KEYWORDS: Anatase, hydrothermal synthesis, morphology control structuring agents.

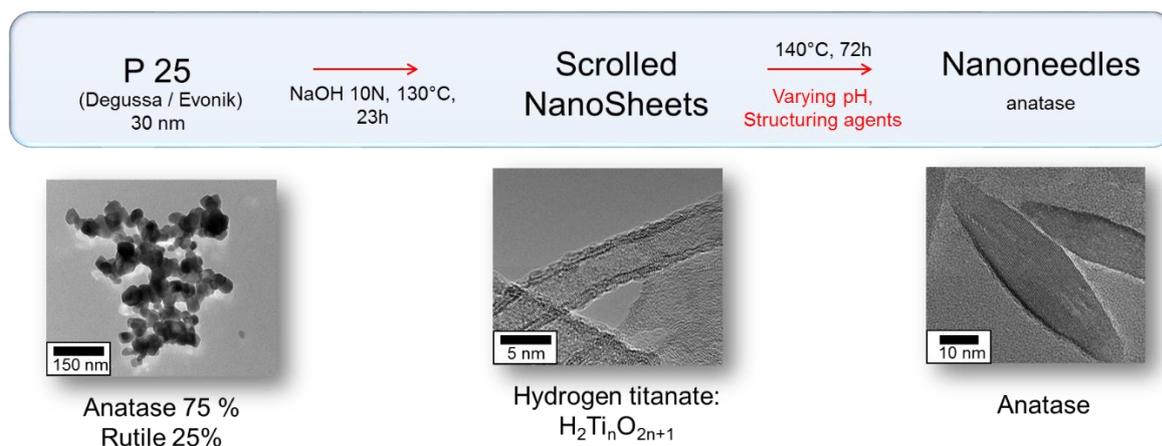

## ABSTRACT

Mild hydrothermal conditions used for the treatment of titanate scrolled nanosheets (SNSs) suspensions (140°C, 72h) resulted in a large variety of anatase TiO<sub>2</sub> anisotropic nanoobjects depending on the studied parameters: influence of the medium pH, the presence or not of structuring agents. The present work shows that such a hydrothermal treatment of the SNSs, whatever the pH, resulted in the formation of single-crystalline anatase nanoneedles (NNs) with a specific crystal-elongation direction and a pH-dependent morphological anisotropy with aspect ratios from 1 to 8. The SNSs suspensions were prepared by the conventional ultra-basic treatment of TiO<sub>2</sub> with NaOH, followed by washing with HNO<sub>3</sub> to different pH values. The crystal size of the anatase TiO<sub>2</sub> obtained from this hydrothermal treatment increased with the pH of the suspensions, from 15 nm nanoparticles (NPs) (aspect ratio AR = 1) at pH 2.2 to 500 nm NNs (AR = 8) at a pH 10.8 with a long axis systematically along the anatase [001] direction. Triethanol amine (TEOA) and Oleic acid (OA) were used as structuring agents (SAs). Their respective influence when acting on their own, had little influence on the control of the size, shape or polydispersity of the NNs. However, their concomitant use provided a much better control of not only the size and polydispersity which was strongly reduced, but also on (i) the shape and morphology giving rise to a controlled access to well-defined nanorods as opposed to nanoneedles (ii) the crystal phase purity eliminating the few % brookite still visible in the XRD patterns of samples prepared in SA free conditions. This approach offers an on-demand control over the production of anatase morphologies with defined aspect ratios.

## INTRODUCTION

Nanosized titanium dioxide has attracted much attention, over the past decades, due to exceptional optical and electronic properties,<sup>1</sup> high efficiency and high photo-stability, strong oxidizing power,<sup>2</sup> chemical stability<sup>3-4</sup> leading to many applications<sup>5</sup> in catalysis, photocatalysis,<sup>6-7</sup> solar cells,<sup>8-9</sup> (bio)sensing<sup>10-11</sup> and biomedicine.<sup>12</sup> The photo-activity of TiO<sub>2</sub>,<sup>13-14</sup> is influenced not only by different properties such as the surface area, the crystallinity, the nanoparticle (NP) size or the crystal structure,<sup>14-15</sup> but also by the specific morphology of the particles, which determines which crystal facets are exposed, and then has a strong influence on the photocatalytic performance of the particles.<sup>16</sup> Both theoretical and experimental studies have shown that the (001) surface of the TiO<sub>2</sub> anatase truncated bipyramid which exhibits 100% of Ti five-fold coordinated (Ti5c) is much more reactive than the thermodynamically more stable (101) facet presenting 50% of Ti5c and 50% of Ti six-fold coordinated Ti6c.<sup>17-22</sup> On the other hand, when NPs are expected to be very reactive, one cannot ignore their impact and their potential toxicity.<sup>23-32</sup> The latter depends not only on the chemical nature of the nanomaterial, but also on its size, morphology and surface chemistry.<sup>12, 25, 30, 33-43</sup> Therefore, for toxicology and other purposes, the synthesis of well-crystallized and nanostructured TiO<sub>2</sub> particles with tailored morphology is still the object of intense research and represents a current major challenge using either no capping agent, inorganic (F<sup>-</sup>) or organic capping agents (amines, long chain organic acids).<sup>5, 21, 44-49</sup> These agents that specifically adsorb on different facets can play a critical role in assisting the anisotropic growth of specific facets so that the NP develops in targeted directions and controlled morphology. Besides the numerous molecular titanium precursors<sup>41, 50</sup> (alkoxides, halides, titanium bis(ammoniumlactato) hydroxide, sulfate and oxysulfate, atranes, carboxylates) to grow TiO<sub>2</sub> NPs, the use of the so-called titania-based nanotubes was successfully tested by Nian *et al.* in 2006.<sup>51</sup> The synthesis of these titania-based nanotubes (TNTs), also referred to as scrolled nanosheets (SNSs), is based on the hydrothermal

treatment of TiO<sub>2</sub> powder, at high temperatures in a highly concentrated NaOH solution without sacrificial templates and was first reported by Kasuga *et al.*<sup>52-53</sup> in 1998. This simple and cost-effective hydrothermal method provides a large scale quantity of pure titania-based nanotubes with small diameter (9-10 nm) and lengths as high as several hundred nms and has been the subject of many efforts.<sup>33, 37, 54</sup> The different studies on the reactivity of these SNSs in various media<sup>19, 33, 55-64</sup> show they can be effectively used as a cost-effective starting material as compared to titanium alkoxides for the controlled synthesis of targeted morphologies of TiO<sub>2</sub>. We propose in this paper to use these SNSs in hydrothermal conditions under mild conditions (140°C, 3 days) and scan the influence of parameters such the pH and the nature of the capping agents suggested by Sugimoto to direct NPs growth starting from molecular precursors.<sup>65</sup> We show that over a wide pH range (2.2-11) it is possible to control the morphology of the anatase TiO<sub>2</sub> from nanocuboids to high aspect ratio nanoneedles (NNs) as illustrated in Scheme 1.

**Scheme 1.** Illustration of the reaction procedure to control the NNs aspect ratios: in red the parameters are varied in this study.

These nanoobjects with controlled morphology can then provide a panel for further use in biological studies to find correlations in between cells discrepancy and the aspect ratio of the NNs.

## EXPERIMENTAL SECTION

*Synthesis of SNSs:* The scrolled nanosheets were synthesized by a traditional hydrothermal route based on the initial work by Kasuga and co-workers.<sup>52-53</sup> The synthetic procedure for TiO<sub>2</sub> based scrolled nanosheets was as follows: P25 from Evonik (2 g, 25 mmol) a generous gift from Evonik was introduced into a Teflon vessel with an inner volume of 50 mL and added with a freshly prepared under Argon 10 N NaOH aqueous solution (30 mL (prepared in a Teflon Erlenmeyer), 0.3 mol.) (*caution should be taken to avoid carbonation of sodium hydroxide solution*). The Teflon vessel was sealed and placed on a roller mixer for 1 hour; it was then introduced inside a stainless steel autoclave and subjected to a hydrothermal treatment at 130°C for 23 hours. The autogenous pressure is not an issue because the saturation pressure of 10 N NaOH is ca. 1.2 bar at this temperature, thus it varies very little between 100 and 150°C, and can be easily controlled by strictly controlling the filling fraction of the PTFE container.<sup>66</sup> The mixture was then naturally cooled down, the transparent supernatant removed. The white solid was collected, and washed with 150 mL of 0.1 N HNO<sub>3</sub> solution for 15 minutes and submitted to centrifugation steps of 5,000 rpm for 10 minutes. This process was repeated until pH became acidic (an overall volume of 600 mL was necessary). Finally, the colloidal solution was neutralized with deionized water to get a stable pH of 7. The same procedure was used for the treatment with 1 N HNO<sub>3</sub> and 0.1 N and 1 N HCl.

