#### 11 Abstract

12 The interplay between mechanical stresses and electrochemical reactions may lead to stress

13 corrosion cracking or hydrogen embrittlement for many materials. In this work, the effect of

- 14 the tensile stress on the electrochemical properties of AISI 304 stainless steel was studied
- 15 using scanning Kelvin probe (SKP) in air and scanning electrochemical microscopy (SECM)
- 16 in an aqueous  $0.5 \text{ M} \text{ Na}_2 \text{SO}_4$  electrolyte. The measurements were performed under load- and
- 17 load-free conditions.
- 18 No influence of the elastic stress on the electrochemical potential of the steel was found. In
- 19 contrast, the plastic strain induces dislocations and dislocation pile-ups, which emerge to the
- surface. The formation of new active surfaces is accompanied by an increase in the roughness
   and a 150-200 mV decrease in the steel potential. After activation, the potential increased due
- to passivation of the emerging surfaces by a newly grown oxide film, which took place under
- both the load and load-free conditions and followed a time dependence of  $\boldsymbol{\varphi} = A \log t + B$ .
- Formation and then passivation of the new surfaces increased and then decreased the
- reduction current of the mediator in the SECM measurements. The effect of residual stress
- stored in the steel due to the development of dislocations on the reactivity of the re-passivated
- 27 surface was investigated.
- 28

## 32 **1. Introduction**

33 The passivity and stability of passive oxide films play important roles in the susceptibility of

- 34 stainless steels to local corrosion phenomena such as pitting and stress corrosion cracking
- (SCC). The breakdown of the passive film by either mechanical or chemical factors is one of
   the important issues in the theory and understanding of SCC. According to the slip–
- dissolution model, cracks develop due to cycling processes resulting in successive active film
- rupture and dissolution and film repassivation processes. The film rupturing occurs due to the
- application of tensile stress generated by mechanical loading of the bulk of the material [1].
- 40 In addition, breakdown of the passive film can result from the migration of dislocations and
- dislocation pile-ups to the metal surface [2]. The strain rate and the surface repassivation rate
- 42 inside the crack are key factors in the propagation of SCC [3-6]. Metallic structures are often
- 43 working under an elastic stress load. The impact of elastic stress and plastic deformation on
- 44 electrochemical properties is worth studying in detail.

- 45 Plastic deformation significantly increases the anodic dissolution rates of many metals when
- 46 compared with the influence of elastic deformation [7]. The dissolution rate shows a marked
- 47 rise at the beginning of the plastic region, whereas an increase in sample elongation leads to
- an asymptotic value for the dissolution rate. Plastic deformation increases the surface
- 49 roughness and creates slip edges and dislocations, which contributed to and accelerate the
- anodic dissolution of the metal [7]. The effect of yielding on the anodic dissolution has been
- observed for stainless steel and was explained by Gutman using a thermodynamic approach
  [8, 9]. Selective slip dissolution is the result of a local excess in the Gibbs potential of an
- elastic stress field at the dislocation and slip bands [9]. Additionally, Sahal et al. [10] and
- 54 Saito and Kuniya [11] showed that the dissolution rate of Ni in an acidic electrolyte is
- 55 proportional to the dislocation density created by the plastic strain. Thus, the surface
- roughness associated with the emergence of slip bands accelerated the dissolution process
- 57 [12].
- 58 Surface passivation is a competitive process for mechanical activation in the stress field. To
- 59 describe the kinetics of passivation, scratched or abraded electrodes of different types of steel
- 60 have been used in aqueous electrolytes following a technique developed by Burstein [13].
- After mechanical removal of the surface oxide, rapid repassivation can be observed with currents reaching  $10 \text{ A/cm}^2$  for AISI 304 steel. The rate of film growth has been shown to be
- 63 controlled by a high-field ion conduction mechanism. For stainless steel, the first step of
- 64 oxide film formation is oxygen adsorption. Thickening then occurs by migration of metal 65 cations, oxide anions, or their vacancies under the influence of an electric field [14]. Thus, 66 according to the field assisted ion migration theory, film growth is limited by ion migration, 67 which is driven by the electric field in the oxide, and the growth of the film decreases the 68 electric field, thus reducing the growth rate. Normally, the repassivation kinetics of AISI 304 69 austenitic steel follow the relation  $i = K \cdot t^b$ . Here, b characterizes the ability of the surface to 70 passivate [14], and the thickness of an oxide film (L) can be obtained through integration of 71 the current decay during passivation at a fixed potential according to equation 1:
- 71 72

#### L=A log(t) + const.

73

On the other hand, the Cabrera–Mott theory for the growth of a passive film predicts that the inverse of the oxide thickness varies logarithmically with time, as given in equation 2 [15]:

76

#### $1/L = B \log (t) + const.$

#### Eq. 2,

Eq. 1

- 77 where A and B are constants and t is the time of passivation.
- 78 Plastic deformation of stainless steel may modify the passive oxide film [16-20] and the alloy
- bulk [21-24]. It has even been shown that elastic deformation due to local microplasticity can
- 80 produce microcracks in the passive film and accelerate dissolution [16]. Plastic deformation
- of austenitic stainless steels leads to the formation of  $\alpha$ -martensite, which decreases the
- 82 ability of the steel to passivate [21-23]. Martensite has been found in deformed areas, where
- slip planes had intercepted the passive film and a large number of dislocations were
- 84 concentrated. A less protective passive film is the result of cold work, which has been
- attributed to the presence of defects such as dislocation pile–ups at the grain boundaries [21].
- From the point of view of Y. Boudinar et al., steel hardening, residual back stress,
- dislocations and slip bands enhance the surface reactivity and kinetics of anodic dissolution[24].
- 89 The properties of stressed surfaces have been investigated using classical electrochemical
- 90 techniques, such as measurement of the open circuit potential (OCP), DC polarization
- 91 techniques and electrochemical impedance spectroscopy (EIS). Normally, tensile deformation

