Abstract :

The spark plasma sintering (SPS) behaviour of pure SnO₂ has been studied. **Two different SnO₂ powders have been studied: a commercial 50-200 nm one and 4-6 nm nanoparticles obtained by precipitation.** It has demonstrated that it is not possible to keep pure SnO₂ above **1223 K** by SPS. Indeed, at **1248 K**, SnO appears whereas at higher temperatures, samples are composed by SnO₂ and metal Sn. Three different cycles have been

developed that allow achieving high densities ($\geq 94\%$). The study of the grain size shows that when the density increases the grain size increases to reach 60-70 nm for the high density samples. Therefore, SPS can be successfully used to produce dense nanostructured SnO₂ ceramics without any sintering agent. Nanostructuring is very efficient to lower thermal conductivity as values as low as 6.59 and 3.99 W.m⁻¹.K⁻¹ at 373 and 1000 K respectively, are measured in SPS nanostructured ceramics. Moreover, the transport properties of the dense ceramics are the best reported for undoped SnO₂.

Keywords : Tin oxide ; Spark Plasma Sintering ; Thermoelectric ; Nanostructuring ; Thermal conductivity

1. INTRODUCTION

SnO₂ exhibits a rutile-type structure (space group : P4₂/mm, a = b = 4.7382 Å and c = 3.1871 Å, theoretical density = 6.994, PDF card 41-1445) [1]. It is an n-type semiconductor with a wide band gap of 3.6 eV [2]. It combines high electrical conductivity with high optical transparency in the visible range of the electromagnetic spectrum [3]. Therefore, it is used for numerous applications such as transparent conducting oxide [4, 5], solid state gas sensor [3, 6-8], electrode [9], catalyst material [10], photoluminescence [11], varistor [12, 13], thermoelectric material [14-16] or for photovoltaic devices [17].

It is well known that achieving high density SnO₂ ceramics by conventional sintering is not possible due to non-densifying mechanisms such as the transformation of SnO₂ into SnO and vaporization of tin monoxide which occurs at a high rate above **1373 K** or surface diffusion and evaporation-condensation [18, 19]. Therefore, to overcome such a difficulty, one route has been to add sintering agents into SnO₂, such as CoO, Co₃O₄, MnO₂, CuO, ZnO, Sb₂O₃, ... [18, 20-24]. However, the sintering agent can also affect properties and especially transport properties that are very sensitive to small amounts of dopants in that kind of oxides [23, 25]. Another route was to use high pressure. For instance, Park et al. [26] have obtained more than 97 % dense undoped SnO₂ ceramics by hot isostatic pressing carried out under 150 MPa at **1673 K** for 12 hours. However, such high temperature and long treatments leads also to grain growth and are not therefore a suitable solution for nanostructuring.

Spark Plasma Sintering (SPS) is now a well-known technique to sinter, in a few minutes, dense ceramic bodies of oxide materials at low temperature [27-35]. Therefore, SPS appears as a suitable technique to avoid or limit grain growth during sintering [28].

Few controversial reports have been published on spark plasma sintering of undoped SnO₂. Park et al. [36] obtained dense ceramics (relative density > 95 %) from commercial and home-made SnO₂ nanopowders at **1323 K** under 37.5 MPa during 5 minutes under vacuum whereas at **1273 K** in the same conditions, the relative density is only circa 72 %. Li et al. [37] have studied various sintering parameters on commercial SnO₂ powders. At **1323 K** under 37 MPa during 5 minutes under vacuum, they similarly found a relative density above 95 %. However, in the same conditions but at **1273 K**, they already had a 95 % dense ceramic. They also reported that increasing the pressure (up to 40 MPa), or the heating rate (up to **200 K.min⁻¹**) leads to higher relative densities and that 3 minutes are enough to reach the plateau of highly dense materials.

Vo et al. [16] have reported a very different SPS cycle to sinter undoped SnO₂ ceramics with relative density higher than 95 %. The sintering temperature is lower **1223 K** and the pressure higher, 90 MPa during 5 minutes under an argon atmosphere. Moreover, they add first a dwell at **773 K** during 2 minutes to reach the pressure. However, as their aim is to study thermoelectric properties of tantalum-doped SnO₂ ceramics, they do not explain the reasons for such a cycle.

Therefore, as the final aim of this article is to reach nanostructured dense SnO₂ without sintering agent, the influence of spark plasma sintering cycle parameters on the density of undoped SnO₂ ceramics will be first investigated. Then, grain size evolution will also be characterized as well as electrical and thermal conductivities of ceramics.

