Abstract

We say that a given graph $G = (V, E)$ has *pathbreadth* at most ρ , denoted $\text{pb}(G) \leq \rho$, if there exists a Robertson and Seymour's path decomposition where every bag is contained in the ρ -neighbourhood of some vertex. Similarly, we say that G has *strong pathbreadth* at most ρ , denoted $\text{spb}(G) \leq \rho$, if there exists a Robertson and Seymour's path decomposition where every bag is the complete ρ -neighbourhood of some vertex. It is straightforward that $\text{pb}(G) \leq \text{spb}(G)$ for any graph G . Inspired from a close conjecture in [Leitert and Dragan, COCOA'16], we prove in this note that $\text{spb}(G) \leq 4 \cdot \text{pb}(G)$.

Keywords: pathbreadth, strong pathbreadth, path decomposition, dominating pair, AT-free graphs

We refer to [1] for any undefined graph terminology. Graphs in this study will be finite, simple, connected and unweighted. Our purpose in this note is to relate two pathlikeness invariants, first introduced in [3, 7]. Specifically, a (Robertson and Seymour's) *path decomposition* of a given graph $G = (V, E)$ is any sequence (X_1, X_2, \dots, X_p) of subsets of V , called *bags*, that satisfies the following three properties:

1. Every vertex $x \in V$ is contained in at least one bag;
2. Every edge $xy \in E$ has its two ends contained in at least one common bag;
3. For every $x \in V$, the bags that contain x induce a consecutive subsequence.

The width of a path decomposition is equal to the largest size of its bags minus one. The pathwidth of a graph G is the minimum possible width over its path decompositions. Pathwidth is often used in parameterized complexity as it has many algorithmic applications. Motivated by the efficient resolution of routing and distance-related problems on graphs [4], we rather focus in this note on the metric properties of the bags instead of their size.

Given some non-negative r , the *r -neighbourhood* $N_G^r[v]$ of a vertex $v \in V$ is the set of vertices with distance at most r to v , i.e., $N_G^r[v] = \{u \in V \mid d_G(u, v) \leq r\}$. – We will omit the subscript if the graph G is clear from the context. – The *breadth* of a path decomposition is equal to the smallest integer ρ such that every bag is contained in the ρ -neighbourhood of some vertex (this vertex may not be in the bag). The *pathbreadth* of a graph G , denoted $\text{pb}(G)$, is the minimum possible breadth over all its path decompositions. We stress that bounded-pathbreadth graphs comprise the interval graphs and the convex bipartite graphs, that are two important graph classes with unbounded pathwidth. However, computing the pathbreadth of a given graph is an NP-hard problem [6].

A slightly more amenable parameter than pathbreadth – unfortunately still NP-hard to compute [5] – is *strong pathbreadth*, defined as follows. The strong pathbreadth of a graph G , denoted $\text{spb}(G)$, is the minimum integer ρ such that there exists a path decomposition of G where all bags are the *complete* ρ -neighbourhood of some vertex. Note that we clearly have $\text{pb}(G) \leq \text{spb}(G)$. It is natural to ask whether, conversely, there exists a universal constant c such that $\text{spb}(G) \leq c \cdot \text{pb}(G)$. In fact, a similar question was asked in [7] for

the related parameters treebreadth and strong treebreadth (defined using the more general object of tree decompositions). In this note, we answer positively to this question for pathbreadth and strong pathbreadth. Namely, we prove the following result:

Theorem 1. *For every graph G , we have $\text{pb}(G) \leq \text{spb}(G) \leq 4 \cdot \text{pb}(G)$.*

In order to prove Theorem 1, we describe in Algorithm 1 below how to construct a path decomposition with strong breadth at most $4 \cdot \text{pb}(G)$ for a given graph G . The *eccentricity* of a shortest path P in G is defined in what follows as the maximum distance between any vertex in V and a closest vertex in $V(P)$.

Algorithm 1 takes as input a path P with eccentricity λ . – Such a P can be extracted from any path decomposition with breadth $\lambda/2$ [3]. – It then selects a set Q of vertices from P which will be the centers of the bags in a path decomposition with strong breadth 2λ . These vertices are distributed evenly across P such that consecutive vertices are at distance 2λ to each other.

Algorithm 1: Computes a path decomposition with strong breadth 2λ for a given graph and a given shortest path with eccentricity λ .

Input: A graph $G = (V, E)$ and a shortest path $P = (v_0, v_1, \dots, v_\ell)$ with eccentricity λ .

Output: A path decomposition Φ for G with strong breadth 2λ and the centers Q .