*Synthesis of Nanoneedles:* The synthesis of nanoneedles using the previously prepared scrolled nanosheets is adapted from Nian's.<sup>51</sup> A 1 N NaOH solution was added dropwise to one-third of the freshly prepared scrolled nanosheet suspension corresponding to 0.7 g of powder, in order to reach the required pH (measured with a pH-meter), and to adjust the volume to 28 mL. It was then added to a 50 mL Teflon vessel in a stainless steel autoclave which was placed in an oven at 140 °C for 72 hours after which the mixture was naturally cooled down and washed with deionized water until pH 7 (centrifugation steps: 9,000 rpm, 10 minutes). The addition of

the structuring agents, (triethanolamine (TEOA), oleic acid (OA)), to freshly synthesized scrolled nanosheets was performed before adjusting the pH.

Then, the pH was adjusted to the desired value and the volume to 28 mL with NaOH or HNO<sub>3</sub> solutions and distilled water. Finally, the mixture was introduced to a Teflon-lined stainless steel autoclave and subjected to hydrothermal treatment at 140°C for 72 hours. The two other thirds were also used as starting materials, as soon as prepared. The overall yield of such a process starting from 2g of TiO<sub>2</sub> based on the two reactions in Scheme 1 and taking into account the many washing steps per batch was in the range 85-87%.

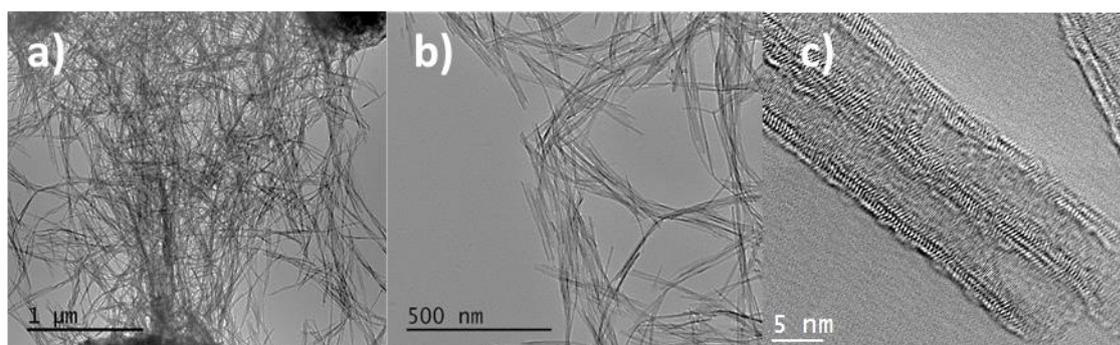

The samples were heated in a programmable Memmert oven. The phase identification of the samples was performed with X-Ray Diffraction (XRD) using a powder diffractometer (PANalytical X'Pert Pro) equipped with CuK $\alpha$ 1 radiation,  $\lambda = 1.540598 \text{ \AA}$ . Transmission Electron Microscopy (TEM) images were obtained with either a TEM 1400 JEOL using 120 kV voltage or on an Hitachi H7650 operating at 120 kV. HRTEM images were obtained with a TEM-FEG HR (JEOL 2200FS) at 200 kV.

## RESULTS AND DISCUSSION

The alkaline-based hydrothermal synthesis developed by Kasuga *et al.* has rapidly turned out to be the dominant non-templated method for producing scrolled nanosheets<sup>52</sup> and/or layered titanate nanomaterials.<sup>67</sup> The main advantages of the procedure as mentioned in the introduction is that it relies on the use of cheap raw materials (TiO<sub>2</sub> whatever its nature: anatase, commercial P25,<sup>52, 67-68</sup> rutile,<sup>53, 68-69</sup> or amorphous TiO<sub>2</sub><sup>70</sup>, NaOH or KOH<sup>67</sup>, water), exhibits high yields of single phase nanomaterial as well as the possibility to control the product morphology by tuning the composition of the reaction mixture. In a typical SNSs synthesis, anatase TiO<sub>2</sub> is mixed into a 10 M NaOH aqueous solution until a white suspension is obtained, the suspension is then

aged in a closed Teflon-lined autoclave at a determined temperature for a given time without shaking or stirring except in one case.<sup>71</sup> The product is then washed with either deionized water or acidic solutions at various concentrations, to reach a chosen pH at which point the slurry is filtered, and the titanate nanotubes are dried in air or kept in solution depending on their further use.

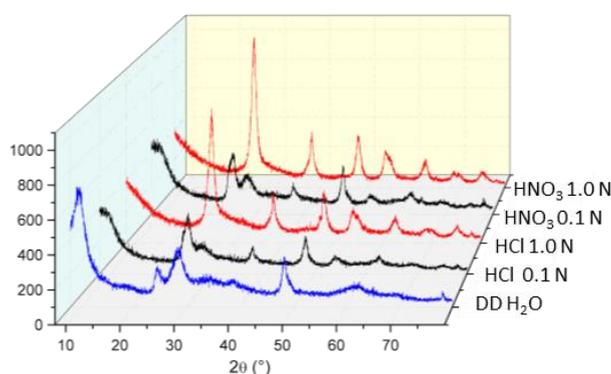

The result of these different treatments is that the number of papers, which were published on the structure and formation of hydrothermally synthesized titanium oxide nanotubes/scrolls/nanosheets, led to controversial reports especially concerning their crystalline structure.<sup>33, 72-73</sup> We therefore here were cautious to always use exactly the same experimental conditions, in terms of concentration of P25, use of freshly prepared sodium hydroxide solution (under argon), reaction time and temperature, as well as the washing procedure to ensure a constant reproducibility of the SNSs. The accurate control of this procedure was indeed mandatory to better understand the influence of the different studied parameters when these SNSs were used as starting materials for further syntheses. As shown in Figure 1, each SNS consists of a thin curved structure of several layers of a single nanosheet wrapped on itself, along with the c axis, leading to a nanotube with an average external diameter of about 8 nm with a multiwall thickness of about 2 nm and a length of several hundred nanometers.<sup>74</sup> The interlayer spacing of these nanotubes is 0.7 nm, close to the values reported in the literature.<sup>55, 70, 75-77</sup>

**Figure 1.** a) and b) TEM images of scrolled nanosheets at two magnifications after the acid

washing at 0.1N HNO<sub>3</sub>; c) HRTEM of the same SNSs showing the scrolled nature of the objects.

The XRD patterns (Figure 2) of these scrolled nanosheets were analyzed at the different steps of the washing process: with doubly distilled water, HCl (0.1 N and 1 N) and HNO<sub>3</sub> (0.1 N and 1 N) solutions respectively and a subsequent drying at 40 °C for one night.

**Figure 2.** XRD Patterns of scrolled nanosheets after various washing procedures showing the importance of the pH on the resulting structure.

