for practical input optimization is given by $\frac{T}{T_{stage}}$, where $T$ is the fixed test time chosen a priori and $T_{stage}$ is the constant value of the stage time (depending on the dynamics of system and instrumentation).

5.3 Parameter estimation

To highlight the efficiency of the proposed optimal input design, we compare the estimation results obtained by using two different inputs: the first one is an optimal input proposed in [5] for the same case study (with Gaussian noise and parameters in an a priori known box) and the second one is the optimal input obtained above (with five stages) $u^*(t) = \delta_{m0} + a\sum_{i=1}^{5}(\varepsilon_i - \varepsilon_{i-1})H(t - \tau_{i-1})$ with $a = 1.6$ degrees and $\tau_0 = 0$ s, $\tau_1 = 0.2$ s, $\tau_2 = 0.4$ s, $\tau_3 = 0.6$ s, $\tau_4 = 0.8$ s.

![Fig. 1. Non optimal input (left); optimal input (right).](image)

In Table 2, we give the eliminated percentage of initial parameter box, where the eliminated percentage $\%\mathbf{p}$ is calcu-
lated by $\% = 1 - \frac{w(\mathbf{p}_{\text{accepted}})}{w(\mathbf{p}_0)}$, in which $\mathbf{p}_{\text{accepted}}$ means the boxes which have been proved to be solution.

Through this Table, we see that $C_{\alpha}$ is not well estimated by using the non-optimal input contrary to the case with optimal input. For the other parameters, the use of optimal input clearly improves the estimation.

6 Conclusion

In this contribution, two set-membership optimal input criteria have been proposed to improve parameter estimation: the set-membership-T-(and A)-optimality criteria. They concern a class of nonlinear dynamical models requiring a parametrization of the input with a finite number of parameters. The set-membership-T-optimality criterion has been successfully used to improve parameter estimation of a case study providing from the aeronautical domain. Moreover, with the set-membership-T-optimal input, the computing time for parameter estimation process of the model is reduced compared to the computing time obtained with a non-optimal input.

Other optimality criteria could be considered. One of our future research directions is to reduce the computational time of the parameter estimation process by minimizing the total number of sample times to obtain a given accuracy on parameter estimation.