- 1 Let $P = (v_0, v_1, \dots, v_\ell)$, set $L := \lfloor \frac{\ell}{2\lambda} \rfloor$, and set $\delta := \lfloor (\ell \bmod 2\lambda)/2 \rfloor$.
 - 2 **for** $i := 0$ **to** L **do**
 - 3 Let $j = 2\lambda \cdot i + \delta$ and set $q_i := v_j$.
 - 4 Compute the bag $B_i := N^{2\lambda}[q_i]$ by performing a BFS which starts at q_i and is limited to distance 2λ .
 - 5 Output $Q = \{q_0, q_1, \dots, q_L\}$ and $\Phi = (B_0, B_1, \dots, B_L)$.
-

Lemma 2. *Algorithm 1 constructs a path decomposition Φ for G with strong breadth 2λ in linear time.*

Proof. For the first part of the proof, we show that the sequence

$$\Phi = \left(N^{2\lambda}[q_0], N^{2\lambda}[q_1], \dots, N^{2\lambda}[q_L] \right)$$

constructed by the algorithm is a path decomposition for G . In order to prove this claim, it suffices to prove that Φ satisfies all the properties of a path decomposition. Clearly, in that case, Φ has strong breadth 2λ .

- We first show that each vertex is contained in a bag. Observe that, by construction of Q , $d(q_i, q_{i+1}) = 2\lambda$ for all $i < L$ and $\min \{d(v_0, q_0), d(q_L, v_\ell)\} \leq \lambda$. It follows from this observation that Q is a λ -dominating set of P . Since P is a λ -dominating path for G , we obtain that $\bigcup_{i=0}^L N^{2\lambda}[q_i] \supseteq \bigcup_{i=0}^{\ell} N^\lambda[v_i] = V$. Hence, every vertex is contained in a bag.

- Next, we show that each edge is contained in a bag of Φ . Let xy be an arbitrary edge. Suppose for the sake of contradiction that, for every $q_i \in Q$, we have $\{x, y\} \not\subseteq N^{2\lambda}[q_i]$. Since P λ -dominates G , P contains two vertices x' and y' with $d(x, x') \leq \lambda$ and $d(y, y') \leq \lambda$. Note that $x' \neq y'$ (otherwise, since $x' \in N^\lambda[q_i]$ for some i , we would get $x, y \in N^{2\lambda}[q_i]$, a contradiction).

Furthermore, we claim that $d(x, x') = d(y, y') = \lambda$, and that $d(q_i, x')$ and $d(q_i, y')$ are at least λ for each $q_i \in Q$. Indeed, suppose by contradiction $d(x, x') < \lambda$, and let $q_i \in Q$ be such that $d(q_i, x') \leq \lambda$ (such a q_i always exists because Q is a λ -dominating set of P). Then, $d(q_i, y) \leq d(q_i, x') + d(x, x') + 1 < 2\lambda + 1$ and, hence, $\{x, y\} \subseteq N^{2\lambda}[q_i]$. A contradiction. In the same way, suppose by contradiction that there is a vertex $q_i \in Q$ with $d(q_i, x') < \lambda$. Then, we also obtain $d(q_i, y) \leq d(q_i, x') + d(x, x') + 1 < 2\lambda + 1$

and, hence, $\{x, y\} \subseteq N^{2\lambda}[q_i]$. It follows as claimed that $d(x, x') = d(y, y') = \lambda$, and that $d(q_i, x')$ and $d(q_i, y')$ are at least λ for each $q_i \in Q$.

Recall that the distance between two consecutive vertices in Q is exactly 2λ . Hence, x' and y' are respectively in the middle of two consecutive vertices in Q with equal distance λ to them. Note that $d(x', y') \leq d(x, x') + 1 + d(y, y') \leq 2\lambda + 1$. Therefore, since P is a shortest path, there is a vertex $q_i \in Q$ such that $d(x', q_i) = d(q_i, y') = \lambda$, and $d(x', y') = 2\lambda$ (otherwise, $d(x', y')$ would be larger than $2\lambda + 1$ or x' and y' would be equal). But then, $d(q_i, x) \leq d(q_i, x') + d(x, x') \leq 2\lambda$, $d(q_i, y) \leq d(q_i, y') + d(y, y') \leq 2\lambda$, and, therefore, $\{x, y\} \subseteq N^{2\lambda}[q_i]$. This contradicts with our assumption that no such q_i exists. Altogether combined, it follows that every edge is contained in a bag.

