Climate Response to Negative Greenhouse Gas Radiative Forcing in Polar Winter

M. G. Flanner<sup>1</sup>, X. Huang<sup>1</sup>, X. Chen<sup>1</sup>, and G. Krinner<sup>2</sup>

<sup>1</sup>Department of Climate and Space Sciences and Engineering, University of Michigan, Ann Arbor, MI, USA, <sup>2</sup>CNRS, Université Grenoble Alpes, Institut des Géosciences de l'Environnement, Grenoble, France

Key Points:

- Increased GHG concentrations in polar inversion layers cause negative top of atmosphere instantaneous and effective radiative forcing
- Polar and global surface temperatures warm despite this negative radiative forcing
- Surface warming and tropospheric cooling result from high stability and increased surface downwelling longwave flux

**Abstract** Greenhouse gas (GHG) additions to Earth's atmosphere initially reduce global outgoing longwave radiation, thereby warming the planet. In select environments with temperature inversions, however, increased GHG concentrations can actually increase local outgoing longwave radiation. Negative top of atmosphere and effective radiative forcing (ERF) from this situation give the impression that local surface temperatures could cool in response to GHG increases. Here we consider an extreme scenario in which GHG concentrations are increased only within the warmest layers of winter near-surface inversions of the Arctic and Antarctic. We find, using a fully coupled Earth system model, that the underlying surface warms despite the GHG addition exerting negative ERF and cooling the troposphere in the vicinity of the GHG increase. This unique radiative forcing and thermal response is facilitated by the high stability of the polar winter atmosphere, which inhibit thermal mixing and amplify the impact of surface radiative forcing on surface temperature. These findings also suggest that strategies to exploit negative ERF via injections of short-lived GHGs into inversion layers would likely be unsuccessful in cooling the planetary surface.

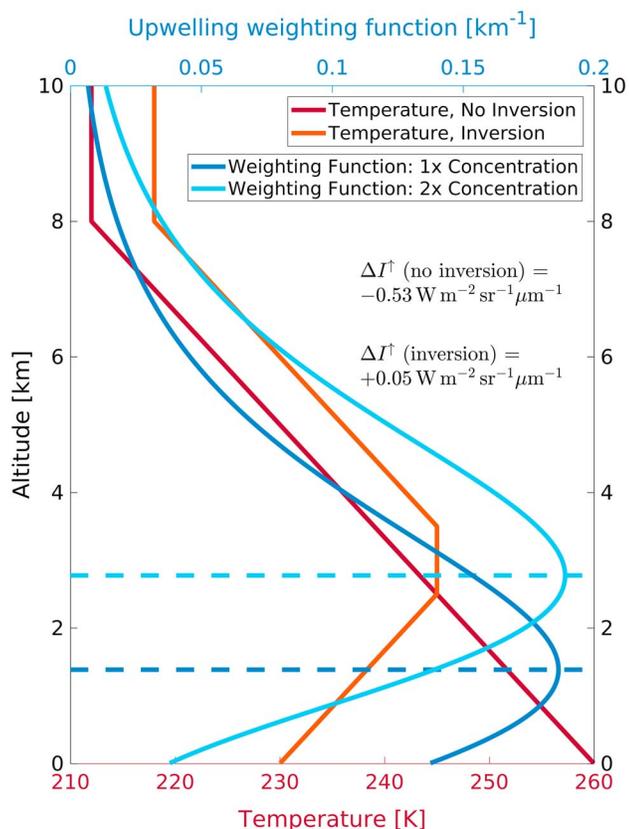

1. Introduction

Increasing concentrations of greenhouse gases (GHGs) warm Earth by causing an immediate reduction in the flux of outgoing longwave radiation (OLR) from the planet to space (e.g., Arrhenius, 1896). OLR decreases because the atmosphere is generally colder than the underlying surface, and atmospheric emissivity increases with elevated GHG amounts. In atmospheric environments with temperature inversions (i.e., where temperature increases with height), however, increased GHG concentrations can actually increase OLR by raising the emissivity of a relatively warm portion of the surface-atmosphere column (e.g., Huang et al., 2016; Schmithüsen et al., 2015; Sejas et al., 2016). This effect can be demonstrated analytically if we neglect scattering, in which case top-of-atmosphere (TOA) outgoing nadir-view radiance from an absorbing atmosphere is (e.g., Thomas & Stamnes, 1999)

$$I_{\lambda}^{\uparrow}(\infty) = B_{\lambda}[T_s] \mathcal{T}_{\lambda}^* + \int_0^{\infty} B_{\lambda}[T(z)] \frac{\partial \mathcal{T}_{\lambda}(z, \infty)}{\partial z} dz \quad (1)$$