2. MATERIALS AND METHODS

Two kinds of SnO₂ powders have been used for this study. The first one is from Aldrich (\geq 99.9 % purity, \approx 325 mesh, **50-200 nm grain size**) and is similar to the commercial powder used by Park et al. [36], and the second one was nanopowder synthesized according to the process described by Dujardin et al. [38] (**figure 1**). Briefly, it consists in precipitating SnO₂ nanoparticles (4-6 nm) from the dropwise addition of a 1 M NaOH aqueous solution into a 2 M SnCl₄ aqueous solution at **373 K** under reflux.

Sintering was performed by Spark Plasma Sintering (Syntex 515 S). The synthesised powders were placed in a 15 mm diameter graphite die (MERSEN - carbon grade 2333) in argon atmosphere. Samples were separated from punches and die by graphite foils. Several conditions have been tested, as detailed below. Note that for experiments with pressure higher than 100 MPa, high strength composite graphite dies were used (TOYO TANSO - carbon grade CX31V).

The obtained pellets were then polished to remove the graphite foils used during the SPS process and cut with a diamond wire saw as bars perpendicular to the pressure axis for electric properties measurements or thin 6 mm squares parallel to the pressure axis for thermal diffusivity measurements to prevent any orientation effect.

Thermoelectric properties of the sintered samples were determined from simultaneous measurement of resistivity and Seebeck coefficient in a ZEM-3 equipment (ULVAC Technologies) and thermal conductivity. Seebeck coefficient and electrical conductivity have been measured first from 323 to 1000 K. The thermal diffusivity was measured using the laser flash diffusivity technique (Netzsch LFA 457) from 373 to 1000 K in vacuum after graphite coating. The thermal diffusivity measurement of all specimens was carried out three times at

each temperature. The heat capacity of the materials was measured from 300 to 1000 K, with a heating rate of **20 K.min⁻¹** in platinum crucibles and in nitrogen atmosphere, using differential scanning calorimetry (Netzsch STA 449 F3 Jupiter).

Apparent density of the samples was calculated from the weight and dimensions of the bars cut from the pellets for ZEM-3 characterization and theoretical density [1].

Powder X-ray diffraction (XRD) patterns have been performed on a BRUKER D8 Advance $\theta/2\theta$ diffractometer equipped with a Linxeye energy-dispersive one-dimensional detector, using Cu-K α radiation and operating at 40 kV and 40 mA at room temperature. The scans have been recorded from 20 to 70°(2 θ) with a step of 0.02° and a counting time of 0.5 s per step.

The scanning electron microscopy (SEM) observations have been performed using Tescan Mira 3 field emission microscope coupled with an Energy Dispersive Spectrometer (EDS Oxford INCA X-Act) without prior coating of the samples.

3. RESULTS AND DISCUSSION

As the first SnO₂ nanopowder used in this study is similar to the one used by Park et al. [36], their SPS conditions were tried first, i.e. **1323 K** under a pressure of 37.5 MPa during 5 minutes (heating and cooling rate of **100 K.min⁻¹**). At the end of the SPS cycle, small Sn beads appear on the top of the graphite die (figure 2). The XRD pattern measured on the pellet is shown in figure 3a) and also exhibits presence of metal Sn peaks. A cross section observed

by SEM shows that metal tin (data not shown) can be observed on the surface of the pellet as well as in the core. The formation of metal tin is probably related to the reaction of SnO₂ with graphite on the surface of the pellet. Moreover, it has already been noticed that graphite can diffuse within ceramics [39, 40]. Indeed, replacing the graphite foil between the die and the sample by boron nitride or alumina powder allows to reduce the Sn amount but it is still possible to find some metal tin in the core of pellets. Moreover, similar results have been obtained for higher pressure (100 MPa) and with the nanoparticles synthesized using Dujardin et al.'s route [38].

The influence of temperature decrease has been studied with the nanoparticles synthesized using Dujardin et al.'s route [38]. The applied pressure is 100 MPa and the temperature dwell duration is 5 minutes with heating and cooling rate of **100 K.min⁻¹**. PXRD patterns (figure 3b) show that at **1248 K**, the peaks relative to Sn metal have disappeared. However, the phase is not pure SnO₂ as some peak corresponding to SnO can be observed. At **1223 K**, only the peaks related to SnO₂ are present (figure 3c). This is the temperature used by Vo et al. [16]. Moreover, PXRD patterns also shows that when temperatures decrease, the peaks intensity decreases and the full-width half-maximum increases. According to SEM images (figure 4) no secondary phase was observed, confirming the XRD results. Moreover, a small porosity can be observed: this is consistent with a poor relative density of 76 %. On the contrary to the results presented by Vo et al. [16], the addition of a dwell at **773 K** during 2 minutes before reaching **1223 K** doesn't allow to achieve relative density higher than 95 %, but leads to unchanged density.