decreases OCP and the modulus of the impedance of steel. However, the data obtained using 92 these global measurements were averaged over the entire surface area exposed to the 93 electrolyte, which makes difficult to associate any variations in the results to breaks in the 94 oxide film, pitting formation, and the emergence of dislocation or slip bands. However, local 95 electrochemical microprobe techniques can be used to correlate the surface heterogeneities 96 (phases, grains, inclusions, etc.) to the electrochemical processes at the microscale. Thus, 97 98 local electrochemical impedance spectroscopy (LEIS) [25], scanning electrochemical microscopy (SECM) [26-28], and scanning Kelvin probe (SKP) [25, 29, 30] provide efficient 99 ways to characterize the surface reactivity due to plastic deformation. Using SECM in the 100 electrolyte, it has been found that the rate of electron transfer from the steel surface (oxide 101 film) to a molecule of the redox mediator decreased with increasing of strain [26]. This 102 unusual result indicated the inhibiting influence of the tensile strain on the rates of 103 104 electrochemical processes. However, this effect was also in line with an SECM study [27] that showed elastic stress applied to stainless steel electrodes slightly decreased the surface 105 electrochemical activity. Conversely, an SECM study of a notched sample [28] noted that 106 residual plastic stress increased the electrochemical activity. Thus, SECM studies have shown 107 108 conflicting results regarding the effect of stress on the reactivity of a stainless steel surface. SKP mapping of the Volta potential in air has been useful for finding the electrochemical 109 heterogeneity above stressed stainless steel electrodes [25, 29, 30]. Thus, the application of 110 the tensile and compressive stresses locally decreased the Volta potential of 301LN austenitic 111 steel because the plastic deformation creates dislocations and dislocation slips that break 112 down the oxide film. 113 Thus, only a small number of studies have used local electrochemical techniques to study 114 stressed steel surfaces, whereas these surfaces play significant roles in phenomena such as 115 stress corrosion cracking. The present study reports the effect of tensile stress on the 116

- electrochemical properties of AISI 304 steel surfaces. SKP and SECM were applied to study the electrodes either in air or in electrolytic environments. The potential variations in air due
- to stress constraints were compared with open circuit potential (OCP) transients measured in
   a non-aggressive aqueous Na<sub>2</sub>SO<sub>4</sub> electrolyte. The potential measurements provide
   information regarding the steel passivation and possible electrochemical reactions occurring
- at specific locations. SECM allowed us to determine the rate of electron transfer and the local
   reactivity of the strained surface in an aqueous electrolyte. X-ray photoelectron spectroscopy
- 124 (XPS) was employed to characterize the effect of stress on the composition of the oxide film.
- 125

### 126 **2. Experimental**

### 127 2.1 Materials and mechanical properties of the samples

128 The composition of the AISI 304L stainless steel used in this study is reported in Table 1. The initial grain sizes were in the range of 10-20 µm. A thermomechanical treatment was used to 129 increase the grain sizes to the range of 50 to 80 µm, and the final microstructure of the 130 surface is shown in Figure 1. For this, the samples were tensile pre-strained at 30%, heated at 131 1030°C for 20 min under argon gas flux and cooled in air. Prior to the heat treatment, the 132 samples were mechanically ground with 4000 grit SiC paper. After the heat treatment, 133 grinding was used to remove the oxide layer. Finally, fine polishing was performed using 1 134 um diamond paste. The samples were degreased in ethanol, rinsed in deionized water and 135 stored in dry air. It was previously found [29] that the potential of steel significantly depends 136 on the conditions of the oxide film. To obtain more uniform surface oxide films, the samples 137 were heat treated at 100°C for 1 h. 138

- Tensile samples were prepared from a 0.5 mm thick plate that was machined to obtain 139
- samples compatible with both the local probe techniques used and the *in situ* tensile setup. A 140
- schematic representation of the samples is shown in Figure 2. This specific shape was 141
- selected to obtain stress/strain gradient in the diminution area of the sample. The initial gauge 142
- length of the specimen was 10 mm. Local measurements were performed over the gauge 143 section of the sample, which is the location with the maximum stress and strain, and over the 144
- surrounding diminution areas of the sample. The mechanical properties were determined by 145
- tensile testing of flat samples (Figure 2. a) with a strain rate of 0.0067 s<sup>-1</sup> using a hydraulic 146
- tensile testing machine (HC25 from Zwick). Figure 2. b shows a representative stress-strain-147
- load relationship for a sample. The yield strength (YS) was evaluated at 300 MPa. 148
- corresponding to 1.5 kN. The ultimate tensile strength (UTS) was 650 MPa with an 149
- experimental load of 3.25 kN. The elongation to failure was in the range of 46-48%. 150
- To evaluate the local plastic strain and stress, calculations were performed by finite elements 151
- modeling with ABAQUS software using the tensile properties of the steel. An example of a 152
- local strain distribution in a tensile sample for an imposed total displacement of 6 mm is 153 shown in Figure 2. c. In this figure, the indicated values of 12.1 and 43 mm are set to show 154
- the spreading of the plastic deformation over the gauge section of the specimen, which was 155
- initially 10 mm long. Indeed, some non-negligible plastic deformation was found up to 21.5 156
- mm from the center of the specimen. The deformation in the gauge section was 157
- approximately 27% in this case corresponding to a plastic of 0.267. Based on these 158
- simulations, the extent of the plastic strain over the sample can be estimated. To compare the 159
- experimental data and simulation results, the total elongation of the tensile sample and the 160
- applied load were used as entry data for simulations. 161
- 162 To apply the load during the SKP and SECM measurements, a constant load cell was used.
- After mounting the sample on the setup, a load gauge was installed either in the SKP chamber 163
- or on the moving table of the SECM instrument. A detailed description of the setup has 164
- previously been reported [25, 29]. A load gauge and "Mitutoyo" digital caliper were used to 165
- control the load and elongation, respectively. 166
- 167

