Abstract: Chronicle recognition is an efficient and robust method for fault diagnosis. The knowledge about the underlying system is gathered in a set of chronicles, then the occurrence of a fault is diagnosed by analyzing the flow of observations and matching this flow with a set of available chronicles. The chronicle approach is very efficient as it relies on the direct association of the symptom, which is in this case a complex temporal pattern, to a situation. Another advantage comes from the efficiency of recognition engines which make chronicles suitable for one-line operation. However, there is a real bottleneck for obtaining the chronicles. In this paper, we consider the problem of learning the chronicles. Because a given situation often results in several admissible event sequences, our contribution targets an extension to multiple event sequences of a chronicle discovery algorithm tailored for one single event sequence. The concepts and algorithms are illustrated with representative and easy to understand examples.

Keywords: temporal pattern, chronicle, learning, data mining, event abstraction.

1. INTRODUCTION

Chronics are temporal patterns well suited to capture the behavior of dynamic processes at an abstract level based on events. They are among the formalisms that can be used to model timed discrete event systems. Chronicles may represent the signatures of specific situations, and are hence very efficient for diagnosis. They may also be associated to decision rules specifying which actions must be undertaken when reconfiguration is needed.

The chronicle approach has been developed and used in a large spectrum applications (Cordier and Dousson, 2000): in the medical field for ECG interpretation and cardiac arrhythmia detection (Carrault et al., 1999), in intrusion detection systems (Morin and Debar, 2003), in telecommunication networks (Laborie and Krivine, 1997). More recently, chronicles have been used in the context of web services (Cordier et al., 2007; Pencolé and Subias, 2009). Chronicles are also applied on activity recognition in the setting of unmanned aircraft Systems and unmanned aerial vehicles operating over road and traffic networks (Fessant et al., 2004).

Among the challenges raised by the chronicle approach is the problem of acquiring the chronicles. On one hand, model based chronicle generation approaches have been developed. For instance, in (Guerraz and Dousson, 2004) the patterns are built from Petri net models of the situation to recognize. Nevertheless, most of the works addressing this problem are data driven. They rely on analyzing logs and extract the significant patterns by temporal data mining techniques (Mitsa, 2010).

The objective of temporal data mining techniques is to discover all patterns of interest in the input data, by means of an unsupervised approach. There are several ways to define the relevance of a pattern. Among them, the frequency criterium is widely used (Dousson and Duong, 1999; Cram et al., 2012). One can distinguish two main frameworks: sequential patterns (Agrawal and Srikant, 1994) and frequent episodes (Mannila et al., 1997).

- The sequential pattern framework is based on the discovery in a collection of sequences of all possible time ordered sets of event (i.e. sequence of events) with sufficient number of occurrences w.r.t a user-defined threshold. The number of occurrences of a set of events is defined as the number of times the set of events can be observed in the collection. Further, a sequence of events is said to be maximal if it involves the highest possible number of events. Sequential pattern discovery relies on the systematic search of maximal sequences that have a number of occurrences at least equal to the a user-defined threshold. Many methods for unearthing sequential patterns are designed along the lines of the Apriori algorithm (Agrawal and Srikant, 1994).
- Frequent episode framework uses a single (long) sequence and considers the discovery of temporal patterns, called episodes, that occur with sufficient frequency in the sequence. An episode is a partially ordered set of event types. Similarly to the case of sequential patterns, the notion of frequent episode and sub-episode are defined. In Mannila et al. (1997) episode discovery focusses on two types of episodes: serial episodes when the order between the event
types is total and parallel episodes when there is only partial order between the events types.

Chronicles are designed to afford for total order and partial order temporal patterns but also patterns combining the two types. Moreover, chronicles consider temporal constraints between event type occurrences.

One of the main difficulties of chronicle discovery is to guarantee robustness to variations. The chronicle discovery approach proposed in this paper aims at discovering frequent chronicles common to multiple sequences representing variations of a unique situation, that is to say chronicles that are frequent in each sequence of a collection. This is motivated by the fact that the event sequences arising from the same situation generally present variants that must be accounted for.