Here  $B_{\lambda}$  is the Planck function evaluated at temperature  $T$  and wavelength  $\lambda$ ,  $T_s$  is the blackbody surface temperature,  $\mathcal{T}_{\lambda}^*$  is the whole-atmosphere transmittance,  $\mathcal{T}_{\lambda}(z, \infty)$  is the transmittance between  $z$  and the TOA, and subscript  $\lambda$  indicates the wavelength-dependent quantities. With a GHG that has vertical density profile  $\rho(z)$  and mass absorption cross-section  $k_{\lambda}$ , the transmittance function is  $\mathcal{T}_{\lambda}(z, \infty) = \exp[-k_{\lambda} \int_z^{\infty} \rho(z) dz]$ . Assuming idealized and carefully chosen gas and temperature profiles depicted in Figure 1, we see that the peak of the weighting function ( $\partial \mathcal{T}_{\lambda} / \partial z$ ) shifts to a higher and colder location of the atmosphere with elevated GHG under normal atmospheric conditions but shifts to a higher and warmer location under the temperature inversion scenario, in this case producing an instantaneous increase in upwelling radiance at the model top.

Regions of Earth's atmosphere with persistent temperature inversions include the stratosphere and winter lower troposphere of polar regions (e.g., Connolley, 1996; Phillpot & Zillman, 1970; Serreze et al., 1992). Hence, negative TOA radiative forcing can result from increased GHG concentrations occurring in isolation in these regions, as seen from the water vapor radiative kernels depicted in Figure 2 of Soden et al. (2008) and Figure 1 of Shell et al. (2008). Schmithüsen et al. (2015) and Huang et al. (2016) showed that increased CO<sub>2</sub> throughout the atmospheric column can produce negative TOA forcing over central Antarctica, where the stratosphere (and origin of OLR near the center of the 15 μm CO<sub>2</sub> absorption band) is often warmer than the surface.

**Figure 1.** Red curves: Idealized temperature profiles without and with a near-surface temperature inversion. Blue curves: Weighting functions ( $\partial T / \partial z$ ) for  $11 \mu\text{m}$  outgoing nadir-view intensity ( $I^\dagger$ ) in columns with a hypothetical greenhouse gas that has a mass absorption cross section of  $1.0 \text{ m}^2 \text{ kg}^{-1}$ , scale height of 2 km, and surface densities of  $1.0$  and  $2.0 \text{ g m}^{-3}$ , respectively, in the 1x and 2x concentration scenarios. Dotted horizontal lines show the altitudes where the weighting functions peak. With additional greenhouse gas,  $I^\dagger$  at the model top (equation (1)) decreases when there is no temperature inversion but increases when there is an inversion.

Similarly, smaller surface-atmosphere temperature contrast in polar regions leads to weaker annual mean longwave forcing from increased  $\text{CO}_2$  (Hansen et al., 2005; Myhre & Stordal, 1997; Shine & Forster, 1999) and tropospheric ozone (Stevenson et al., 2013). Early studies of nuclear winter also noted that the global greenhouse effect becomes inhibited when the upper troposphere and lower stratosphere experience extreme warming (Turco et al., 1983).

Under both non-inversion and inversion scenarios, however, downwelling longwave flux at the surface increases with elevated GHGs, despite the opposite sign of TOA radiative perturbation that can occur in these two scenarios. This leads us to the following question: “How does the climate system respond to GHG increases occurring in tropospheric temperature inversion environments?” Judging only from the TOA or tropopause forcing, one might expect surface cooling. Indeed, in the context of near-zero TOA forcing over central Antarctica from increased  $\text{CO}_2$ , Schmithüsen et al. (2015) note that this region has not warmed in recent decades. If surface cooling is expected, this even raises the possibility that injections of short-lived GHGs into polar inversion layers could cool the planetary surface. We show here that although the troposphere cools in response to such radiative forcing, which is negative in both the instantaneous and effective forcing contexts defined by the Intergovernmental Panel on Climate Change (Myhre et al., 2013), the local surface warms.