#### 2.2 Scanning Kelvin probe 168

SKP is a non-invasive technique that measures the contact potential difference between a 169

working electrode (*i.e.*, the AISI 304) and a vibrating reference electrode (CrNi alloy needle). 170

- In air, the two surfaces are separated to create a capacitor in which, due to the vibration and 171 the variation of the distance, an AC current is generated. The current amplitude is
- 172
- proportional to the contact potential difference between the two electrodes. The potential of 173
- the probe is calibrated, which makes it possible to determine the potential of the working 174 electrode relative to that of the reference. Thus, SKP is able to either determine the surface 175
- distribution of the Volta potential or monitor the Volta potential at a single point above the 176
- surface. Details and the theory of SKP can be found in the literature [31]. 177
- In this study, a height-controlled SKP instrument from Wicinski & Wicinski GbR was used. 178
- 179 The reference electrode was a needle with a tip diameter of 100  $\mu$ m, and the distance to the
- working electrode surface was approximately 50 µm. Surface contour mapping (topographic 180
- profile) was performed simultaneously with the potential mapping. Prior to the measurement, 181
- the potential of the probe was calibrated relative to that of a Cu/CuSO<sub>4</sub> electrode, but all 182
- potentials are given versus the standard hydrogen electrode (SHE). The measurements were 183
- performed in ambient air at 50-60% RH. 184

SKP measures the Volta potential that, after calibration using a reference reversible electrode, 185 corresponds to the electrochemical potential [31, 32]. In dry air conditions, the measurement 186 relates to the potential of steel in the passive state. The potential is controlled by the redox 187 potential of the surface species [31]. In air, the steel is covered by an oxide film, maintaining 188 passive conditions. The thickness of the oxide film influences the Volta potential [29]. The 189 formation or failure of the passive film significantly changes the steel potential as measured 190 by SKP [29]. We can expect SKP to measure the potential drop  $(X_w)$  across the oxide film 191 and in the Helmholtz layer of the molecules adsorbed from the air (Eq. 3). 192

193

$$X_w = \frac{\mu_{ox} - \mu_e}{e} + F_b + \beta_{ox/air}$$
(Eq.3)

194 The first term is the contact potential difference between the bulk alloy and oxide film, which 195 relates to the difference in the corresponding Fermi levels of the electrons in the metal ( $\mu_e$ ) 196 and in the oxide ( $\mu_{ox}$ ), *e*- is the elementary charge. The second potential drop ( $F_b$ ) relates to 197 the adsorption of environmental components (molecules of oxygen, water, etc.), which alters 198 the conduction and valence bands in the semiconducting oxide film. The electric charges in 199 the oxide are compensated for by the charges of the adsorbed species (e.g.,  $O_2^-$  ions), creating 200 a potential drop ( $\beta_{ox/air}$ ).

201

#### 202 2.3 Scanning electrochemical microscopy (SECM)

SECM was used to measure the effect of stress on the local electrochemical reactivity of the 203 steel surface in an aqueous electrolyte (0.5 M Na<sub>2</sub>SO<sub>4</sub>) in the presence of a redox mediator 204 (either 10 mM K<sub>3</sub>(Fe(CN)<sub>6</sub>) or 1 mM ferrocene methanol). The measurements were 205 performed in a 4-electrode electrochemical cell (using a Pt-grid counter electrode and a 206 saturated calomel reference electrode). The cell was attached to the surface of the gauge 207 section of the tensile sample using O-rings. The area of the sample exposed to the electrolyte 208 was 0.35 cm<sup>2</sup>, and the volume of the aqueous electrolyte in the cell was approximately 10 209  $cm^3$ . 210

211 The radius of the platinum microelectrode was  $12.5 \ \mu m$ . SECM approach curves were

212 performed to position the Pt microelectrode at a controlled distance from the sample. The

electrolyte resistance was simultaneously monitored with the local current. As such, the

current variation gives information about the surface reactivity whereas the electrolyte

resistance gives information about the topography. The size of the scanned area was 500 x  $500 \text{ }\mu\text{m}^2$  at a scan rate of 10  $\mu\text{m/s}$ . This value was selected as a tradeoff value between the

experiment duration (about 40 min. per map) and minimizing the risk of crashing the tip into

the working electrode surface. All the experiments were performed at least 2 or 3 times at

- 219 different locations above the sample.
- 220

#### 221 2.4 XPS analysis

222 X-ray photoelectron spectrometry (XPS, Kratos Axis Ultra DLD) was used to investigate the

effect of plastic strain on the passive layer of 304L stainless steel. Specific samples were

prepared from 20 mm width and 0.5 mm thick strips. An unstrained reference sample and a

sample strained at 20% plastic deformation were investigated using angular analysis at  $0^\circ$ ,

 $30^{\circ}$  and  $60^{\circ}$ . High-resolution spectra were obtained for the Fe, Cr, O and C elements. From

the relative intensities of the Cr and Fe oxides and their corresponding metallic peaks, the

- thickness of the passive layer was evaluated by considering a bilayer, with a  $Cr_2O_3$  inner
- layer and a  $Fe_2O_3$  outer layer. Physical data were obtained from the literature [33]. The

spectrum of the O element was de-convoluted to evaluate the relative amounts of  $-O_2$ , -OH