The first observation concerns the absence of an influence of the chemical nature of the acid, only the acid concentration plays a crucial role. Comparing the effects of neutral and acidic washings on the XRD patterns shows the major expected diffraction peaks at  $2\theta = 9.3^\circ$ ,  $24.4^\circ$ ,  $28.5^\circ$  and  $48.3^\circ$  characteristic of the tubular  $\text{Ti}_3\text{O}_7^{2-}$  layer resulting from the NaOH treatment of  $\text{TiO}_2$  nanopowder, shifts to  $2\theta = 8.7$ ,  $25.2^\circ$ ,  $27.9^\circ$  and  $48.6^\circ$  for 0.1N HNO<sub>3</sub> while a peak appears at  $38^\circ$  as well as an inversion of 2 peaks intensities in the 25-28° range with a complete disappearance of the latter after 1 N acid washing. This evolution of the diffraction patterns matches the structural modification with the acid treatment: while  $\text{Na}^+$  ions are replaced by the bigger  $\text{H}_3\text{O}^+$  between the sheets during the washing process ( $\text{Na}_2\text{Ti}_3\text{O}_7 \rightarrow \text{Na}_x\text{H}_{2-x}\text{Ti}_3\text{O}_7$ ).<sup>52, 78-</sup>

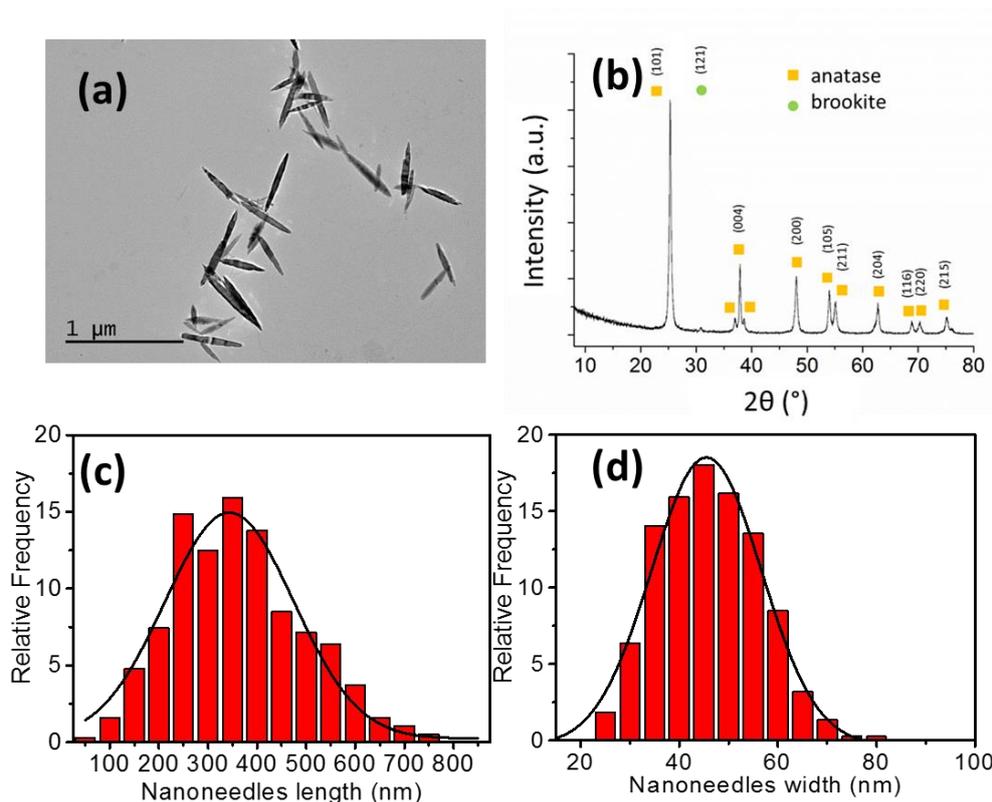

<sup>80</sup> Many explanations have been given in the literature for the same type of XRD patterns.

Authors claimed that in the  $\text{Ti}_3\text{O}_7^{2-}$  layer they obtained, three edge-shared  $\text{TiO}_6$  octahedra joined

at the corner to form the stepped  $\text{Ti}_3\text{O}_7^{2-}$  layers; sodium ions and water molecules located between the layers were exchangeable and assumed a general formula of  $\text{Na}_x\text{H}_{2-x}\text{Ti}_3\text{O}_7$  depending on the washing.<sup>61, 81</sup> However, such XRD patterns were also attributed to  $\text{H}_2\text{Ti}_2\text{O}_5 \cdot \text{H}_2\text{O}$ <sup>51, 69, 82-86</sup> or orthorhombic protonic lepidocrocite ( $\text{H}_x\text{Ti}_{2-x/4}\square_{x/4}\text{O}_4$  with  $x \sim 0.7$  and  $\square$ : vacancy).<sup>20</sup> This is why the obtained product is very often considered to be a protonated form of titanium oxide or hydrogeno titanate, formulated under pressure.<sup>33</sup>

In the following, we took special care to use the same washing procedure, like equal volumes of 0.1 N  $\text{HNO}_3$  and the same periods of time, to be sure to obtain identical SNSs. The SNSs then underwent a hydrothermal treatment at  $140^\circ\text{C}$  with an identical autoclave filling fraction of 60% in all the experiments, during which we varied different parameters: the reaction time, the aging of the precursor SNSs, the pH of the reaction medium as well as the presence of structuring agents such as TEOA and/or OA. The SNSs were transformed into  $\text{TiO}_2$  NNs with various lengths and aspect ratios depending on the studied parameters. As an example, when a suspension of 0.7 g of scrolled nanosheets underwent reaction at  $140^\circ\text{C}$  for 72 hours at pH 9.8 treatment, nanoneedles as shown in Figure 3 a) are obtained. The XRD analysis (Figure 3b) shows the characteristic peaks of the well-crystallized anatase structure (JCPDS 21-1272) are dominant with a few % of brookite (JCPDS 029-1360) barely detectable.<sup>45</sup>

The statistical distribution of their lengths and widths measured on at least 300 NPs (Figures 3 c) and d)) provided an average length of 350 nm ( $\pm 130$  nm), and width of 46 nm ( $\pm 10$  nm) and aspect ratio (AR) of 7.5.

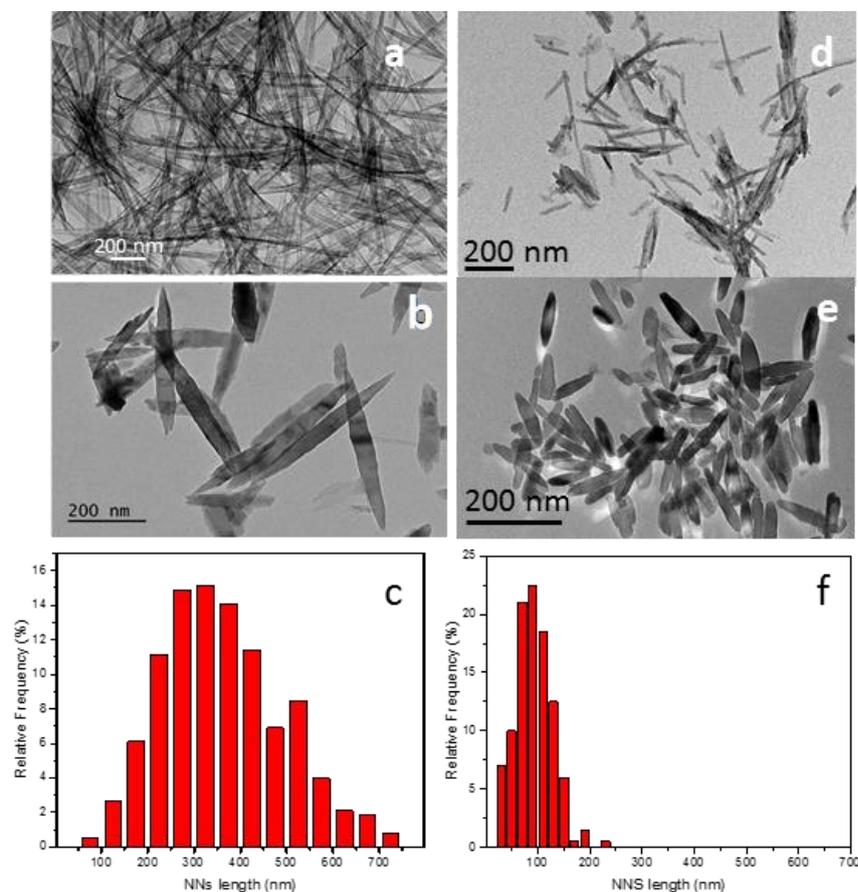

**Figure 3.** (a) TEM image and (b) XRD pattern of TiO<sub>2</sub> nanoneedles (c) and (d) statistical distribution of nanoneedles length and width respectively. (140 °C for 72 hours at pH 9.8).

*Influence of the reaction time:* In most of the papers, the required operating time used for the transformation of the SNSs into other TiO<sub>2</sub> morphologies at 140°C is generally 3 days, we effectively confirmed that 24h and 48h reaction times respectively have a % conversion of only 50% and 80% of the SNSs at 140°C.