Our contribution precisely targets an extension to multiple event sequences of the chronicle discovery algorithm proposed by Cram et al. (2012), which is tailored for one single event sequence. Moreover, we target to discover the chronicles not only for a given frequency but for all the possible frequencies higher than a specified threshold.

The paper is organized as follows. Section 2 provides the concepts and definitions underlying the proposed approach. Section 3 first presents the algorithm for building a database representing the sequences at hand. It then presents the chronicle learning algorithm that uses the constructed database. Section 4 summarizes and concludes the work.

2. CONCEPTS AND DEFINITIONS

In this section, the concepts that underly our chronicle mining algorithm are presented and formalized. Chronicles have been introduced as a way to express temporal information about a domain (Dousson et al., 1993).

The domain is assumed to be described through a set of features whose values change over time with the evolutions of the domain.

The data samples are hence given in terms of the set of features \( \{x^1, \ldots, x^n\} \). Every feature \( x^j \) takes its value in the set \( U^j \), called the domain of \( x^j \). The universe \( U = U^1 \times \cdots \times U^n \) is defined as the Cartesian product of the feature domains. Therefore any sample can be represented by a vector \( x = (x^1, \ldots, x^n)^T \) of \( U \), so that every component \( x^j \) corresponds to the feature value \( x^j \) qualifying the object \( x \). The subset of \( U \) formed by these vectors is called the database.

When samples need to be indexed by time, a sample taken at time \( t_i \) is represented by a vector \( x_{t_i} = (x_{t_i}^1, \ldots, x_{t_i}^n)^T \). The value taken by the feature \( x^j \) across time can be considered as a random variable \( x^j_t, t \in Z \). The corresponding time series, taken from time \( t_i \) to time \( t_f \) is noted \( X_{t_i \rightarrow t_f} = \{x_{t_i}, t = t_i, \ldots, t_f\} \) = \( \langle x_{t_i}, \ldots, x_{t_f} \rangle \).

The concept of event type expresses a change in the value of a given domain feature or set of features. Let us define \( E \) as the set of all event types and define the concept of event.

Definition 1. (Event). An event is defined as a pair \((e_i, t_i)\), where \( e_i \in E \) is an event type and \( t_i \) is an integer called the event date.

Time representation relies on the time point algebra and time is considered as a linearly ordered discrete set of instants whose resolution is sufficient to capture the environment dynamics.

Definition 2. (Temporal sequence). A temporal sequence on \( E \) is an ordered set of events denoted \( S = \{(e_i, t_i)\}_{i \in \mathbb{N}_l} \) such that \( e_i \in E, i = 1, \ldots, l \) and \( t_i < t_{i+1}, i = 1, \ldots, l-1 \), where \( l \) is the dimension of the temporal sequence \( S \).

The size of a sequence \( S \) is the number of events in \( S \): \( |S| = l \). The temporal sequence typology is the set of event types \( E' \in E \) that occur in \( S \).

To represent specific domain evolutions, we consider that event dates may be constrained. A time interval \( I \) is expressed as a pair \( I_{ij} = [t^-, t^+] \) corresponding to the lower and upper bound on the temporal distance between two time points \( t_i \) and \( t_j, i \leq j \). Given two event dates \( t_i \) and \( t_j \), we express temporal constraints \( \tau_{ij} \) of the form \( t_j - t_i \in [t^-, t^+] \). Consider two events \((e_i, t_i)\) and \((e_j, t_j)\), then if their dates \( t_i \) and \( t_j \) satisfy the temporal constraint \( t_j - t_i \in [t^-, t^+] \), we write \( e_j[t^- , t^+]_{e_i} \) and say that the events are temporally constrained by \( \tau_{ij} \). \( I_{ij} = [t^-, t^+] \) is called the support of \( \tau_{ij} \), or equivalently of the pair of event types \((e_i, e_j)\).