- and  $H_2O$  bonding.
- 232

### 233 2.5 3D Optical profiling for surface topography visualization

Plastic deformation creates dislocations and dislocation pile-ups. To evaluate the effect of

- stress on the surface roughness, a light profiler (Veeco/Wyko NT1100) was used. The
- technique is based on using light interferometry to obtain high-resolution 3D surface images.
- 237

#### 238 **3. Experimental Results**

#### 239 3.1 Effect of tensile stress on the potential of 304 stainless steel.

SKP was used to find the effect of stress on the electrochemical potential of steel at the center 240 of the specimen including the gauge section and the surrounding area of the tensile sample as 241 shown in Figure 2.a. The initial potential distribution across the gauge section was constant at 242 ca.  $370 \pm 5 \text{ mV}$  vs. SHE. Figure 3 shows the distribution of the potential after application of a 243 350 MPa tensile load, corresponding to approximately 3% of deformation in the gauge 244 section. As shown in the stress-strain dependence graph (Figure 2.b), this load corresponds to 245 the beginning of the plastic deformation range. The stress decreases the potential at all 246 measured areas (corresponding to a length of 30 mm). However, at the center of the gauge 247 section, the potential was more negative than at the other measurement locations, which is in 248 249 good agreement with the stress distribution model depicted in Figure 2.c. When the sample was exposed to the load for 5 h, the potential at all points along the sample increased by 20 250 mV (Figure 3.b). However, removing the load and performing the potential measurement at 251 252 the rest does not change the potential profile, as shown in Figure 3.c. Loading to yield sets the 253 elastic stress, whereas unloading removes the elastic stress. Because unloading does not change the electrochemical potential, it is assumed that the elastic stress has no influence on 254 255 the thermodynamics of the electrode. The measurement was repeated 24 h after unloading, and the potential above all the surfaces increased by 10-20 mV (Figure 3.d). 256

- 257 The stress and stain distributions in the sample were modeled using the same deformation of
- 258 3%. The plastic strain profile is shown in Figure 3.a. The plastic strain was mainly
- concentrated at the center of the sample in the gauge section but also spread out from this
- area. At this elongation, plastic strain existed up to 10 mm from the center of the sample with a steep gradient moving outwards from the gauge section
- a steep gradient moving outwards from the gauge section.
- A higher load (2.7 kN 540 MPa) was applied to a tensile sample, reaching a deformation of 263 20% in the gauge section, and the potential distribution presented in Figure 4 shows that the
- length of the stress-affected area was approximately 35 mm. A similar length was determined
- using the model presented in Figure 2.c. The initial potential profile was constant at 0.38 V
- vs. SHE, and due to the strain, the central area and the edges of the affected zone were
- characterized by lower potentials of 0.2 0.16 V vs. SHE. Thus, the plastic deformation
- decreased the potential of AISI 304 steel by about 180-220 mV, which is in agreement with
- the effect reported for 301LN stainless steel [25, 29].
- 270 The profile presented in Figure 4.b was measured after unloading and exposure to ambient
- air. The potential in the gauge section increased to 0.32 V vs. SHE and corresponded to the
- presence of residual stress, which can be ascribed to the dislocation field. Thus, it is possible
- to conclude that plastic deformation initially decreased the potential and then subsequently

increased the potential. It can be assumed that the decrease in the potential was linked to the
emergence of new strain-induced surfaces (dislocations) [25, 29]. The increase in potential
was related to the passivation of the newly formed metallic surfaces.

The impact of the tensile stress on the potential in the center of the gauge section was 277 measured as a function of the load (Figures 5 and 6). At 220 MPa, corresponding to 0.33 % of 278 strain, in the elastic domain, no effect of the load on the potential was observed. However, 279 further increasing the load in the plastic deformation domain proportionally decreased the *in* 280 281 situ potential of the surface measured under loading (Figures 5.a, c and Figure 6.a). The 282 potential in Figures 5.a, c varies over a range from 7 to 10 mV, which is close to the noise level. Thus, the potential was relatively uniformly distributed without forming any ordered 283 structures (taking into account a spatial resolution limit of 70-100 µm for the SKP 284 instrument). However, the plastic stress creates dislocations that increase the surface 285 roughness Figures 5.b, d (Table 2). 286

- 286 Toughness Figures 5.0, d (Table 2).
- 287 The graph presented in Figure 6.a shows that at lower loads, the potential decreased
- proportionally with the strain, and for larger elongations, the potential approaches a limit
- value of approximately 0.14 V vs. SHE. The graph contains the data for the maximal and
   minimal potentials measured in each map. After the profile measurements (Figure 5), the SKP
- tip was positioned above the surface to monitor possible changes in the potential (Figure 6.b).
- The evolution of the potential over 1000 s under a constant applied load shows that the=
- potential slowly increased during exposure in air, which can be ascribed to the passivation of=
- the newly formed surface.
- 295 The passivation process in air at 60% RH for a pre-strained sample was monitored for a longer period of time (*i.e.*, 19 h, as shown in Figure 7). The potential variations were modeled 296 using a regression function,  $\varphi = A \log(t) + const$ , which can mimic equation 1 related time-297 dependent growth of the oxide film. In Figure 7, regression line 2 shows that the experimental 298 dependence can be described by a logarithmic function. Coefficient A relates to the rate of 299 passivation, and R is a regression coefficient (Table 3). A small amount of strain shows a low 300 rate of passivation that then increases for higher loads. The probe is localized above a surface 301 302 containing unaffected passive areas and the newly formed low-potential surfaces of the emerged dislocations. At low loads, the potential is averaged over the active and passive 303 locations. At high loads, all the surfaces in the gauge section are relatively active. In this case, 304 the probe monitors the passivation kinetics, which is nearly logarithmic (Table 3). Thus, the 305 coefficient A depends on the ratio of active to passive surfaces, whereas the rate of 306 passivation for a single dislocation must be determined using high spatial resolution 307 electrochemical measurements. 308
- 309 To evaluate the effect of the elastic stress, the SKP maps were measured for the pre-strained
- 310 gauge section (20% straining) under loading and load-free conditions (Figure 8.a, b).
- 311 Unloading does not change the potential. This is in agreement with results obtained for low
- strains (Figure 3.b, c). Thus, it can be assumed that the potential of the strained surface is
- mainly determined by the density of the emerging dislocations and by their passivation due to
- 314 coming into contact with air.
- 315 These results show that the emerged dislocations could be passivated either under an applied
- load or at the rest condition. The elastic stress has no influence on the potential of the
- 317 plastically strained surface. However, it can increase the distance between surface atoms,
- 318 which will affect the surface reactivity, *i.e.*, on the oxygen adsorption and the formation of
- the surface oxide film. Thus, it is important to compare the rates of passivation and the
- 320 reactivity of the strained surfaces under loading and at rest. To determine the effect of loading