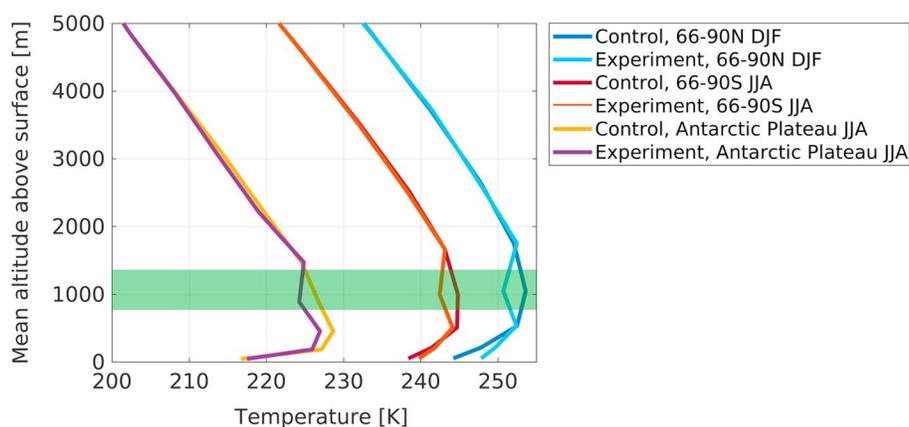

## 2. Methods

To explore the effects of increased GHG amounts within polar near-surface inversion layers, we conduct model simulations with sharply elevated concentrations of CFC-11 ( $\text{CCl}_3\text{F}$ ). This agent is used for convenience because it is a potent greenhouse gas, but the type of gas assumed here is relatively unimportant because our fundamental question pertains simply to how surface and atmospheric temperatures respond to a negative radiative forcing caused by increased emissivity of a tropospheric inversion layer.

First, to illustrate the effect of our designed perturbation with a detailed radiative transfer solution, we apply high spectral resolution ( $1 \text{ cm}^{-1}$ ) calculations from the MODerate resolution atmospheric TRANsmission Model 5 (MODTRAN) (e.g., Berk et al., 2014). We apply typical clear-sky polar

winter vertical profiles of temperature, specific humidity, and ozone from ERA-Interim reanalysis (Dee et al., 2011). The Antarctic profile is an average over the high plateau (elevations over 2 km) from July 2008, identical to the profile applied by Chen et al. (2014), and the Arctic profile represents an average over  $66\text{--}90^\circ\text{N}$  during January 2008. Both profiles exhibit a strong near-surface inversion. We set CFC-11 concentrations to zero in baseline simulations and specify a burden of  $7.3 \text{ g m}^{-2}$  ( $0.12 \text{ atm cm}$ ) within the tropospheric layer of maximum temperature in perturbed simulations. This value matches that specified in global simulations described next, and was chosen to achieve radiative forcings of order  $1 \text{ W m}^{-2}$ .

We conduct two simulations (control and experiment) with the Community Earth System Model (CESM) version 1.0.6 (e.g., Hurrell et al., 2013), configured with fully coupled atmosphere, ocean, and land model components (component set “B\_1850” with horizontal resolution of  $1.9 \times 2.5^\circ$ ). Both simulations start in 1850 from identical equilibrium climate states and have annually repeating boundary conditions, including prescribed 1850 concentrations of carbon dioxide, methane, nitrous oxide, and ozone. As with the MODTRAN simulations, all CFC concentrations are zero in the control simulation, and in the idealized experiment we apply a CFC-11 mass mixing ratio of 10 ppm within a single atmospheric layer (the fourth from bottom, spanning roughly 770–1,365 m above the surface), uniformly over  $66\text{--}90^\circ\text{N}$  during the months of December through February, and uniformly over  $66\text{--}90^\circ\text{S}$  during the months of June through August. These polar winter environments exhibit persistent near-surface inversions. In the control simulation, peak tropospheric temperatures occur, on average, in the layer where we apply CFC-11 (Figure 2). However, temperatures peak

**Figure 2.** Vertical profiles of temperature from CESM simulations, averaged over the Arctic (66–90°N) during December–February, the Antarctic (66–90°S) during June–August, and a portion of the East Antarctic Plateau (80–85°S, 54–86°E) during June–August. The control simulation has no CFC-11, whereas the experiment applies a mass mixing ratio of 10 ppm in the model layer with mean extent shown in green shading.