Definition 3. (Chronicle). A chronicle is a pair \( C = (E, T) \) such that \( E \subseteq E \) and \( T = \{\tau_{ij}\}_{1 \leq i < j \leq |E|} \). \( E \) is called the typology of the chronicle and \( T \) is the set of temporal constraints of the chronicle.

Example: Figure 1 gives the time constraints satisfaction graph associated to a chronicle \( C \). The nodes of the graph are associated to the event types, and the edges are labeled by the time constraints. \( C \) is defined by \( E = \{A, B, C, D\} \) and \( T = \{T_{AB}, T_{AC}, T_{BD}, T_{CD}\} \). Moreover, \( I_{AB} = [1, 3], I_{AC} = [2, 5], I_{BD} = [4, 6] \) and \( I_{CD} = [0, \infty] \).

Fig. 1. A chronicle example

A chronicle \( C \) represents an evolution pattern involving a subset of event types \( E \) and a set of temporal constraints \( T \) linking event dates. Chronicles are a special type of temporal pattern, where the temporal order of events is quantified with numerical bounds and reflects the represented piece of temporal evolution.

The episodes of Mamili et al. (1997) are a particular type of chronicle. A parallel episode is a collection of event types that occur in a given partial order whereas the event types of a serial episode are totally ordered. In the case of episodes, temporal constraints do not specify
precise numerical temporal bounds but are just precedence constraints of the form \( t_j - t_i \in [0, +\infty] \) or \( t_j - t_i \in [-\infty, 0] \). Conversely, chronicles are parallel episodes with additional temporal information.

The occurrences of a given chronicle \( \mathcal{C} \) in a temporal sequence \( \mathcal{S} \) are denoted by subsequences called chronicle instances.

**Definition 4.** (Chronicle instance). An instance of \( \mathcal{C} = (\mathcal{E}, \mathcal{T}) \) in a temporal sequence \( \mathcal{S} \) is a subset of event types \( \mathcal{E}^\prime \) of \( \mathcal{S} \) such that \( \mathcal{E}^\prime \) is isomorphic to \( \mathcal{E} \), in other words \( |\mathcal{E}^\prime| = |\mathcal{E}| \) and the event types of \( \mathcal{E}^\prime \) satisfy all temporal constraints \( \mathcal{T} \) of the chronicle \( \mathcal{C} \).

**Definition 5.** (Frequency of a chronicle). The frequency of a chronicle \( \mathcal{C} \) in a temporal sequence \( \mathcal{S} \), noted \( f(\mathcal{C}|\mathcal{S}) \), is the number of instances of \( \mathcal{C} \) in \( \mathcal{S} \).

In the literature, it is hardly the case that all the instances of a given chronicle are returned by a chronicle recognition engine. Additional constraints are generally used to form a recognition criterion \( \gamma \). For example, Mannila et al. (1997) returns the shortest instances in the sense of the instance duration in the sequence. Dousson and Duong (1999) returns all the recognized at the earliest disjoint instances, i.e. all the instances that do not overlap in the sequence and that occur earliest in the sequence. The frequency of a chronicle \( \mathcal{C} \) in a temporal sequence \( \mathcal{S} \) can be defined according to the recognition criterion \( \gamma \) and it is then noted \( f_\gamma(\mathcal{C}|\mathcal{S}) \).

Given a set of event types \( \mathcal{E} \), the space of possible chronicles can be structured by a generality relation.

**Definition 6.** (Generality relation among chronicles). A chronicle \( \mathcal{C} = (\mathcal{E}, \mathcal{T}) \) is more general than a chronicle \( \mathcal{C}^\prime = (\mathcal{E}^\prime, \mathcal{T}^\prime) \), denoted \( \mathcal{C} \sqsubseteq \mathcal{C}^\prime \), if \( \mathcal{E} \subseteq \mathcal{E}^\prime \) or \( \forall \tau_{ij} \in \mathcal{T}, \tau_{ij} \geq \tau_{ij}^\prime \) in every \( \mathcal{C} \). Equivalently, \( \mathcal{C}^\prime \) is said stricter than \( \mathcal{C} \).