- It remains to show that, for each vertex, the bags containing it are consecutive. Let x be an arbitrary vertex of G . Suppose for the sake of contradiction that there exist two vertices $q_j, q_k \in Q$ with $j < k - 1$ such that $x \in N^{2\lambda}[q_j] \cap N^{2\lambda}[q_k]$ and $x \notin N^{2\lambda}[q_i]$ for every $i \in \{j + 1, \dots, k - 1\}$. Observe that $d(q_j, q_k) \leq d(q_j, x) + d(x, q_k) \leq 4\lambda$. Since P is a shortest path and $j < k - 1$, we deduce that $d(q_j, x) = d(q_k, x) = 2\lambda$ and, hence, that there is a vertex $q_i \in Q$ with $d(q_j, q_i) = d(q_k, q_i) = 2\lambda$, i.e., q_i is between q_j and q_k . However, since P is a λ -dominating path for G , P contains a vertex x' with $d(x, x') \leq \lambda$. By the triangle inequality, we have $d(q_j, x') \leq d(q_j, x) + d(x, x') \leq 3\lambda$, and in the same way $d(x', q_k) \leq 3\lambda$. Since $d(q_j, q_k) = 4\lambda$, this implies that x' is between q_j and q_k in P and that $d(x', q_i) \leq \lambda$. Thus, $x \in N^{2\lambda}[q_i]$ which contradicts with our original assumption. Therefore, all the bags that contain x induce a consecutive subsequence.

Overall, Φ satisfies all the properties of a path decomposition, thereby proving the claim.

We now show that Φ can be constructed in linear time. For that, we start by observing that the minimum λ such that P λ -dominates G can easily be computed in linear time (by performing a modified BFS). Then, calculating L and δ (line 1) as well as determining all vertices q_i (line 3) can easily be done in linear time as well. To show that constructing all bags (line 4) requires linear time in total, we recall that the distance between two consecutive vertices in Q is exactly 2λ . Thus, if a vertex v is contained in the bags $B_i = N^{2\lambda}[q_i]$ and $B_j = N^{2\lambda}[q_{i+2}]$ for some i , then $d(q_i, v) = d(q_{i+2}, v) = 2\lambda$. That is, v is on the boundary of the bags B_i and B_j . As a result, each vertex of G can be in at most three bags and each edge of G is in at most two bags. Therefore, performing a BFS which is limited to distance 2λ on each vertex q_i requires at most $\mathcal{O}(3n + 2m) = \mathcal{O}(n + m)$ operations, i.e., line 4 runs in total linear time. \square

Based on Algorithm 1, we can now prove Theorem 1.

Proof of Theorem 1. Note that each graph G contains a shortest path P with eccentricity $\lambda \leq 2 \text{pb}(G)$ [3]. Performing Algorithm 1 on P then creates a path decomposition for G with strong breadth $2\lambda \leq 4 \text{pb}(G)$. It follows that $\text{spb}(G) \leq 4 \text{pb}(G)$ for any graph G , thereby proving Theorem 1. \square

We do not know if the bound in Theorem 1 is sharp. It therefore remains an open question if there is a graph G such that $\text{spb}(G) = 4 \text{pb}(G)$.

Algorithmic applications. An *asteroidal triple* in a given graph G is an independent set of size three in G such that each pair of two vertices in the triple is joined by a path that avoids the closed neighbourhood of the third one. A graph is called *AT-free* if it does not have any asteroidal triple. We get the following result for AT-free graphs (improving a result from [3]):

Theorem 3. *If a graph G is AT-free, a path decomposition for G with strong breath 2 can be computed in linear time.*

Proof. It is known that each AT-free graph G has a vertex pair x, y such that each path from x to y has eccentricity 1; such a pair can be found in linear time [2]. We can now compute a shortest path P from x to y and perform Algorithm 1 on P . The output is a path decomposition with strong breath 2 for G . \square

Figure 1: An AT-free graph G . The decomposition $(N^2[v_0], N^2[v_2], N^2[v_4])$ (as constructed by Algorithm 1) has strong breadth 2. The decomposition $(N[v_0], N[y], N[z], N[v_2], N[v_4])$, however, has strong breadth 1.

Note that a decomposition as constructed by Algorithm 1 is not necessarily optimal for all AT-free graphs. See Figure 1 for an example.

Algorithm 1 also allows to approximate the strong pathbreadth of a given graph with a constant approximation factor. For a given graph G , one can compute a shortest path with eccentricity at most $2 \text{pb}(G)$ in $\mathcal{O}(n^2m)$ time and with eccentricity at most $4 \text{pb}(G)$ in linear time [3]. By performing Algorithm 1 on such a path, we get a path decomposition with strong breadth $4 \text{spb}(G)$ or strong breadth $8 \text{spb}(G)$, respectively. Therefore, we can conclude as follows:

Theorem 4. *The strong pathbreadth of a given graph can be approximated by a factor 4 in $\mathcal{O}(n^2m)$ time and by a factor 8 in linear time.*