- on the rate of passivation, the tensile sample was strained at 20%. Figure 9.a shows the
- monitored potential in the center of the gauge section after application of the strain ( $1^{st}$  cycle).
- After 2400 s, the sample was unloaded, and the potential was monitored at the same location 224
- (unloaded, 2<sup>nd</sup> cycle). Figure 9.a shows that the curves of the first and the second cycles are
   parallel, indicating similar rates of steel passivation under the elastic stress and at rest. Figure
- 9.b compares the passivation curves obtained from two different samples after straining up to
- 20% in the gauge section. In one sample, the potential was monitored under loading, and in
- the second sample, the potential was monitored at rest. Both curves approach the potential
- measured before the stress was applied (Figure 9.b, curve 1). The experimental results show
- similar rates of passivation without significant influence from the applied elastic stress.
- The surface of AISI 304 was pre-ground by using 4000 grit emery paper and then rinsed in ethanol. The potential above the steel was monitored 5 min after the surface treatment. Figure
- 10 compares the transient potentials after grinding and after straining at 15%. For the
- 334 prestrained surface, potential monitoring was carried out under load-free conditions. Grinding
- produced a small amount of compressive stress without the emergence of dislocations [16]. In
- the case of plastic deformation, dislocations participate in passivation, and the potential was
- mainly determined by the dislocation density. The potential monitoring (Figure 10) shows the
- 338 qualitative similarity of steel surface passivation after either straining or grinding.
- 339

### 340 3.2 Straining of an AISI 304 tensile sample in an aqueous electrolyte

The effect of tensile stress on the OCP was measured by a saturated calomel reference 341 electrode in an aqueous 0.5 M Na<sub>2</sub>SO<sub>4</sub> electrolyte. For this purpose, a small electrochemical 342 cell was attached to the gauge section of a tensile sample using a rubber O-ring. Figure 11 343 shows the OCP response after straining at 10% of plastic strain. The application of stress 344 decreased the OCP by 150-200 mV, and then the potential increased due to passivation of the 345 newly formed surfaces. The same sample was strained by an additional 10% of plastic strain, 346 and a similar decrease in the OCP was obtained, followed by a slow increase. Thus, the 347 influence of plastic deformation on the potential in an aqueous electrolyte compared 348 favorably to the SKP results obtained in air (Figure 7, 10). Another sample was directly 349 350 strained at 20% of plastic strain, and the passivation was monitored, as illustrated in Figure 11.b. The resulting passivation curve in the electrolyte could be fit with a logarithmic 351 regression with a coefficient A equal to 0.03 (Table 3). The passivation curve in an aqueous 352 353 electrolyte was also measured after grinding a steel electrode, which gave a similar passivation curve. Thus, the effects of stress on surface activation and subsequent passivation 354

- in an aqueous electrolyte are similar to those observed under ambient air conditions. These
- data are in agreement with previously reported OCP measurements performed on AISI 305
- 357 steel in a NaCl electrolyte [18].
- 358

## 359 3.3 SECM study of the passivation of AISI 304 steel

360 The effect of the tensile strain on the local electrochemical reactivity was studied in the same

- 0.5 M Na<sub>2</sub>SO<sub>4</sub> aqueous electrolyte. SECM was used to assess the passivation of the emerging
   dislocations under loading (Figure 12).
- Figure 13 shows the logarithmic scale time dependencies for the mediator reduction currents
- 364 (measured at the open circuit potential). The rates of passivation (slopes of the straight lines)
- are the same for strains of 5% and 8%. On the other hand, an increase in the strain is

accompanied by an increase in the tip current, which was attributed to an increase in the
density of dislocations emerging from the surface. Thus, the rate of passivation as a function
of the plastic deformation can be determined. These results show that after the application of
a plastic deformation, the steel becomes more active (from an electrochemical point of view),
and passivation upon exposure to air or in an inert aqueous electrolyte is a relatively longterm process.

#### 372 3.4 SKP and SECM studies of surfaces containing residual stress.

Plastic deformation often occurs during the production of steel. The deformation results in a 373 high defect density in the matrix, resulting in a less protective passive film [18, 22]. Thus, it 374 was reasonable to use SKP and SECM to study the surface of AISI 304 samples containing 375 residual stress. Figure 14.a shows the potential profile after applying 20% elongation using a 376 tensile machine followed by exposure to dry air for two weeks. We assumed that after this 377 time, the surface of the steel sample was close to the steady-state conditions. The left side of 378 the sample was under elastic stress and thus has no additional dislocations and can be 379 considered a reference. The right side of the samples was plastically deformed (Figure 14.a). 380 The gauge section (right side) showed a potential that was 30-40 mV lower than that of the 381

382 reference side.