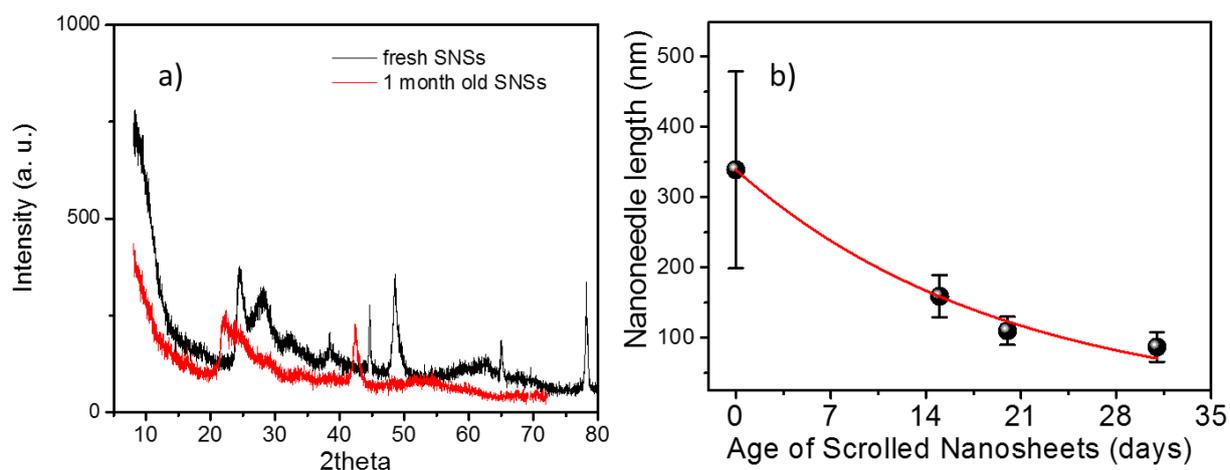

*Influence of the SNS aging.* The parameters of a pH of 9.8 and a hydrothermal treatment at 140 °C for 3 days, were fixed to study the influence of the SNSs aging. Figure 4 compares the freshly-prepared SNSs (Figure 4a) and the morphology (Figure 4b) and size distribution (Figure 4c) of the resulting TiO<sub>2</sub> NNs and the same SNSs stored in water solution at pH 7 for 31 days at room temperature (Figure 4d) and their resulting TiO<sub>2</sub> NNs (Figure 4e and Figure 4f). At such a pH, no phase transformation of the SNSs into more stable nanoobjects was detected<sup>55</sup>, they tend to shorten as well as un-scroll leading to smaller nanoobjects when submitted to

hydrothermal treatment. Their XRD pattern is also detrimentally influenced by a long storage in neutral water as shown in Figure 5a.

**Figure 4.** (a and d) TEM images of fresh and 1-month old SNSs respectively; TEM images (b and, e) and length distribution (c and f) of NNs obtained from fresh and 1-month old SNSs respectively (pH 9.8, hydrothermal treatment at 140 °C for 3 days).

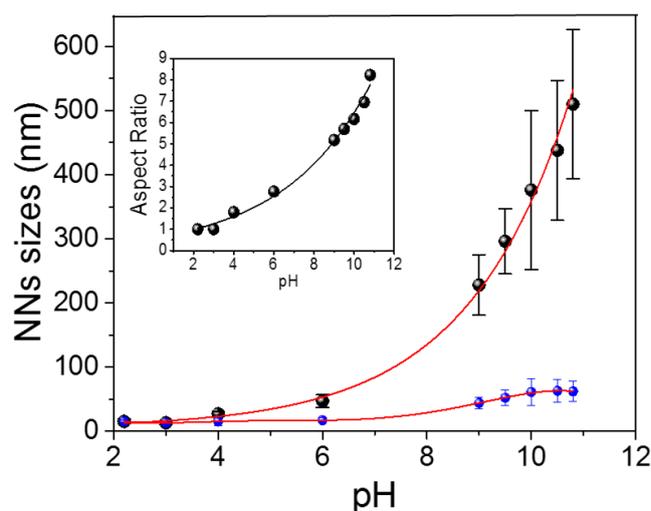

Figures 4b and 4e are the TEM images of their corresponding NNs with the size distribution made on the length of more than 300 particles (Figures 4c and 4f). NNs obtained from freshly-made SNSs exhibit an average length of 350 nm ( $\pm 140$  nm) whereas SNSs obtained from “old” SNSs are much smaller with an average length of 92 nm ( $\pm 30$  nm). The same trend is observed with the NNs width. A more systematic study of the aging of the nanosheets from 0 to 31 days was performed to determine the impact on the nanoneedles length as shown in Figure 5b.

**Figure 5.** a) Variation of the XRD pattern of the SNSs with time; b) variation of NNs length as a function of the age of SNSs (pH 9.8, hydrothermal treatment at 140 °C for 3 days).

These results are in agreement with some work also reported by Bavykin<sup>55-56</sup> who showed that the stability of the SNSs in solution could not necessarily be assumed and that it also depended on the pH and on the counter-anions present in solution. Playing with SNS aging to decrease TiO<sub>2</sub> nanoparticle size is then an option to control the nanoneedles size, but it is far too time-consuming. Indeed the exponential fit gives a characteristic time of dissolution of the SNSs of 20 days.

*Influence of the medium initial pH.* The initial pH of the reaction medium was then adjusted to different values from 2 to 11 at least 3 times for each value and up to 8 times in some cases. In each case, the statistics on the NNs length were performed on at least 300 NPs from the TEM images, and the variation of the NNs length with the pH is illustrated in Figure 6.

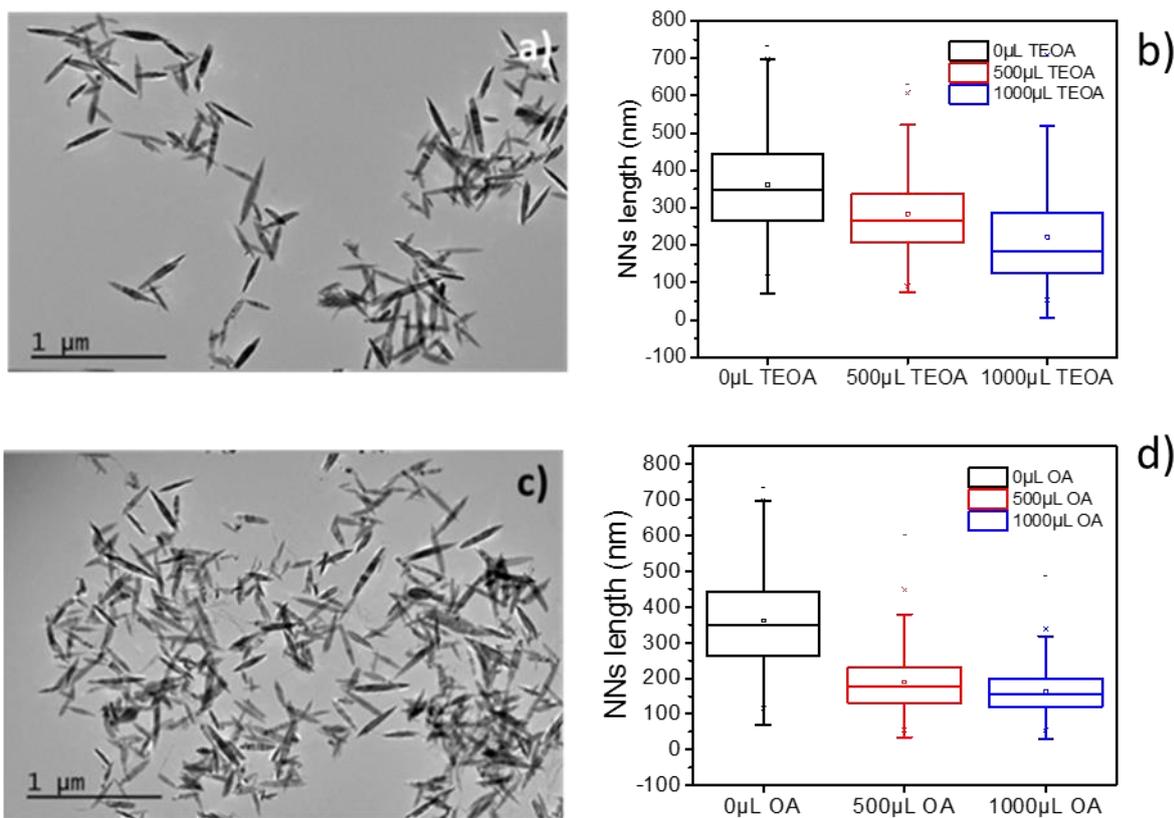

**Figure 6.** Variation of the sizes of nanoneedles with the pH. Each dot represents an average of 3 to 8 experiments: black dots for NNs length, blue ones for NNs width (each experiment being representative of a statistic on at least 300 NPs), bars represent the statistic errors on these experiments; inset: variation of the NNs aspect ratio with the pH. In all cases, lines are guides for the eye.