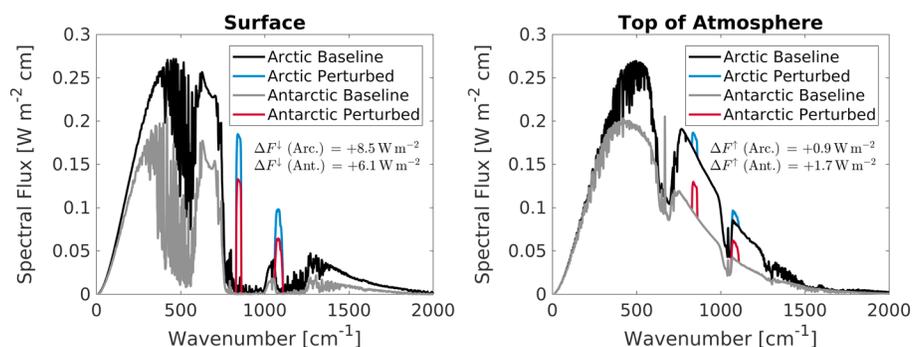

nearer to the ground over high-elevation areas of Antarctica (Figure 2) and Greenland (not shown), and hence, the radiative impact of this perturbation is somewhat reduced in these regions. The atmosphere component of CESM adopts a terrain-following hybrid-sigma pressure coordinate system, so the altitude above surface of the forcing layer is rather consistent, with standard deviation of 40 m over all perturbed grid cells. Although this experiment is unrealistic because it prohibits gas diffusion and mixing outside of the specified forcing layer, it serves as a boundary case for evaluating the impact of elevated GHG amounts in tropospheric inversion layers. We compare climatological mean states of the final 20 years of 100 year control and experiment simulations. Linearly regressed trends in surface temperature and net TOA radiative flux in the control run were not significant. We calculate the direct instantaneous radiative forcing (IRF) of CFC-11 at the TOA, 200 hPa, and surface by differencing radiative transfer calculations conducted each time step with and without the CFC-11 perturbation.

We conduct a second pair of CESM simulations to diagnose effective radiative forcing (ERF) (Hansen et al., 2005). ERF is calculated with fixed sea surface temperatures (SSTs) but allowing for all rapid adjustments to the atmosphere. ERF was adopted by the Intergovernmental Panel on Climate Change Assessment Report 5 and is suggested to be a better proxy of eventual surface temperature change but has the disadvantage of being noisier than IRF and requiring longer model integration (Forster et al., 2016; Myhre et al., 2013). Following techniques described by Forster et al. (2016), we conduct two 50 year atmosphere simulations with fixed annually repeating SSTs and sea-ice distributions representative of 1850 (component set “F\_1850”), with and without the 10 ppm CFC-11 perturbation. We derive ERF as the difference in net TOA radiative energy flux between these runs, with confidence intervals determined from interannual variations.

### 3. Results and Discussion

In general, longwave radiative perturbations induced by gas or cloud changes occurring at any particular altitude will depend on the vertical distributions of temperature and molecules that absorb in the same spectral region as the perturbed agent (e.g., Stephens et al., 2012). Single column MODTRAN simulations of clear-sky TOA and surface spectral fluxes for the situation explored here are shown in Figure 3. It is evident that the perturbation increases both OLR and surface downwelling irradiance, primarily via the strong CFC-11 absorption bands near  $840\text{ cm}^{-1}$  and  $1,080\text{ cm}^{-1}$ , which both lie in the water vapor window. Spectrally integrated changes in these fluxes (listed in the figure) are greater in the Arctic than Antarctic at the surface, and greater in the Antarctic at the TOA. These relative effects result from a warmer Arctic troposphere and a stronger Antarctic temperature inversion.