The same sample was slightly ground using 4000 grit emery paper, rinsed and then exposed
to dry air for 2 weeks. The potential map presented in Figure 14.b shows that the substrate
containing residual stress (dislocations) was covered by an oxide film with a low potential.
Thus, a surface containing dislocations is able to re-passivate, but the oxide film shows

- different properties than those of the reference material (*i.e.*, the sample without residual
- stress). This can be explained as a result of an increase in the density of defects and changes in either the conducting properties of the oxide film its thickness on its composition. In fact
- in either the conducting properties of the oxide film, its thickness or its composition. In fact,grinding can add additional compressive or shear stress [16]. It can complicate the final
- distribution of residual stress and potential. Thus, more studies in this field is required.

After pre-straining the samples at different levels using a straining technique (see the 392 Experimental Section), they were exposed to dry air in a desiccator to stabilize the potential 393 and passivate the surface. The surfaces were then characterized by SECM and SKP to 394 evaluate the changes in their surface reactivity (Figure 15). SECM was performed using 395 396 ferrocene methanol as a redox mediator in an aqueous Na<sub>2</sub>SO<sub>4</sub> (0.5 M) electrolyte to study the reactivity of the surfaces as a function of the strain. The current variations (Figures 15.c 397 and e) indicate that the reactivity of the surfaces increase with increasing levels of applied 398 strain and, correspondingly, with increasing amounts of dislocations and residual stress. 399 Additionally, the SECM images show that even if the overall reactivity increases with 400 increasing loads, the reactivity is no longer homogeneous for loads corresponding to 20% and 401 30% deformations. 402

The SECM data are in good agreement with the SKP results (Figure 15.d, f), in which islandlike structures were also found. However, the differences in potential are relatively small (10-20 mV). It can be supposed that the island-like structures are the result of variations in the properties of the surface oxide film (thickness, composition, electron-hole density and conductivity) near the dislocations.

408

### 409 3.5 XPS study of the influence of strain on the passive film

- 410 XPS spectra were obtained for unstrained sample and a sample after 20% elongation. The
- time between applying the strain and the XPS measurements was rather long; thus,
- 412 repassivation of the surface had occurred. Using the model for a  $Cr_2O_3/Fe_2O_3$  bilayer, the
- total thickness of the passive layer on the unstrained sample was estimated to be 1.65 nm,
- with 0.64 + 0.13 nm of Cr oxide and 1.01 + 0.14 nm of Fe oxide. After straining, a slightly
- thicker layer was obtained, with a total thickness of 1.87 nm, corresponding to  $0.65 \pm 0.14$
- 416 nm of Cr oxide and  $1.22 \pm 0.04$  nm of Fe oxide. These measurements are in agreement with
- 417 literature data, which indicate a thickness of the passive film in the range of 1.5-2 nm for a
- 418 304L alloy [34].
- 419 The oxygen in the sample was also investigated, and the relative amount of  $-O_2$  and -OH
- 420 bonding was estimated using peak deconvolution. A representative example of the
- 421 deconvolution is given in Figure 16 for the unstrained sample analyzed at  $0^{\circ}$ . The
- 422 concentration was estimated using the area of each peak.
- 423 The results are shown in Figure 17. With increasing analysis angle, which results in an
- analysis closer to the top surface, the contribution of -OH increased for both the unstrained
- and strained samples. Thus, the top layer was most likely enriched with iron hydroxides, such
- as FeOOH. Interestingly, the contribution of -OH was systematically higher for the strained
- 427 sample and rather stable with respect to analysis angle. The increased amount of -OH groups
- 428 close to the interface in the pre-strained steel sample can result from the formation of a less
- dense oxide film. XPS analysis showed that the composition of the passive layer was affectedby the plastic deformation, without a strong influence on the thickness of the passive layer.
- 431

#### 432 **4. Discussion**

433 It is important to discuss the links between the potential measured by the SKP technique and

- the properties of the steel surface that influence mechanical activation. Equation 3 shows that
- the measured potential is proportional to the potential drop of the passive oxide film.
- According to the work of N. Sato, the potentials of different metals are proportional to the
- thickness of their oxide film [35]. For example, a linear dependence was experimentally
  determined for different alloys (e.g., Fe-Ni alloy) over a range of potentials related to the
- passivity [36]. Equation 4 shows the link between the potential of a passive metal ( $\varphi_M$ ) and
- 40 the corresponding oxide thickness and dielectric constant:
- 441

442 
$$\varphi_H = \varphi_M \left( 1 + \frac{L}{\partial} \frac{\varepsilon_H}{\varepsilon_{ox}} \right)^{-1}$$
 (Eq. 4),

443

where  $\varphi_H$  is the potential drop across the Helmholtz layer of the electrolyte,  $\varphi_M$  is the overall 444 potential drop of the metal-solution interface, L is the thickness of the oxide film,  $\partial$  is the 445 thickness of the Helmholtz layer, and  $\mathcal{E}_{ox}$  and  $\mathcal{E}_{H}$  are the dielectric constants of the film and 446 of the Helmholtz layer, respectively [35]. The linear dependence between the SKP-measured 447 potential and the thickness of the oxide film that grows after grinding of 301LN stainless 448 steel was determined by SKP in a previous report [29]. XPS shows that the plastic strain does 449 not significantly influence the composition and thickness of the surface oxide, and we can 450 451 assume that the measured potential is proportional to the oxide film thickness.