The variation of the pH can effectively adjust the length/width of the resulting NNs and control the NNs aspect ratio over a wide range from 1 at pH 2, to 3 at pH 6 and 8 at pH as high as 10.8. In fact at 140°C, the SNSs revealed to be very stable in concentrated basic media, and it was only when pHs were below 11 that it became possible to corrode them and generate long anatase NNs. As illustrated in Figure S1, the XRD patterns of these anatase nanoobjects only differ in the fact that there is a tendency at pH 9 to form the brookite phase, with increasing brookite content with increasing pH values.

It has been proposed<sup>56</sup> that the pH-dependent transformation of the SNSs to TiO<sub>2</sub> nanostructures could occur by the dissolution of the initial nanotubes at the edges accompanied by the simultaneous crystallization of TiO<sub>2</sub> nanostructures, with a rate of the transformation at room temperature proportional to the steady-state concentration of dissolved Ti<sup>IV</sup>, which is itself a function of the pH. When performed in hydrothermal conditions, the crystal nucleation-growth

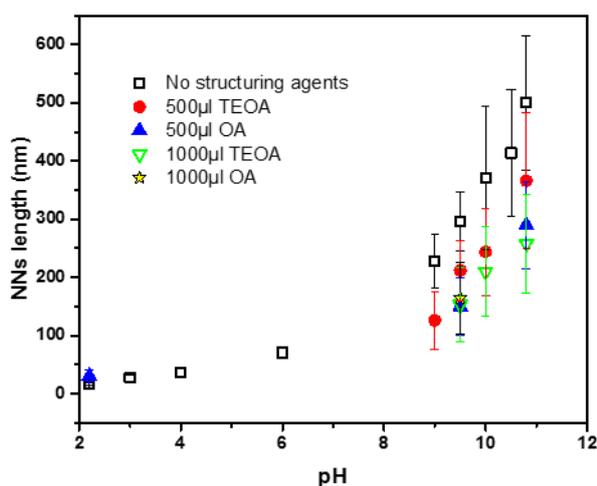

is controlled by kinetics, rather than thermodynamics, leading to the formation of metastable anatase.<sup>51</sup> These NNs exhibit a preferential direction along the [001] axis of anatase during the crystal growth, which can be easily explained by the selectivity of the constraint induced by the configuration and crystalline structure of the scrolled nanosheets used as precursors. Thus, the correlation between the crystalline structures of the SNSs and the resulting nanoobjects is crucial for the morphology of the later. Upon the hydrothermal treatment of the SNSs, the reaction proceeds with their partial dissolution followed by the rearrangement of the resulting bilayered fragments to form anatase nanoobjects; the size of these fragments being strongly pH- and temperature-dependent and controlling the final aspect ratio of the NNs. The preferential elongation [001] in the anatase is strongly dependent on the specific feature of the nanotubes. Both SNSs titanate and anatase have common structural characteristics<sup>87</sup>: their lattices consist of octahedra sharing four edges and forming zigzag ribbons. Additionally, the titanate SNSs framework exhibits a majority of under-coordinated titanium sites located on the interior wall of the tube,<sup>88</sup> and because of the pH the interplay between the ions in solution and the subsequently related possibility of generating Ti-O-Ti bonds, this framework shrinks locally by reducing the interlayer distances and rearranges, leading to the anatase TiO<sub>2</sub> structure. Even if adjusting the pH effectively allows a control of the NNs length through changing fragment size, the final NNs size distribution may still be a problem depending on the required applications, particularly for biological ones. The use of structuring agents (SAs) is a way to overcome this drawback and control the morphology of nanoobjects as well as their polydispersity, and many of these SAs have already been used in the literature: using basic<sup>15, 17, 44, 64-65, 89-99</sup> and acidic<sup>15, 17, 100-101</sup> agents, on their own or in varied proportions; in hydrothermal<sup>1, 5, 7, 18, 33, 37, 41, 46, 50-51, 54, 72-73, 83, 91, 102-108</sup> and non-hydrolytic<sup>5, 16-17, 41, 50, 54, 106, 109-111</sup> processes.

*Influence of structuring agents:* Among all those which were used, we focused our attention on triethanolamine (TEOA) and oleic acid (OA) which have been up to now used by Sugimoto *et al.* in the gel-sol process.<sup>65, 95, 98, 112-115</sup> These authors showed the influence and the role of TEOA as a trap in the release of the reactive  $Ti^{4+}$  species from the gel formed from titanium alkoxides before the formation of the  $TiO_2$  nanoparticles, at a temperature above 100 °C. Our goal here was to apply this approach to a top-down approach, using the progressive destruction of the scrolled nanosheets as the source of “ $Ti^{4+}$ ” and these two SAs separately or in combination under various pH conditions. Figure 7 illustrates the result of the synthesis of nanoneedles performed in the presence of TEOA and OA separately, at pH 9.8. The same batch of starting scrolled nanosheets was used to make sure results were comparable. TEOA or OA was added to the scrolled nanosheets (0.7 g) and the pH adjusted to 9.8 with an aqueous solution of 0.1 N NaOH. They were reacted in a Teflon-lined stainless steel autoclave, for 72 hours at 140 °C with 0, 500 and 1000  $\mu$ L of the respective structuring agent (3.76 and 7.52 mmol for TEOA (molar ratios between TEOA and Ti are 0.45 and 0.9) and 1.59 and 3.18 mmol for OA (molar ratios between OA and Ti are 0.2 and 0.4). For the sake of clarity, results are presented as a function of the SA varying volumes. The TEM images on Figure 7a and 7c show that the morphology of the resulting objects does not change, whatever the chemical nature of the SA (TEOA *or* OA) at the chosen pH. A slight decrease of the average length seems to take place while keeping the standard deviation relatively high (~100 nm) (Figure 7b and 7d).

**Figure 7.** TEM images of NNs prepared with 500  $\mu\text{L}$  of a) triethanolamine (TEOA) and c) oleic acid (OA); b) and d) NNs length distribution for an initial pH of 9.8.

Experiments performed at different pH values confirmed the role of the SAs when used separately (Figure 8). TEOA containing both amino and OH groups is susceptible to interact with the SNSs in two potential ways: on the one hand, it can limit the growth rate of the planes parallel to the c-axis of  $\text{TiO}_2$  tetragonal crystal system because of its specific affinity for these planes in this pH range,<sup>98</sup> its adsorption on the surface of  $\text{TiO}_2$  being negligible or extremely weak in neutral and acidic media<sup>112</sup>; on the other hand, it also contributes to the fragmentation of the titanate layer since for a given pH value of 9, for example, the NNs length is divided by 2 in the presence of TEOA. Oleate anions provide both smaller NNs and reduced polydispersity.

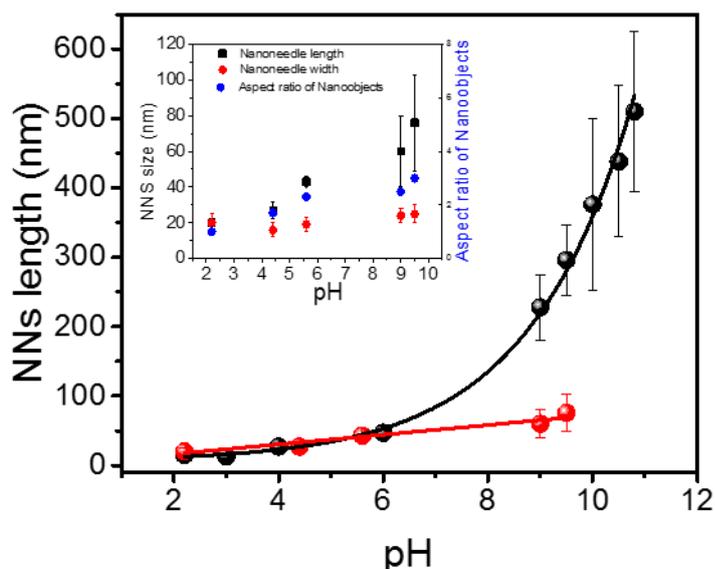

**Figure 8.** Average NNs length without (as in Figure 6) and with structuring agents (TEOA or OA). The error bars are obtained by means of at least 3 experiments.