Figure 4 shows the all-sky IRF of the CFC-11 perturbation in the CESM experiment, averaged over December–February (Arctic) and June–August (Antarctic) of the first year of simulation. Consistent with the single-column MODTRAN calculations, we see that the TOA and 200 hPa IRFs are negative while the surface IRF is positive. The winter season TOA and surface IRFs averaged over the Arctic are  $-0.16$  and  $+1.11\text{ W m}^{-2}$ ,

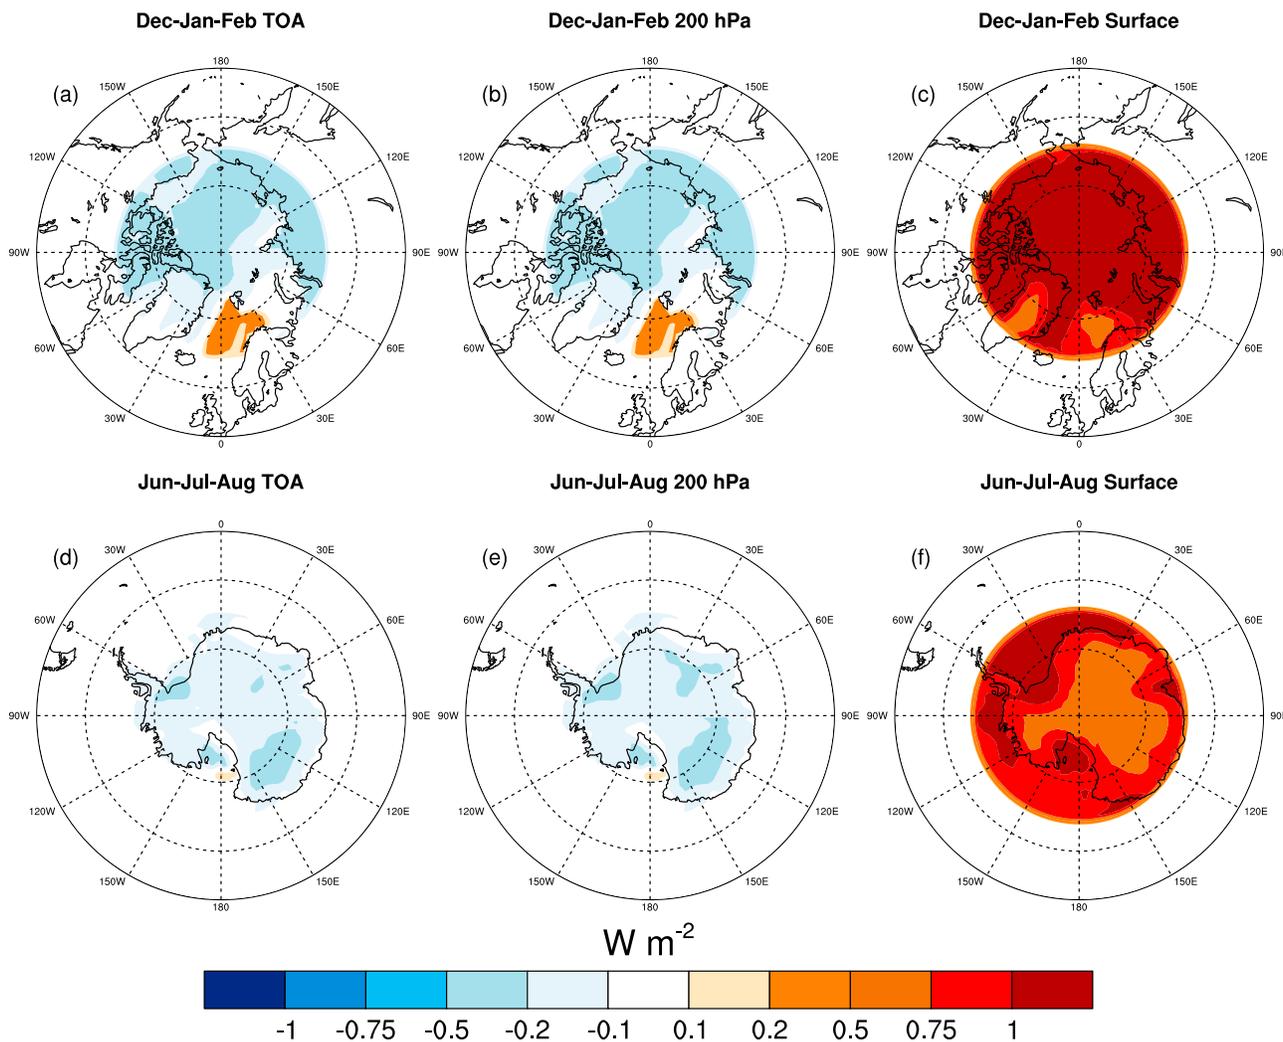

**Figure 3.** Surface (left) and top-of-atmosphere (right) clear-sky spectral fluxes calculated with MODTRAN using vertical atmospheric profiles from ERA-Interim reanalysis. Arctic profiles are from January 2008 and Antarctic profiles are from July 2008. The perturbed scenarios assume CFC-11 burdens of  $7.3 \text{ g m}^{-2}$  ( $0.12 \text{ atm cm}$ ) in the model layer of maximum tropospheric temperature.

respectively, and over the Antarctic they are  $-0.11$  and  $+0.88 \text{ W m}^{-2}$ . Figure 4 shows that the 200 hPa IRF, an approximation of forcing at the tropopause, is nearly identical to the TOA forcing, an unsurprising feature given that the perturbation is introduced in the lower troposphere. The TOA and 200 hPa IRFs are slightly positive in the Norwegian Sea where inversions are absent or weak. Moreover, the IRF is greater over low-elevation areas than over the high plateaus of Antarctica and Greenland. Temperature profiles show that the inversion tends to peak closer to the surface over high-elevation areas (Figure 2), slightly beneath the layer of imposed GHG increase. Hence, if the perturbation had been introduced lower, we would have seen larger forcing over central Antarctica and Greenland, and smaller forcing at lower elevations. We also note that the IRF weakens slightly throughout the simulation, due to Arctic warming and reduced inversion strength, with global annual mean IRFs of  $-28$ ,  $-27$ , and  $-25 \text{ mW m}^{-2}$  in the first year, years 2–20, and years 81–100, respectively.