In this study, SKP and SECM techniques were shown to be able to determine the effects ofthe stress on the local electrochemical properties of the steel electrode. SKP was able to

characterize the level of passivity of the AISI 304 steel surface as a function of the strain. 454 Because plastic deformation creates dislocations (Figure 5) that cross the initial oxide film, 455 the decrease in the potential was explained by the formation of new surfaces. Indeed, the 456 emergence of dislocations increases the surface roughness and the real surface area of the 457 electrode (Table 2). The distribution of the local strain in the gauge section corresponds to the 458 distribution of the potential (Figures 3 and 4). Thus, we can assume that a potential decrease 459 corresponds to the dislocation density and depends on the applied stress. Figure 6.a shows 460 that for a low strain, the potential proportionally decreases, and at higher elongations, the 461 potential approaches the minimum steady-state value. This is in agreement with the effect of 462 the strain on the dislocation density [37]. Thus, at low strains, the density of dislocations 463 proportionally increases, but at high strain, the density is stable due to the interaction and 464 annihilation of dislocations [37]. The elastic stress does not create dislocations and has no 465 466 influence on either the initial potential of the steel surface or the potential of a surface containing dislocations. 467

468 SKP measurements started approximately 5 min after the application of stress. The potential

- increased due to passivation of the new surfaces. Extrapolation of the time-dependence
  curves (e.g., Figures 7 and 9) to the initial time show that the initial potential is more positive
- 470 curves (e.g., Figures 7 and 9) to the initial time show that the initial potential is more positive471 than the either reversible potential of oxide formation or the flat band potential of the oxide
- than the either reversible potential of oxide formation or the flat band potential of the oxide
  film (-0.3 V vs. SHE at pH 9.2) [20, 38]. Thus, rapid oxygen adsorption at the active
- dislocations and formation of the first layers of the oxide could not have been studied with
- the approach used here. The time dependence of the potential follows a logarithmic
- regression curve (Figure 7, Table 3). Deviation of the potential (Figure 7) from the basic
- logarithmic dependence was mainly observed at the beginning of the passivation process.
- 477 Exposure to air of the pre-ground surface also increased the potential due to passivation
- 478 (Figure 10). It is possible that the passivation kinetics can be described by the high-field Mot-
- 479 Cabrera model for oxide film growth, whereas surface grinding may mimic the formation of
  480 new surfaces due to strain.

481 Plastic deformation creates "active" surfaces that accelerate the electron transfer and

- 482 efficiency of the cathodic reduction of the oxidizer (mediator) in the SECM experiments. Due
  483 to surface passivation, the reduction currents decreased during exposure to the electrolyte
- (Figure 13). However, this process takes a relatively long time. These findings are in
- agreement with the study of G.T. Burstein [39], which determined that newly formed surfaces
- accelerate the water reduction and hydrogen evolution reactions. The subsequent decay of thecathodic current over time is relatively small, and the new surfaces remain catalytically active
- towards hydrogen evolution [39]. The SKP measurements in air correspond to the OCP
- measurements in a passivating aqueous electrolyte using a reversible reference electrode
   (Figure 11). Transient of OCP also show that passivation of a strained surface takes a long
- 491 time. The difference in potentials between the stressed and stress-free areas promotes
- 492 galvanic corrosion of the anodic locations that contain residual stress.
- 493 Different studies have interpreted the stress-induced acceleration of corrosion and anodic
- dissolution from the point of view of the mechano-electrochemical effect introduced by E.
- 495 Gutman [8, 9]. This theory explains the acceleration of anodic dissolution from a
- 496 thermodynamic perspective. The equilibrium potential of the metal is more negative than  $\Delta \varphi$ 497 (in volts) for an excess external pressure ( $\Delta P$ ):
- 498

499 
$$\Delta \varphi = -\frac{\Delta PV}{zF}$$
 (Eq. 5),

500

501 where V is the molar volume of the metal, z is the valence of the metal ion, and F is the 502 Faraday constant. Thus, an increase in the external pressure ( $\Delta P > 0$ ) accelerates the metal

- dissolution rate. However, thermodynamic analysis [40] showed that the change in free
- energy due to elastic deformation is insufficient to significantly alter the active dissolution
- rate. Moreover, SKP measurements of the effect of the elastic tensile stress do not show a
- shift in the electrochemical potential of the AISI 304 electrode (Figures 3 and 8). However, it
- 507 is worth to note that the effect was studied for well passivating alloy and in passive
- conditions. Perhaps this point cannot be directly applicable to systems corroding underactivation control.

510 For the stress corrosion cracking mechanism, the important question concerns the impact of

- the elastic stress on the kinetics of passivation and the general reactivity of the strained
- 512 surface. Figure 9 shows that the kinetics of oxide growth either under loading or at rest are
- 513 similar. However, the properties of the oxide films formed under different conditions, such as
- film homogeneity and composition, were not determined in particular work.Internal stress created by cold work changes the corrosion properties of metal surfaces. The
- steel incorporates the internal stress and back stress due to the interaction of the dislocations
- with the grain boundaries [22, 24]. Concerning the oxide film, the deformation increases the
- 518 doped charge density (concentration of donors and acceptors) in the passive films of stainless
- steels [18-20, 41]. For pure iron, dislocations exposed to the iron surface increase the number
- of donors, resulting in a highly defective passive film [42]. In this particular study, after
- tensile straining and repassivation, SKP showed that the surface of the AISI 304 steel did not
- return to the initial level of passivity and that the potential was 30 mV lower than that of the unstrained reference area (Figure 14.a). It is important to note that, after removing the oxide
- film by grinding, repassivation creates a new oxide film that exhibits a lower potential drop in
- the regions with residual stress (Figure 14.b). Figure 15 shows that residual stress creates
- 526 macroscale areas with non-uniform distributions of the potential and SECM current. In
- 527 general, the electron transfer rate across the strained areas is higher relative to that of the
- initial reference surface (Figure 15). Thus, residual stress due to the formation of adislocation field modifies the oxide film and increases the surface reactivity, which shows
- biocation field modifies the oxide fifth and increases the surface reactivity, which showslocalization on the microscale.
- 531

### 532 **4. Conclusions:**

1. The effect of tensile stress on the electrochemical potential of 304 stainless steel was
studied in air using SKP. The effect of elastic stress on the electrochemical potential of the
steel electrode was not found. The plastic stress decreased the potential of the AISI 304 steel
by 150-200 mV. This was ascribed to breaks in the passive film due to the emergence of

537 dislocations and the formation of new active surfaces.