High pH values ( $> 11.5$ ) did inhibit the formation of NNs in the presence of TEOA, probably because the SNSs were too stable in these conditions and the rate of dissolution of the SNSs and formation in solution of the titanium hydroxide aquo complexes postulated to induce the nucleation of  $\text{TiO}_2$  by this pathway is too low.<sup>113</sup> Indeed, instead of starting from an amorphous gel of  $\text{Ti}(\text{OH})_x$  as in Sugimoto's case<sup>65, 98</sup> where the OH group can be easily replaced by TEOA or OA, the process here starts from scrolled nanosheets which are first partially dissolved, and then restacked in the right configuration. It should be added that TEOA has also been observed to act as a capping agent.<sup>116-117</sup>

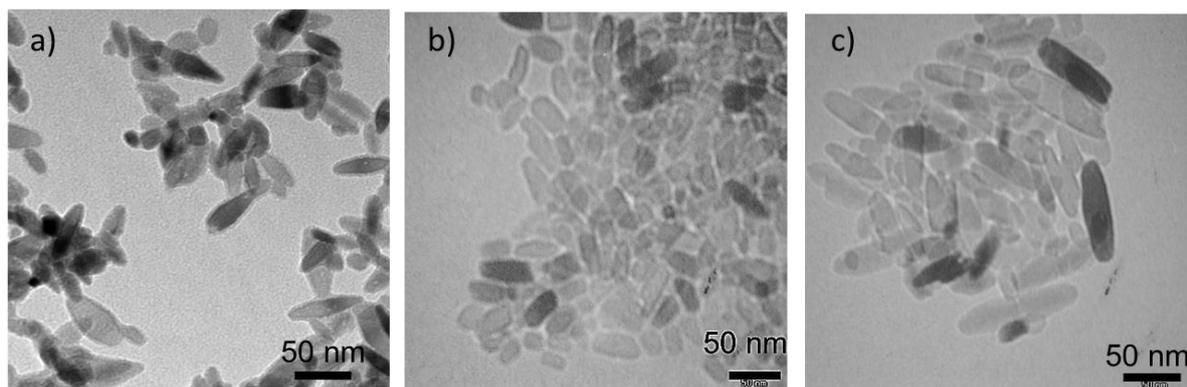

In the low pH range ( $\text{pH} < 6$ ), the NPs exhibit the identical size and shape as in the absence of structuring agent (Supporting Information Figure S2).

*Influence of the combination of the structuring agents:* We then combined these two SAs fixing the quantities of TEOA at 500  $\mu\text{L}$  (3.76 mmol) and OA at 500  $\mu\text{L}$  (1.59 mmol) and varied the initial pH of the reaction mixture (Figure 9).

**Figure 9.** Variation of the NNs length, with the pH of the reaction medium in the absence (black dots) and in the presence of 500  $\mu\text{L}$  of both SAs (red dots). Results represent the averages of statistics of at least 300 NPs for each of the 3 sets of experiments per data point. Inset variation of the width and aspect ratio of the same objects obtained in the presence of the two SAs. Lines are guides for the eye.

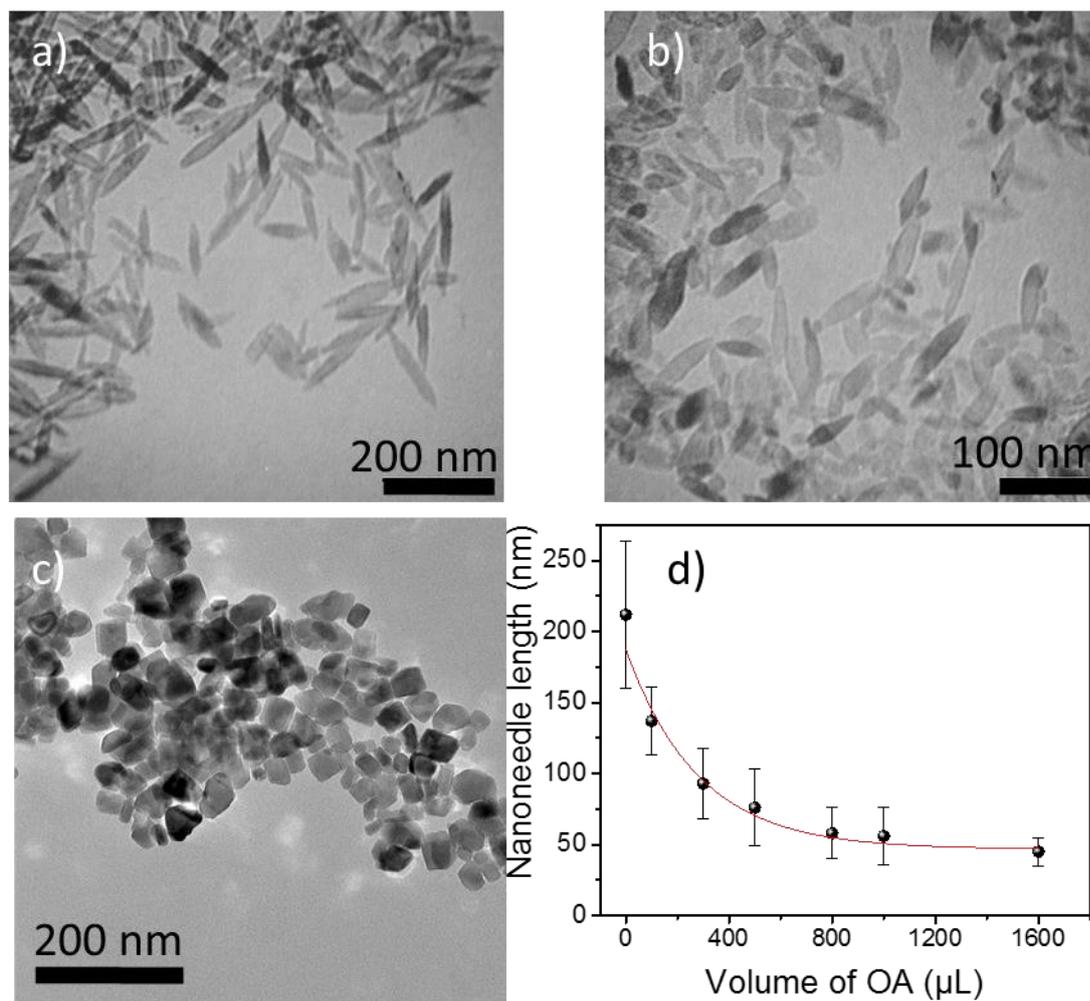

Figure 9 compares the size and aspect ratio of the resulting objects as a function of pH in the presence and absence of the SAs. This figure effectively illustrates the influence of the combination of these two SAs on the size and morphology of the resulting objects. The major impact of this concomitant use is visible under basic conditions (9-10.5) where a higher control over the length as well as over the size distribution of the objects can be performed (compare with Figure 8). Furthermore the NNs shape was a rod-like one with flatter extremities in the low pH range, as illustrated in Figure 10, confirming the affinity of the carboxylate ions for the (001) face and their blocking effect on the crystal growth. Nanorods with various sizes and aspect ratios could be obtained by playing with the ratio between the SNSs and the capping agents, while the absence of these shape controllers led to a mixture of less-specific nanoobjects (Figure 10a).

**Figure 10.** Example of TEM images of TiO<sub>2</sub> nanorods obtained at pH 4.4: a) in the absence of any capping agent; and b) in the presence of 500 μL (3.76 mmol) of TEOA and 500 μL (1.59 mmol) OA starting with 2 g of SNSs (NRs length 34 (±10), width: 15 (±5) aspect ratio: 2 and c) starting with 0.7 g of SNSs (NRs length 73 (±15), width: 21 (±8) aspect ratio: 3).