Atmospheric temperatures respond to this unique forcing by cooling  $2\text{--}3^\circ\text{C}$  within the layer of elevated CFC-11 (Figure 2). Cooling of the warmest layer of the inversion is logically expected because emission from this layer increases more than the increase in absorption that also occurs. As can be seen in Figure 5, however, surface temperatures warm substantially in the months and regions of active forcing. This warming results from increased surface downwelling longwave flux and occurs despite tropospheric cooling caused by negative atmospheric and TOA IRF. The ability for thermal forcings aloft to affect surface temperature depends on the strength of surface-atmosphere coupling and turbulent energy transfer (e.g., Cess et al., 1985; Flanner, 2013; Ghan et al., 1988; Hansen et al., 1997, 2005). The polar winter atmosphere is characterized by high stability and near-surface thermal inversions (e.g., Connolley, 1996; Phillpot & Zillman, 1970; Serreze et al., 1992). Thus, surface perturbations drive larger surface temperature change than in other environments (Bintanja et al., 2011, 2012; Deser et al., 2010; Pithan & Mauritsen, 2014), in this case enabling the longwave surface forcing to dominate over tropospheric cooling, from which the surface is relatively isolated, and cause net warming of the surface. Winter season surface warming in this experiment is  $4.5 \text{ K}$  in the Arctic and  $2.2 \text{ K}$  in the Antarctic, and these changes are highly significant ( $p < 10^{-10}$ ) as indicated by  $t$  tests on pooled annual realizations. Arctic surface warming exceeds that in the Antarctic. Moreover, divergence between control and experiment Arctic surface temperatures continues to grow throughout the 100 year simulations, indicating that Arctic feedbacks operate to enhance surface warming in the experiment. Indeed, Arctic annual mean sea-ice coverage decreases by 9.3% in the experiment, serving to amplify near-surface warming. Weaker surface warming over the Antarctic continent is therefore a consequence of both weaker local feedbacks and lower surface forcing, which results from the slight offset between altitudes of gas perturbation and peak temperature described earlier.