**Definition 7.** (Monotonicity). A frequency \( f_\gamma \) is said to be monotonic for the relation \( \sqsubseteq \) if and only if \( \mathcal{C} \sqsubseteq \mathcal{C}^\prime \) implies that \( f_\gamma(\mathcal{C}|\mathcal{S}) \geq f_\gamma(\mathcal{C}^\prime|\mathcal{S}) \) for any temporal sequence \( \mathcal{S} \) of events.

**Definition 8.** (Minimal and maximal chronicles of a set). Given a set of chronicles \( \mathcal{C} \), the subset of minimal and maximal chronicles of \( \mathcal{C} \) are defined by:

\[
\text{Min}(\mathcal{C}) = \{ \mathcal{C} \in \mathcal{C} \mid \forall \mathcal{C}^\prime \in \mathcal{C}, \mathcal{C} \sqsubset \mathcal{C}^\prime \Rightarrow \mathcal{C} = \mathcal{C}^\prime \},
\]

\[
\text{Max}(\mathcal{C}) = \{ \mathcal{C} \in \mathcal{C} \mid \forall \mathcal{C}^\prime \in \mathcal{C}, \mathcal{C}^\prime \sqsupset \mathcal{C} \Rightarrow \mathcal{C} = \mathcal{C}^\prime \}.
\]

### 3. AN ALGORITHM FOR LEARNING GENERAL CHRONICLES FROM MULTIPLE TEMPORAL SEQUENCES

The chronicle mining process consists in discovering all chronicles \( \mathcal{C} \) whose instances occur in a given temporal sequence \( \mathcal{S} \). However, it is often the case that the same situation does not result in perfectly identical temporal sequences. In this case, we are interested in learning the chronicles whose instances occur in all the temporal sequences. This problem can be stated as: given a set of temporal sequence \( \mathcal{S} = \{ \mathcal{S}_1, \ldots, \mathcal{S}_n \} \) and a minimum frequency threshold \( f_{th} \), find all minimal frequent chronicles \( \mathcal{C} \) such that \( f_{\gamma}(\mathcal{C}) \) is at least \( f_{th} \) in all temporal sequences of \( \mathcal{S} \).

This paper builds on the chronicle learning algorithm proposed by Cram et al. (2012) and presents an extension to the case of multiple temporal sequences. The chronicle learning algorithm by Cram et al. (2012) has two phases:

1. It builds a constraint database \( \mathcal{D} \) representing the temporal sequence \( \mathcal{S} \). This is performed with the Complete Constraint-Database Construction algorithm (CCDC algorithm).
2. It generates a set of candidate chronicles starting with a set of chronicles that were proved to be frequent and using \( \mathcal{D} \) to explore the chronicle space. This is implemented by the Heuristic Chronicle Discovery Algorithm (HCDA algorithm).

Extending this algorithm to multiple temporal sequences requires to redesign the first phase so that the constraint database not only represents one temporal sequence but all the temporal sequences in the set \( \mathcal{S} \).

#### 3.1 Constraint database representing multiple temporal sequences

The constraint database \( \mathcal{D} \) is an object in which every temporal constraint \( \tau_{ij} = e_i[t_i^-, t_i^+]e_j \) is frequent in all the sequences of \( \mathcal{S} \) is stored. It is organized as a set of trees \( T_{ij}^\alpha \) for each pair of event types \( (e_i, e_j) \) with \( i, j = 1, \ldots, |\mathcal{E}|, i \neq j \) and \( \alpha = 1, \ldots, n_{ij} \). The nodes of the trees are temporal constraints and arrows represent is_parent_of relations.

**Definition 9.** (is_parent_of relation). \( e_i[t_i^-, t_i^+]e_j \) is_parent_of \( e_i[t_i^-, t_i^+]e_j \) if \( [t_i^-, t_i^+] \subseteq [t_j^-, t_j^+] \) and \( \exists e_i[t_i^-, t_i^+]e_j \) such that \( [t_i^-, t_i^+] \subseteq [t_j^-, t_j^+] \subset [t_i^-, t_i^+] \).