Therefore, the influence of the SPS parameters (pressure, duration of the high temperature dwell, heating/cooling rate), whereas the highest temperature remains constant (i.e. **1223 K**)

has been studied to reach higher densities. Figure 5 shows the influence of the duration of the high temperature dwell. It clearly appears that the density is not significantly improved even for long SPS experiments of 30 minutes. The best relative density achieved is 79 % for a 10 minutes dwell. Figure 6 shows the influence of the applied pressure: Density increases as pressure increases for low pressures ($P < 100$ MPa) but reach a plateau for higher values. The best density achieved is 81 % at 150 MPa. Figure 7 shows the influence of the heating/cooling rate: An optimum value clearly exists around **200 K.min⁻¹** that allows reaching relative densities as high as 87 %. This effect of high heating rate on sintering has now been largely demonstrated [41, 42] but the reason for an optimum value remains unclear.

Individually, each optimized parameter does not allow to reach samples with relative densities of 95 % or higher. Therefore, they have been combined (**Table 1**). By combining the most influent heating/cooling rate and duration of the high temperature dwell, the following SPS cycle (**Cycle A: 1223 K-100 MPa-10 min-200K.min⁻¹**) allows achieving 95 % relative density. One of the main interests of this sintering cycle is that working at a limited pressure, it is possible to use conventional graphite dies. Combining pressure and duration of the high temperature dwell, the following SPS cycle (**Cycle B: 1223 K-150 MPa-10 min-100K.min⁻¹**) allows achieving 94 % density. However due to high pressure, a composite graphite die is required. Finally, Figure 8 exhibits the three combined parameters (**Cycle C: 1223 K-150 MPa-from 2 to 10 min-200K.min⁻¹**). It clearly allows reaching high relative densities even for time as short as 2 minutes. Finally, cycle **A** (**1223 K-100 MPa-10 min-200K.min⁻¹**) has been used on the commercial powder and a density of 94 % has been achieved showing that these results are not only related to the very small size of the synthesized powders.

As the aim is to reach nanostructured dense ceramics, the grain size of the different samples has been studied by measuring the grain size on SEM micrographs (figure 9) and estimating the size of coherent domain by applying the Scherrer formulae to the (101) peaks of the XRD patterns (figure 10). Figure 9 clearly shows that the samples are composed by grains smaller than 100 nm. Figure 10 shows that the value obtained from the Scherrer formulae is consistent with the median grain size measured from SEM micrographs. Moreover, as the density increases, the grain size increases. However, for the ceramics with the highest densities, the grain size is around 60-70 nm. Therefore, the dense ceramics obtained by SPS are nanostructured.

The Seebeck coefficient and electrical conductivity, from 330 to 1000 K, of the sample sintered at **1223 K**-150 MPa-5 min-**200K.min⁻¹** are displayed in figure 11 a). The Seebeck coefficient shows a negative value which is consistent with the expected n-type conduction [2]. It improves from -234 to -290 $\mu\text{V.K}^{-1}$ at 330 and 855 K, respectively. For higher temperatures, the absolute value slightly reduces. This is 30 % higher than the -195 $\mu\text{V.K}^{-1}$ value measured by Vo et al. [16] at room temperature. The electrical conductivity increases on the whole temperature range which is characteristic of a semiconducting-like behaviour, from 550 to 1005 S.m^{-1} , at 330 and 1000 K, respectively. This is twice the value measured by Vo et al. [16]. The sample presents an unusual interesting feature: indeed, usually in semiconductors, when the electrical conductivity increases, the Seebeck coefficient decreases [25, 30, 43]. Similar behaviour can be observed in other compounds such as $\text{Ca}_3\text{Co}_4\text{O}_9$ or delafossites [27, 44]. However, the origin of this behaviour in SnO_2 remains unknown. Therefore, the power factor ($\text{PF} = S^2\sigma$) increases when temperature increases from $2.95 \times 10^{-5} \text{ W.m}^{-1}.\text{K}^{-2}$ at 330 K to $7.75 \times 10^{-5} \text{ W.m}^{-1}.\text{K}^{-2}$ at 1000 K (figure 11 b)). This value at 1000 K is similar to the one reported by Yanagiya et al. [15]. Temperature dependence of the