The global annual mean surface temperature response in this experiment is  $+0.2 \text{ K}$  (significant at  $p < 0.0001$ ), with weak warming outside of the polar regions (Figure 5c). The ERF diagnosed from fixed-SST runs is  $-0.09 \pm 0.07 \text{ W m}^{-2}$  in the global mean,  $-3.2 \pm 0.9 \text{ W m}^{-2}$  in the Arctic during December–February, and  $-3.1 \pm 1.0 \text{ W m}^{-2}$  over Antarctica during June–August. Thus, surface temperatures warm in this experiment despite negative ERF and IRF at the TOA and 200 hPa. This therefore represents a rare case where radiative forcing is a poor proxy for surface temperature response. Early studies of nuclear winter also expose unusual relationships between radiative forcing and surface temperature change. Cess et al. (1985), in particular,

### Longwave Radiative Forcings

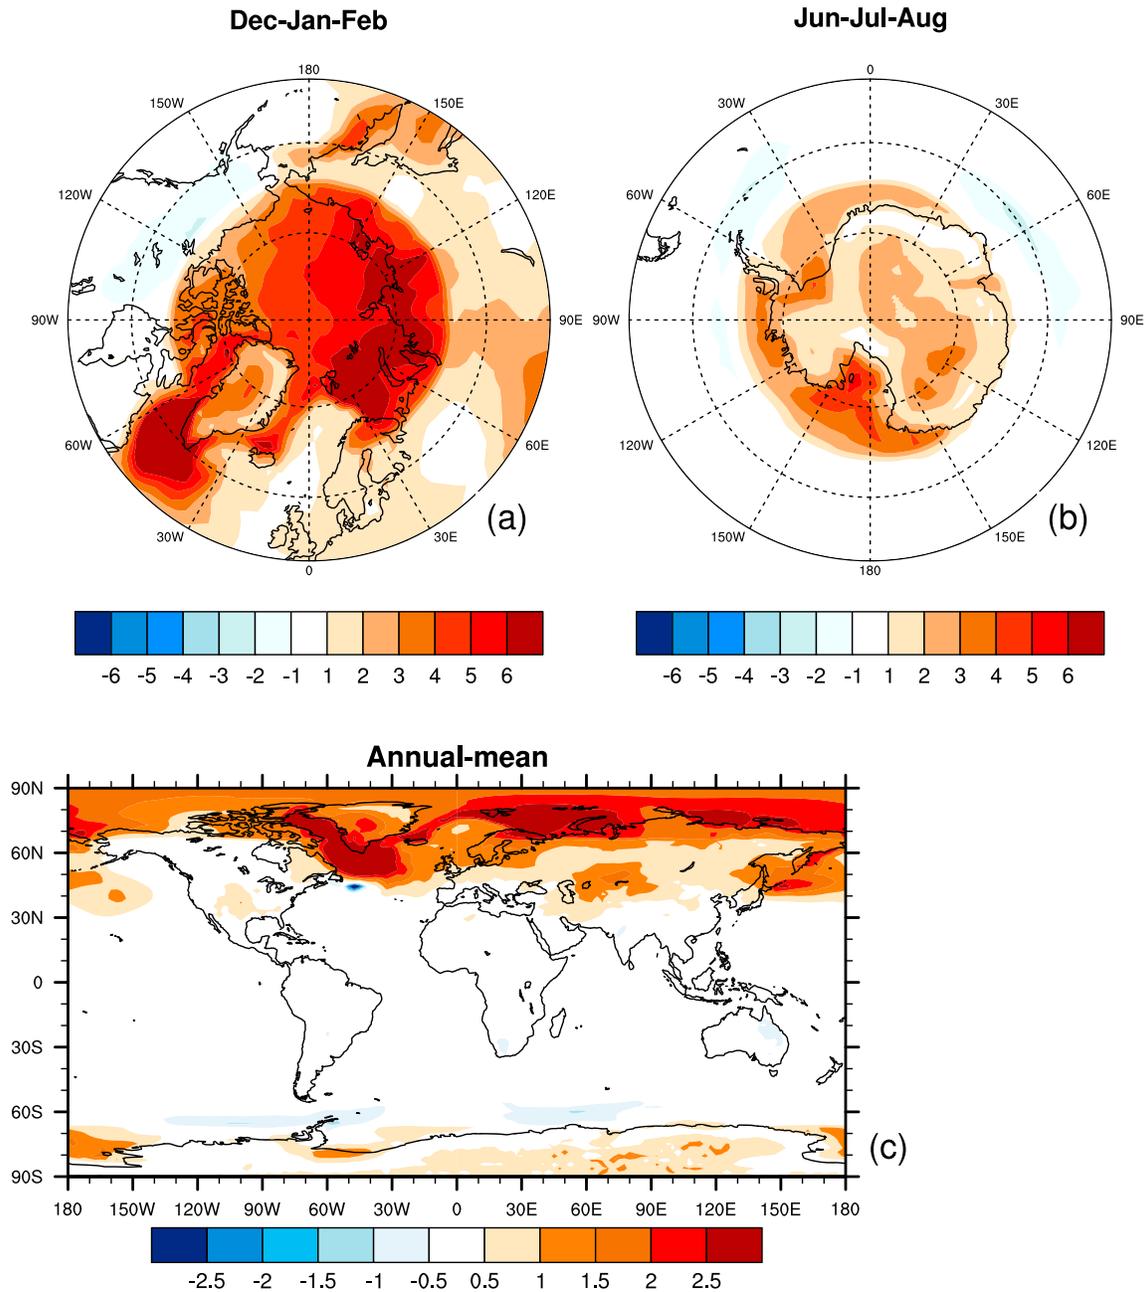

**Figure 4.** Instantaneous perturbations to the (a, d) top of atmosphere, (b, e) 200 hPa, and (c, f) surface radiative energy budgets caused by the addition of CFC-11, averaged over December–February (Figures 4a–4c) and June–August (Figures 4d–4f) in the CESM experiment simulation.

describe the inadequacy of traditional radiative forcing metrics when the surface becomes convectively decoupled from the troposphere, a situation not unlike the weak coupling that exists naturally during polar winter. Ghan et al. (1988) and Thompson et al. (1987) both show that increasing aerosol infrared absorptivity causes the surface to cool less from nuclear explosion-induced smoke, due to the associated increase in downwelling infrared flux at the surface. Although TOA forcings associated with this greenhouse-like effect were not reported, they were presumably negative due to the extreme heating that had occurred within the smoke layer. Hansen et al. (1997) also show that normalized climate response to certain idealized forcings can be “less well behaved,” though not to the extremity shown in our experiment. Despite the deficiency of radiative forcing metrics in this unique situation, we note that ERF is a good proxy for climate response to globally distributed forcings of the type and magnitude that are currently operating (Hansen et al., 1997, 2005; Myhre et al., 2013).