The root of a tree \( T_{ij}^\alpha \) is hence a temporal constraint \( e_i[t_i^-, t_i^+]e_j \) such that the occurrences of \( \{(e_i, t_i), (e_j, t_j)\} \) in all temporal sequences of \( \mathcal{S} \) are maximal. Unlike in (Cram et al., 2012), there may be a number \( n_{ij} \) of such temporal constraints for the same pair \( (e_i, e_j) \), hence \( n_{ij} \) trees. Let us notice that a temporal constraint \( e_i[t_i^-, t_i^+]e_j \) actually defines a 2-length chronicle \( \mathcal{C} = (\mathcal{E}, \mathcal{T}) \) for which \( \mathcal{E} = \{e_i, e_j\} \) and \( \mathcal{E} = \{e_j, e_i\} \). Then, the root of \( T_{ij}^\alpha \) is the 2-length chronicle with topology \( \mathcal{E} = \{e_i, e_j\} \) that is the most general for all temporal sequences of \( \mathcal{S} \) and the child nodes are stricter 2-length chronicles with the same topology. \( \mathcal{D}^T \) is defined as the set of all tree roots.

As we consider multiple temporal sequences, only the pairs of event types \( (e_i, e_j) \) shared by all the temporal sequences \( \mathcal{S}_i \in \mathcal{S} \) are examined.

In a first stage, for each sequence \( \mathcal{S}_i \in \mathcal{S} \) and for each pair \( (e_i, e_j) \in \mathcal{E}^2 \) such that \( (e_i, t_i) \in \mathcal{S}_k \) and \( (e_j, t_j) \in \mathcal{S}_k \), the set of all the occurrences of the pair in the sequence \( \mathcal{S}_k \) (noted \( O_{ij}^{k} \)) is determined. The set of time interval durations between the two event types of the occurrences of \( O_{ij}^{k} \) is given by \( D_{ij}^{k} = \{d_{ij}^{k} = (t_j - t_i)|((e_i, t_i), (e_j, t_j)) \in O_{ij}^{k}\} \). From the frequency \( f_{ij}^{k} \) of \( (e_i, e_j) \) in each temporal sequence \( \mathcal{S}_k \), we introduce \( f_{max} = \min_k(f_{ij}^{k}) \). \( f_{max} \) is the maximal number of occurrences for \( (e_i, e_j) \) present in all the sequences of \( \mathcal{S} \).

**Example:** Let us consider the three temporal sequences of Figure 2. \( \mathcal{S} = \{\mathcal{S}_1, \mathcal{S}_2, \mathcal{S}_3\} \). For the pair \( (e_1, e_2) \), \( O_{e_1,e_2}^{1} = \{((e_1, 3), (e_2, 1)), ((e_1, 3), (e_2, 4)), ((e_1, 3), (e_2, 5))\} \) and \( O_{e_1,e_2}^{2} = \)
\{((e_1, 2), (e_2, 1)), ((e_1, 2), (e_2, 3))\} and finally \(O^2_{e_1, e_2} = \{((e_1, 2), (e_2, 1)), ((e_1, 2), (e_2, 3)), ((e_1, 2), (e_2, 5))\}\).

Additionally, \(\mathcal{D}^1_{12} = \{-2, 1, 2\}\), \(\mathcal{D}^2_{12} = \{-1, 1\}\) and \(\mathcal{D}^3_{12} = \{-1, 1, 3\}\). Finally the frequencies of the pair \((e_1, e_2)\) for each sequence are given by \(f^1_{12} = 3\), \(f^2_{12} = 2\), \(f^3_{12} = 3\), hence \(f_{max} = 2\).

The union of the minimal supports of every combination \(\mathcal{S}_k\) in \(\mathcal{S}\) is equal to \(f_{max}\). The following explains how to obtain these supports.