thermal conductivity (κ) from 373 to 1000 K is shown in figure 11 c). The thermal conductivity of the SnO₂ sample decreases when temperature increases from 6.59 W.m⁻¹.K⁻¹ at 373 K to 3.99 W.m⁻¹.K⁻¹ at 1000 K. These values can be compared to those reported for single crystals at room temperature that are 98 W.m⁻¹.K⁻¹ when parallel to the c-axis and 55 W.m⁻¹.K⁻¹ when perpendicular to c-axis [45] or in polycrystalline samples with micrometer-sized grains : between 25 to 40 W.m⁻¹.K⁻¹ at room temperature for grains from 2.5 to 8 μ m, and around 10 W.m⁻¹.K⁻¹ at 1000 K [46]. This clearly demonstrates the ability of nanostructuring to significantly lower the thermal conductivity in oxides. Moreover, these values are slightly lower than the one recently reported in nanostructured Al-doped ZnO [47]. Figure 11 d) exhibits the temperature dependence of the thermoelectric figure of merit ZT (= PF/ κ): it increases when temperature increases and reach 0.02 at 1000 K.

4. CONCLUSION

The spark plasma sintering behaviour of pure SnO₂ has been studied. It has demonstrated that it is not possible to work above **1223 K** to sinter pure SnO₂ by SPS. Indeed, at **1248 K**, SnO appears whereas at higher temperatures samples are composed by SnO₂ and metal Sn. The influence of each parameters (pressure, duration of the high temperature dwell and heating/cooling rate) has been studied. Three different cycles have been developed that allow achieving high relative densities (≥ 94 %): one of them allows to use conventional graphite die (**1223 K**-100 MPa-10 min-**200K.min⁻¹**) whereas the two others request the use of a high strength composite graphite die (**1223 K**-150 MPa-10 min-**100K.min⁻¹** and **1223 K**-150 MPa- from 2 to 10 min-**200K.min⁻¹**).

The study of the grain size shows that when the density increases the grain size increases to reach 60-70 nm for the high density samples. Therefore, SPS can be successfully used to

produce dense nanostructured SnO₂ ceramics without any sintering agent. The transport properties of the dense ceramics are the best reported for undoped SnO₂. This is the first step to allow studies of electrical properties of doped SnO₂ ceramics without the uncontrolled influence of the sintering agents. Moreover, nanostructuring is very efficient to lower thermal conductivity as values as low as 6.59 and 3.99 W.m⁻¹.K⁻¹ at 373 and 1000 K respectively, are measured in SPS nanostructured ceramics.

FIGURE CAPTION

Table 1: Sintering parameters of the three cycles achieving high relative density.

Figure 1: a) SEM image of the particles of the Aldrich SnO₂ precursor, b) TEM image of the SnO₂ nanoparticles obtained according to the process described by Dujardin et al. [38].

Figure 2: Image of Sn beads appearing on the top of the graphite die after the SPS cycle.

Figure 3: XRD pattern of the pellet sintered at a) **1323 K** under a pressure of 37.5 MPa during 5 minutes (heating and cooling rate of **100K.min⁻¹**), b) **1248 K**-100MPa-5min (heating and cooling rate of **100K.min⁻¹**), c) **1223 K**-100MPa-5min (heating and cooling rate of **100K.min⁻¹**).

Figure 4: SEM image of the microstructure of the pellet sintered at **1223 K**, under 100 MPa during 5 minutes.

Figure 5: Relative density versus duration of the high temperature dwell of the SPS cycle (**1223 K**-100 MPa-**100K.min⁻¹**).

Figure 6: Relative density versus applied pressure during the SPS cycle (**1223 K**-5 min-**100K.min⁻¹**).

Figure 7: Relative density versus heating/cooling rate (**1223 K**-100 MPa-5 min).

Figure 8: Relative density versus duration of the high temperature dwell of the SPS cycle (**1223 K-150 MPa-200K.min⁻¹**).

Figure 9: SEM micrograph of the sample sintered at **1223 K-150 MPa-2 min-200K.min⁻¹**.

Figure 10: Comparison of the grain size of the different samples obtained by SEM measurements and from the Scherrer formulae.

Figure 11: Temperature dependence of a) the Seebeck coefficient and the electrical conductivity, b) the power factor, c) the thermal conductivity, d) the figure of merit, **of the sample sintered with cycle A (1223K-150 MPa-5 min-200K.min⁻¹)**.

| Cycle | Maximum Temperature (K) | Applied Pressure (Mpa) | Dwell Duration (min) | Heating/Cooling Rates (K.min ⁻¹) | Die | Relative Density (%) |
|-------|-------------------------|------------------------|----------------------|--|-----------------------|----------------------|
| A | 1223 | 100 | 10 | 200 | Conventional Graphite | 95 |
| B | 1223 | 150 | 10 | 100 | Composite Graphite | 94 |
| C | 1223 | 150 | from 2 to 10 | 200 | Composite Graphite | from 94 to 96 |