2. After passivity breakdown, the potential increases due to the formation of a new oxide film
and passivation. The growth of the oxide layer is a long-term process. Stabilization of the
potential proceeds after 24 h of exposure to air. The elastic tensile stress does not influence

- the rate of passivation. During passivation, the potential showed a logarithmic dependence
- that may be the result of oxide growth according the field assisted ion migration mechanism.

543 3. Monitoring of the open circuit potential after plastic deformation in an aqueous electrolyte 544 showed that the passivation rate is similar to that measured in air. SECM was shown to be an 545 efficient method for monitoring the passivation in an electrolyte as a function of the level of 546 applied tensile strain. Newly formed surfaces showed long-term activity and an increased rate 547 of electron transfer across the growing oxide film. Thus, long-term galvanic couples

- consisting of anodic ruptured areas and the surrounding cathodic surfaces will lead to
- 549 corrosion at the stress location.

4. After passivation, the locations containing internal tensile stress show a lower potential

- relative to that of the reference surface due to the formation of more defects in the oxide film.
- 552 The areas containing residual stress show a non-uniform potential distribution and
- accelerated electron transfer across the oxide film, which can lead to the development of local
- corrosion. XPS studies show that oxide films formed on plastically deformed steel have a less
- dense structure and an increased density of hydroxide groups than those of other oxide films.
- 556

#### 689 **Captions of the Figures:**

690 *Figure 1: Microstructure of the AISI 304L alloy.* 

Figure 2: A schematic of the tensile samples (a), the relation between stress, load and strain
(b) and the calculated plastic strain distribution in the gauge section for a displacement of 6

693 *mm* (c). Inset in Figure 2.b shows zoom for low strain part of the curve.

694 *Figure 3: The potential distribution along the gauge section with a 3% elongation load. a, b-*

695 samples under loading, a- 20 min after application of stress, b - 5 h after application of

696 stress, c - samples from (b) measured after unloading, d – after resting for 24 h after

697 unloading. Additionally, the inset in (a) shows the potential distribution and modeled

698 *distribution of the plastic strain across the gauge section for 3% elongation.* 

Figure 4: Potential distribution across the gauge section under a 20% elongation strain (a)
after unloading and (b) after unloading and 24 h of exposure in air.

Figure 5: Potential distributions (a, c) measured in the center of the gauge section after the

application of stress and topography of the surfaces (b, d). a, b -12% elongation; c, d-20%

elongation. The potential was mapped under loading in air at 60% RH, and the topography

- 704 was measured using an optical profilometer without an external load.
- Figure 6: Effect of the plastic strain on the potential (a). Monitoring of the steel potential
  under different loads in air at 60% RH (b).

Figure 7: The potential monitored in the center of the tensile sample under load and applied
strains of 8%, 15% and 20%. A logarithmic regression line fits the curve of 15% strain.

*Figure 8: Potential measured by SKP of the pre-strained surface (20% deformation) under* 

710 load (a) and at rest 0 kN (b). The measurements were carried out 5 h after application of the

711 *load*.

- 712 *Figure 9: Monitoring of the potential in the gauge section after application of a 20% strain.*
- a- curves measured under the loaded and unloaded conditions with linear regression lines. b-
- 714 Potential monitoring of two different samples. Curve 1 was measured before loading, curves
- 715 2 and 3 were measured after application of the plastic strain. The measurement was carried
- 716 *out under loading (curve 3) and at rest (curve 2).*
- Figure 10: Monitoring of the electrochemical potential for an unloaded tensile sample after
  straining (15% elongation) and for a sample after grinding (4000 grit emery paper).
- Figure 11: Influence of the tensile strain on the OCP monitored after loading in an aqueous 0.5 M Na<sub>2</sub> SO<sub>4</sub> electrolyte. a- two cycles of 10% of plastic strain ( $\varepsilon_p$ ); b- plastic strain of 20%.
- Figure 12: SECM approach curves in 0.5 M Na<sub>2</sub>SO<sub>4</sub> + 10 mM K<sub>3</sub>(Fe(CN)<sub>6</sub>) measured at different times after the application of strain a- 5% and b- 8%.
- Figure 13: The local currents for the reduction of the mediator 10 mM  $K_3(Fe(CN)_6)$  vs. time
- of exposure to the electrolyte after the application of stress. The tensile sample was strained to 5% (curve 2) and 8% (curve 1) of the total strain.
- Figure 14: Potential distribution across the sample surface with 20% elongation and
- exposure to dry air for 2 weeks (a) and the same sample after grinding and exposure to dry air for 2 weeks (b).
- Figure 15: Maps of the distribution of the SECM current probe in a 0.5 M Na<sub>2</sub>SO<sub>4</sub> electrolyte
- 730 (a,c,e) and SKP maps (b, d, f) of the pre-strained samples a, b- 0%, c, d 20% and e, f- 30% 731 strain.
- Figure 16: Example of a de-convoluted oxygen peak used to evaluate the contributions of O ( $\sim$ 529.5 eV),  $-OH(\sim$ 531.3 eV) and H<sub>2</sub>O ( $\sim$ 532.8 eV).
- 734 Figure 17. Changes in the relative contributions of O and -OH bonds with changing of
- analysis angle for the unstrained (left) and strained (right) samples.