Two sets of supports are considered for each sequence \(\mathcal{S}_k\): the set of minimal supports \(\mathcal{I}^k_{ij}\) and the set of maximal supports \(\mathcal{I}^k_{ij}\) that guaranty exactly \(f_{max} = 2\) occurrences of the pair \((e_i, e_j)\) in \(\mathcal{S}_k\). Whereas minimal supports are used in the algorithm of Cram et al. (2012), maximal supports are a new concept required by our method to deal with multiple sequences. These sets are defined as follows:

\[
\mathcal{I}^k_{ij} = \{I^k_{ij} = [l^k_{ij}, t^k_{ij}] | f^k_{ij} = f_{max}\}.
\]

\[
\text{and } \forall [l^k_{ij}, t^k_{ij}] \subseteq [l^k_{ij}, t^k_{ij}], f^k_{ij} < f_{max}\}.
\]

\[
\mathcal{I}^k_{ij} = \{I^k_{ij} = [l^k_{ij}, t^k_{ij}] | f^k_{ij} = f_{max}\}.
\]

\[
\text{and } \forall [l^k_{ij}, t^k_{ij}] \supseteq [l^k_{ij}, t^k_{ij}], f^k_{ij} > f_{max}\}.
\]

Example: On the example of Figure 2, the minimal and maximal supports that guaranty exactly \(f_{max} = 2\) for each sequence are \(\mathcal{I}^k_{ij} = \{[-2, 1], [1, 2]\}\) and \(\mathcal{I}^k_{12} = \{[-\infty, 1], [-1, +\infty]\}\). The intersection of the maximal supports provides a maximal common interval \(\mathcal{MCI}_{ij}\) that validates the union of the minimal supports \(\mathcal{I}^k_{ij}\), that is:

\[
\mathcal{MCI}_{ij} = \{\mathcal{MCI}_{ij} = \bigcap_k I^k_{ij}, I^k_{ij} = I^k_{ij}, k = 1, \cdots, n,\}
\]

\[
\beta = 1, \cdots, \text{card}(\mathcal{I}^{comb}_{ij})\}.
\]

Proposition 1. A tree root candidate \(R^0_{ij}\) of \(\mathcal{R}_{ij}\) is valid if \(\exists \beta\) such that \(R^0_{ij} \subseteq \mathcal{MCI}_{ij}\), where \(\mathcal{MCI}_{ij} \in \mathcal{MCI}_{ij}\).

A valid tree root candidate for \((e_i, e_j)\) is denoted \(R^0_{ij}\) and the set of such roots is denoted \(\mathcal{R}_{ij}\). The cardinal of \(\mathcal{R}_{ij}\) is \(n_{ij}\).
3.2 Chronicle discovery algorithm

Once the constraint database $\mathbb{D}$ has been built to account for all the sequences in $\mathbb{S}$ as presented in section 3.1, the algorithm for discovering all minimal frequent chronicles for $\mathbb{D}$, given an input frequency threshold $f_{th}$, is the same as the HCDAM algorithm of Cram et al. (2012) but the counting step. This algorithm is hence called HCDAM-modified. The counting step is slightly different because we want HCDAM-modified to provide all the frequent chronicles whose frequency is above the specified threshold. Like in (Cram et al., 2012), the candidate chronicles are called $\mathbb{D}$-chronicles.

The principle of HCDAM is to generate a set of candidate $\mathbb{D}$-chronicles from a chronicle that was proved to be frequent. The set Candidates is initiated with the set of root trees $\mathbb{D}^\mathbb{F}$. The algorithm maintains two lists:

- the list $\mathbb{Frequent}$ includes the candidate $\mathbb{D}$-chronicles that have been proved frequent, i.e. whose frequency is higher or equal to $f_{th}$, and strictest,
- the list $\mathbb{NotFrequent}$ includes the chronicles that have been proved not frequent.