Attribution of surface warming to weak surface-atmosphere coupling in our experiment implies a result whose magnitude is model dependent, and indeed other studies show that model parameterizations of vertical mixing and atmospheric stability can strongly affect surface temperature response (Bintanja et al., 2011, 2012; Ghan et al., 1988). With strong surface-atmosphere mixing, however, the temperature inversion would collapse and radiative forcing from the perturbation would consequently become positive. Hence, the very

### Experiment – Control Surface Temperature Change [K]

**Figure 5.** Differences in surface temperature between the final 20 years of the experiment and control CESM simulations, averaged over (a) December–February, (b) June–August, and (c) the annual mean.

situation that permits negative GHG radiative forcing also enables surface warming to occur in spite of the negative forcing. Furthermore, because the temperature response profile acts to weaken the inversion, the IRF becomes less negative with time in the experiment. Finally, we conclude that because greenhouse gas increases do not produce surface cooling in this extreme scenario, in which the gas perturbation is confined to the inversion layer, it is highly unlikely that surface cooling would result from more realistic scenarios that include transport of gas injections. This is because mixing would promote positive ERF to occur in more regions, leading to tropospheric and surface warming happening through the canonical greenhouse forcing mechanism.

#### 4. Conclusions

Motivated by previous work showing that greenhouse gas radiative forcing can be negative in polar regions (Huang et al., 2016; Schmithüsen et al., 2015; Shell et al., 2008; Soden et al., 2008; Stevenson et al., 2013), we conducted an idealized Earth system model experiment to explore the climate impacts of elevated GHG concentrations within polar tropospheric inversion layers. We find that the polar surface warms in response to increased downwelling infrared flux. This occurs despite cooling of the tropospheric layer subjected to increased greenhouse gas and also despite negative instantaneous and ERF exerted at the TOA and tropopause. These findings demonstrate that negative radiative forcing associated with GHG additions in extreme polar environments should not be used to infer that local surface cooling will result. More generally, these results illustrate the importance of surface radiative forcing for governing surface temperature response in polar regions, where stable atmospheric conditions, especially during winter, act to decouple the surface from the atmosphere.