A pH value of 10.7 which is a usual value given in the literature for the action of amines as structuring agents,<sup>98</sup> revealed to be detrimental in the presence of oleate since the conversion of SNSs was not complete (see Figure S3 in supporting information), and the efficiency became even worse with increasing amounts of oleate. It could be proposed that using a pH above a given value prevails on any other parameter for the shape control of NPs.<sup>65</sup>

We then focused on pH 9.5, which revealed to be the autogenous pH of the resulting mixture after stabilization with 500 μL of TEOA and varied the ratio between TEOA and OA increasing the volume of OA from 0 to 1600 μL. Figure 11 shows characteristic TEM images of particles obtained with different amounts of OA. It illustrates the synergetic effect of the combined use of these two structuring agents and shows the influence of the OA amount on not only the length of NNs but also on their shape since they turn into nanorods and finally give nanocuboid-like particles (Figures 11a,b,c). This is commonly explained by the selective binding of the OA to the anatase (001) face<sup>111, 118</sup> which controls its growth.

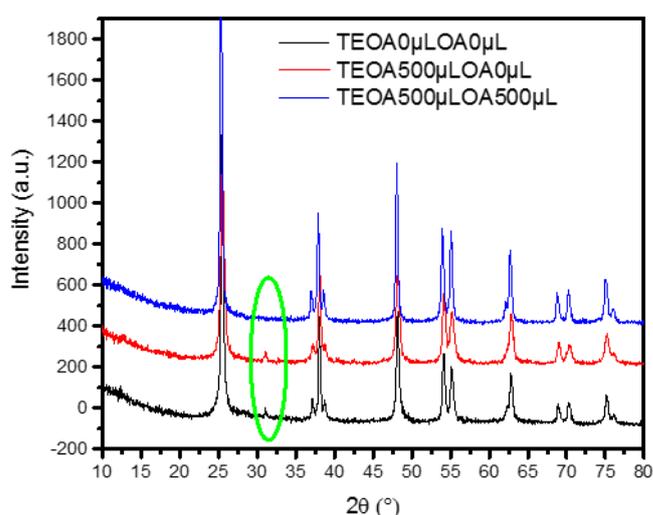

**Figure 11.** TEM images of the different shapes of particles synthesized using 500  $\mu\text{L}$  of TEOA at pH 9.5 and respectively: a) 0  $\mu\text{L}$  of OA, b) 500  $\mu\text{L}$  of OA, c) 800  $\mu\text{L}$  of OA; d) Variation of the NNs length with the amount of oleic acid at a fixed concentration of TEOA (500  $\mu\text{L}$ ) at pH 9.5 on a set of a total of 3 experiments per point.

In this top-down process, the nanosheets can react as follows: (i) depending on the pH, their dimensions are reduced and they are partially dissolved leading to the Ti(IV) complex soluble in the reaction mixture in equilibrium with small fragments, which can then rearrange. The structuring agents participate in the control of these fragments size. They also tune the growth rate of the specific crystal planes by their specific adsorption under different pH conditions (parallel (for TEOA) or perpendicular (for OA) to the *c*-axis,<sup>65, 99</sup>). (ii) In the presence of the SAs the dissolved titanium based octahedra complexes can also agglomerate and exhibit

controlled growth as do SAs, as described by Sugimoto. (iii) Or both processes can take place in a ratio difficult to estimate. Different sets of 3 tests per experiment were performed at pH 9.5 (Figure 11d) to determine repeatability, reproducibility, and statistical parameters. The decrease of the size of the nanoneedles with increase of the oleic acid quantity was confirmed and clearly indicated the crucial role played by this capping agent in the presence of TEOA.

The concomitant use of these two SAs allows the control of not only the morphology but also the purity of the anatase crystal phase by preventing the formation of the brookite-type  $\text{TiO}_2$ , which is often produced (even if only a few %) in the presence of  $\text{Na}^+$  under hydrothermal conditions (Figure 12).<sup>51</sup>

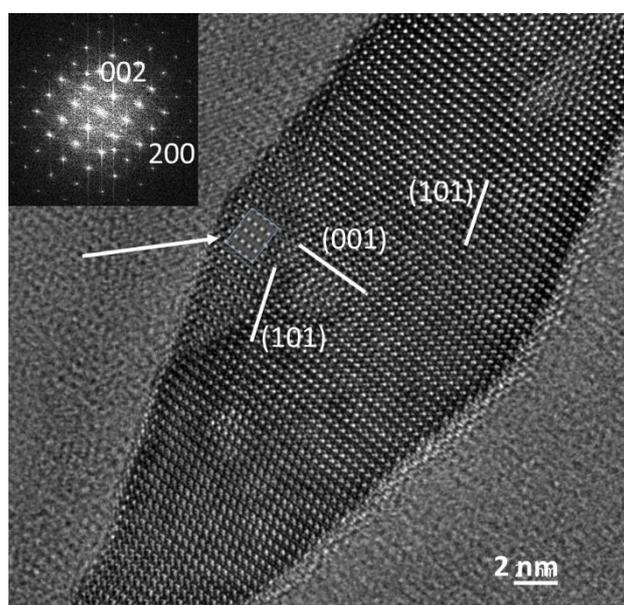

**Figure 12.** XRD pattern of NNs synthesized at initial pH 9.5 with (—) no structuring agent; (—) 500  $\mu\text{L}$  of TEOA and 0  $\mu\text{L}$  of OA, (—) 500  $\mu\text{L}$  of TEOA and 500  $\mu\text{L}$  of OA.

HRTEM was performed on both NNs and NRs morphologies, and Figure 13 shows an example of a nearly perfect NN obtained at pH 9.5 in the presence of the two SAs. The nature of the clearly visible atomic planes is deduced from the indexation of the Fast Fourier Transform (FFT) of the image. In addition, based on the orientation deduced from the FFT, a simulated image has been calculated taking into account the characteristics of the microscope. This

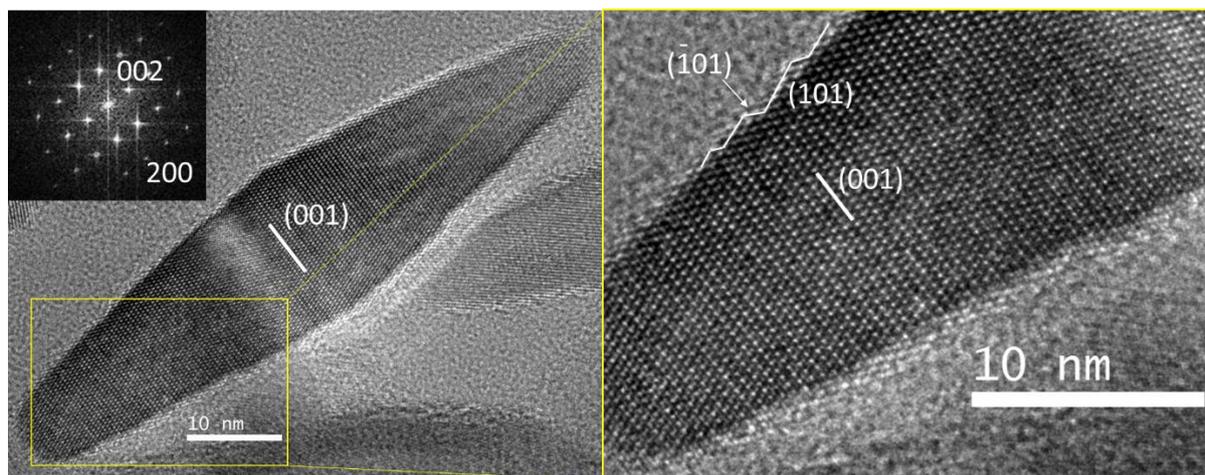

calculated image is inserted into the experimental one and the good agreement between both images confirms the structure and the orientation of the studied material (white arrow). The particle is elongated along the  $[001]$  direction which is consistent with the prediction<sup>15, 119</sup> and with the already published finding.<sup>15</sup>

Indeed, all the observed particles are elongated along the same direction. In this nano-crystal, the facets are parallel to the  $\{101\}$  planes. However, this is not the case for most of the particles.