Instead of immediately counting a candidate $C$, i.e. determining the minimal number of occurrences in the sequences of $\mathbb{S}$, the algorithm first makes use of the generality relation and monotonicity property to discard or accept the candidate without counting:

- if there exists a chronicle $C'$ more general than $C$ in $\mathbb{NotFrequent}$, then $C$ is not frequent as well,
- if there exists a chronicle $C'$ stricter than $C$ in $\mathbb{Frequent}$, then $C$ is also frequent.

If none of the two above situations apply, then $C$ is counted, which is performed with CRS (Chronicle Recognition System) (Dousson et al., 1993).

In our algorithm, the candidate is also counted in the second situation to determine its actual frequency, which is necessarily higher than $f_{th}$ and higher than the frequency of the stricter chronicle $C'$. Obviously, only maximal chronicles are saved in $\mathbb{NotFrequent}$ because this set is used to search for more general chronicles. Conversely, only minimal chronicles are saved in $\mathbb{Frequent}$.

Example: Consider the following sequences of events.

<table>
<thead>
<tr>
<th>Sequence 1</th>
<th>Sequence 2</th>
<th>Sequence 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>$(e_1, 1.049432)$</td>
<td>$(e_1, 13.354919)$</td>
<td>$(e_5, 7.207688)$</td>
</tr>
<tr>
<td>$(e_2, 1.606994)$</td>
<td>$(e_1, 14.1784)$</td>
<td>$(e_7, 7.36308)$</td>
</tr>
<tr>
<td>$(e_3, 1.873512)$</td>
<td>$(e_3, 14.377672)$</td>
<td>$(e_2, 8.00252)$</td>
</tr>
<tr>
<td>$(e_4, 2.18784)$</td>
<td>$(e_4, 14.706472)$</td>
<td>$(e_3, 8.273512)$</td>
</tr>
<tr>
<td>$(e_5, 3.441056)$</td>
<td>$(e_5, 15.196873)$</td>
<td>$(e_3, 8.482312)$</td>
</tr>
<tr>
<td>$(e_6, 5.871024)$</td>
<td>$(e_6, 18.395527)$</td>
<td>$(e_5, 9.8347435)$</td>
</tr>
<tr>
<td></td>
<td></td>
<td>$(e_6, 12.974768)$</td>
</tr>
</tbody>
</table>

The algorithm HCDA-modified has been used to learn the two following chronicles. The second chronicle is a chronicle of frequency 2, which means that it must be recognized twice to sign the situation captured by the three sequences of the example. The first chronicle is the stricter chronicle. It involves the highest set of event with the tightest temporal constraints. It is of frequency 1.

```
chronicle Chronicle1
{ event(c5, t1) 
  event(c2, t2) 
  event(c6, t3) 
  event(c3, t4) 
  t2 - t1 in [−2, −1] 
  t3 - t1 in [−1.5, 3.5] 
  t3 - t2 in [0, 5] 
  t4 - t1 in [−2, −0.5] 
  t4 - t2 in [0, 5] 
} 
```

```
chronicle Chronicle2
{ event(c5, t1) 
  event(c6, t2) 
  t2 - t1 in [−1.5, 3.5] 
} 
```

4. CONCLUSION

This paper deals with the problem of discovering temporal patterns in the form of chronicles that are common to a set of temporal sequences issued from the same situation. The obtained chronicles then sign the situation and can be used for situation assessment or diagnosis purposes. The paper builds on work by Cram et al. (2012) and extends the proposed algorithm that targets learning the frequent chronicles for one single sequence to multiple temporal sequences that represent variants of a unique situation. This requires to deeply revise the algorithm to generate the constraint database representing the temporal sequences. The revised algorithm is illustrated by a simple example which helps understand the different steps of the method.

Future research includes theoretical as well as applied work. The complexity of the modified algorithm, including building the constraint base, should be carefully analyzed and ways to improve efficiency should be studied. On the other hand, it is planned to use this work for a real prognostic problem, applying the algorithm HCDAM to the observable signals of a pressure regulation valve of a modern aircraft in different wear situations.