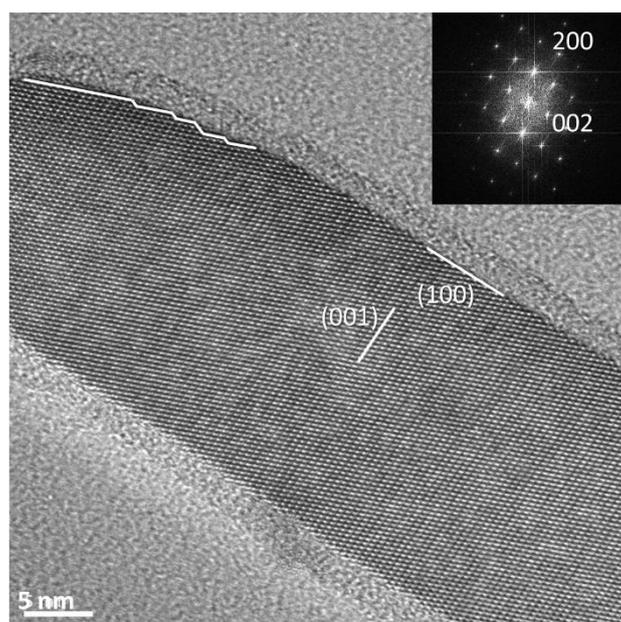

**Figure 13.** HRTEM image and Fast Fourier Transform of a perfect NN. The inserted image in the particle is a simulated image along the  $[010]$  zone axis at Scherer defocus for a 5 nm thickness.

A typical example is shown in Figure 14. The outer faces of the crystal are composed of nano-facets belonging to the  $\{101\}$  planes. Their length is variable making it possible to accommodate different geometries from one crystal to another.

**Figure 14.** TEM image of a typical crystal in a NN form; inset: selected area electron diffraction pattern b) HRTEM image of the same NN showing a saw-tooth-like organization of the (101) planes of the external facet of the crystal.

High resolution images of nanorods have also been obtained (Figure 15). As previously for the NNs, the nanorods are elongated along the [001] direction, but the main external facets are this time parallel to the (100) planes. The curved end of the nanorods is composed of sequences of (101) and (-101) planes as illustrated in the figure.

**Figure 15.** HRTEM image of a typical crystal in a nanorod shape.

## CONCLUSION:

To conclude, in this paper we were able to generate a large family of anatase phase nanoobjects with typical sizes from 15 to 700 nm and aspect ratios from 1 to 8, through a wet chemistry process starting from titanate scrolled nanosheets. Morphology was tailored by playing with different parameters such as (i) the age of the SNSs, (ii) mild hydrothermal temperature 140°C, (iii) a wide pH range 2-11. The concomitant use of structuring agents such as triethanol amine and oleic acid during the hydrothermal process proved to be an additional convenient way to master the phase transformation and control the size and shape as well as the polydispersity of the targeted nanoobjects in basic media.

## ACKNOWLEDGEMENTS

The authors want to acknowledge Eric Lebraud (ICMCB) for XRD measurements. All the TEM observations were performed on the microscopes of the Plateforme Aquitaine de Caractérisation des Matériaux (UMS 3626, CNRS – Université de Bordeaux, Pessac, France) and at the Bordeaux Imaging Center for some of the samples. P25 from Evonik was a generous gift from Evonik Company which is here strongly acknowledged. Financial support from the China Scholarship Council (CSC) of the People's Republic of China (grant to Q. Bai), the French ANR program TITAMIUMS (PhD Grant to Q. Le Trequesser) to the Idex and the University of Bordeaux, and the CNRS are gratefully acknowledged.

Caption to Scheme

**Scheme 1.** Illustration of the reaction procedure to control the NNs aspect ratios: in red the parameters are varied in this study.

Caption to figures

**Figure 1.** a) and b) TEM images of scrolled nanosheets at two magnifications after the acid washing at 0.1N HNO<sub>3</sub>; c) HRTEM of the same SNSs showing the scrolled nature of the objects.

**Figure 2.** XRD Patterns of scrolled nanosheets after various washing procedures showing the importance of the pH on the resulting structure.

**Figure 3.** (a) TEM image and (b) XRD pattern of TiO<sub>2</sub> nanoneedles (c) and (d) statistical distribution of nanoneedles length and width respectively. (140 °C for 72 hours at pH 9.8).

**Figure 4.** (a and d) TEM images of fresh and 1-month old SNSs respectively; TEM images (b and e) and length distribution (c and f) of NNs obtained from fresh and 1-month old SNSs respectively (pH 9.8, hydrothermal treatment at 140 °C for 3 days).

**Figure 5.** a) Variation of the XRD pattern of the SNSs with time; b) variation of NNs length as a function of the age of SNSs (pH 9.8, hydrothermal treatment at 140 °C for 3 days).

**Figure 6.** Variation of the sizes of nanoneedles with the pH. Each dot represents an average of 3 to 8 experiments: black dots for NNs length, blue ones for NNs width (each experiment being representative of a statistic on at least 300 NPs), bars represent the statistic errors on these experiments; inset: variation of the NNs aspect ratio with the pH. In all cases, lines are guides for the eye.

**Figure 7.** TEM images of NNs prepared with 500  $\mu\text{L}$  of a) triethanolamine (TEOA) and c) oleic acid (OA); b) and d) NNs length distribution for an initial pH of 9.8.

**Figure 8.** Average NNs length without (as in Figure 6) and with structuring agents (TEOA or OA). The error bars are obtained by means of at least 3 experiments.

**Figure 9.** Variation of the NNs length, with the pH of the reaction medium in the absence (black dots) and in the presence of 500  $\mu\text{L}$  of both SAs (red dots). Results represent the averages of statistics of at least 300 NPs for each of the 3 sets of experiments per data point. Inset variation of the width and aspect ratio of the same objects obtained in the presence of the two SAs. Lines are guides for the eye.

**Figure 10.** Example of TEM images of  $\text{TiO}_2$  nanorods obtained at pH 4.4: a) in the absence of any capping agent; and b) in the presence of 500  $\mu\text{L}$  (3.76 mmol) of TEOA and 500  $\mu\text{L}$  (1.59 mmol) OA starting with 2 g of SNSs (NRs length 34 (10), width: 15 (5) aspect ratio: 2 and c) starting with 0.7 g of SNSs (NRs length 73 (15), width: 21 (8) aspect ratio: 3).

**Figure 11.** TEM images of the different shapes of particles synthesized using 500  $\mu\text{L}$  of TEOA at pH 9.5 and respectively: a) 0  $\mu\text{L}$  of OA, b) 500  $\mu\text{L}$  of OA, c) 800  $\mu\text{L}$  of OA; d) Variation of the NNs length with the amount of oleic acid at a fixed concentration of TEOA (500  $\mu\text{L}$ ) at pH 9.5 on a set of a total of 3 experiments per point.

**Figure 12.** XRD pattern of NNs synthesized at initial pH 9.5 with (–) no structuring agent; (–) 500  $\mu\text{L}$  of TEOA and 0  $\mu\text{L}$  of OA, (–) 500  $\mu\text{L}$  of TEOA and 500  $\mu\text{L}$  of OA.

**Figure 13.** HRTEM image and Fast Fourier Transform of a perfect NN. The inserted image in the particle is a simulated image along the [010] zone axis at Scherer defocus for a 5 nm thickness.

**Figure 14.** TEM image of a typical crystal in a NN form; inset: selected area electron diffraction pattern b) HRTEM image of the same NN showing a saw-tooth-like organization of the (101) planes on the external facet of the crystal.

**Figure 15.** HRTEM image of a typical crystal in a nanorod shape.

For Table of Contents Only:

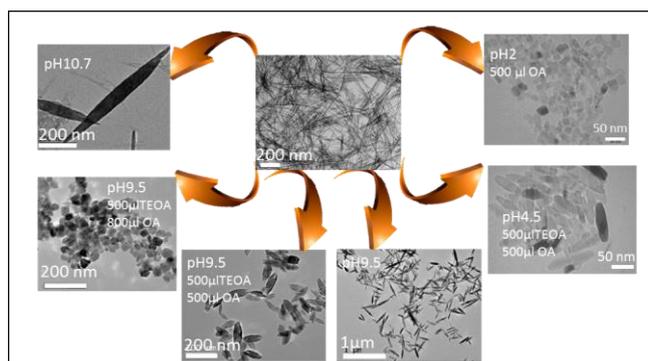

Table of Contents Synopsis: Smart selection of initial pH as well as Structuring Agents concentration and ratio provides a large choice of anatase anisotropic crystalline objects with aspects ratios from 1 to 10 under mild hydrothermal conditions.
