14 **Abstract**

15 Our knowledge of active magmatic hydrothermal system (or magmatic vapors) is largely
16 related to the modeling of geochemical processes including heterogeneous equilibrium calculations
17 with variable bulk composition, temperature or pressure. With the aim to constrain the characteristics
18 of extinct hydrothermal systems it is necessary to look for petrogenic evidence in active ones. The
19 Kudryavy volcano in the Kurile Islands (Russia) provides a unique natural laboratory to study the
20 formation of fumarolic rocks from high temperature fluids (measured temperature for the fumaroles up
21 to 940°C). By studying the minerals chemistry and assemblages and by computing a thermodynamical
22 modelling, we investigated the mineralogical evidence for such high-temperature. We confirm the
23 documented occurrence of Ca-Fe rich minerals as isolated patches, veins or incrustation in cavities and
24 their formation during the alteration of primary minerals. We describe and documented secondary Na-
25 Al rich minerals (davynite, nepheline, sodalite) and their occurrence together with Ca-Fe minerals in
26 cavities. We also documented the presence of Fe-wollastonite, a relatively rare mineral suggesting
27 high-T formation and we observed assemblages including wollastonite + andradite + magnetite
28 suggesting high-temperature decomposition of andradite. This natural laboratory provides a series of

29 concordant petrologic evidences for high-temperature fumarolic rocks and offers guidelines for the
30 study of ancient high temperature hydrothermal environments on Earth and other planets like Mars.

31

32 **Introduction**

33 Fumaroles, emission of magmatic gases in volcanic environments, have been studied for years
34 with the contrasted objectives (i) to link the chemical composition of the gas with intrusion of magma
35 and to monitor eruptive activity, and (ii) to understand how they leach and carry useful elements that
36 are concentrated in economic minerals. The Kudryavy volcano in the Kurile Islands (Russia) provides
37 a unique natural laboratory to study the formation of fumarolic rocks from high temperature (up to
38 940°C; Taran et al., 1995) fluids within a passively degassing volcano. The fumarolic activity of this
39 volcano (e.g. Vlasov & Petrachenko, 1971) is now well constrained, the host-rock being a basaltic
40 andesite (e.g. Taran et al., 1995) and the temperature and elemental and isotopic composition of major
41 gas species having been determined (Botcharnikov et al., 2003; Fischer et al., 1998; Taran et al.,
42 1995). The fumarolic rocks (i.e. rocks altered by the fumarolic activity) of the Kudryavy volcano were
43 particularly characterized because they contain an Re-enrichment (Korzhinsky et al., 1994). Diverse
44 rare-metal mineralization and high HSE abundances are observed in the fluid and sublimates. The
45 source of the rare-metal mineralization was demonstrated to be the magmatic melt using isotopic Pb
46 and Sm-Nd studies (Yudovskaya et al., 2008).

47 The formation of fumarolic rocks is the subtle result of condensation, dissolution and
48 reprecipitation processes. The minerals formed by the condensation are called sublimates whereas the
49 minerals formed by the interactions between the gas phase and the wall rock constitutes the
50 incrustations. The main incrustations of Kudryavy rocks occur as layered filled cavities (Africano et
51 al., 2003) as veins or isolated patches in the rock matrix. Various anhydrous sulfates, Ti-oxide, pyrite
52 and andradite are described in fumaroles with lower temperatures (300-500°C) whereas in addition to
53 the sulfates and andradite, also magnetite, hematite, ilmenite, hercynite, cristobalite, diopside,
54 hedenbergite, sanidine and wollastonite are described in fumaroles with higher temperatures (600-
55 850°C).

56 Africano et al. (2003) computed thermochemical calculations using the program GASWORKS
57 (Symonds and Reed, 1993) to constrain the assemblages produced by the cooling of the high
58 temperature gases and by the gas-rock interaction. They concluded that the leaching of Si, Ca, Mg, Al,
59 Ti and Fe from the wall rock is significant in the formation of silicates in fumaroles. Our shared
60 objective is to understand the formation of incrustations. With this aim, we focused on the
61 assemblages of silicates formed in the fumarolic incrustation of the highest temperature field. Using
62 petrographic observation and a simple thermodynamic modeling, we investigated the characteristics of
63 such low-pressure high-temperature modification of magmatic rocks. Excluding the low-temperature
64 sulfates and focusing on Ca-Fe -rich and Na-Al -rich silicates, we looked for evidences of high
65 temperature in the assemblages and mineral compositions.

66
67

68 **1. Geological setting**

69 The Kudryavy volcano consists of a small cone (996 m elevation) located in the northern end
70 of Iturup island in the south of the Kurile volcanic arc. The last large eruption occurred in 1883 and
71 produced basaltic andesite flows (Gorshkov, 1970) but small-scale phreatic eruption occurred more
72 recently in 1999 (Korzhinsky et al., 2002). The Kudryavy basaltic andesite flows are composed of rare
73 olivine, orthopyroxene (hypersthene), clinopyroxene (augite), plagioclase (labradorite to bytownite),
74 and titanomagnetite (Africano, 2004) and its chemical composition is typical of the calc-alkaline serie
75 ($\text{SiO}_2=54.52$ wt% ; $\text{Al}_2\text{O}_3 = 17.96$ wt% ; $\text{Fe}_2\text{O}_3 = 3.22$ wt% ; $\text{FeO} = 6.18$ wt% ; $\text{MnO} = 0.18$ wt% ;
76 $\text{MgO} = 4.00$ wt% ; $\text{CaO} 8.78$ wt% ; $\text{Na}_2\text{O} = 2.76$ wt% ; $\text{K}_2\text{O} = 0.57$ wt% ; $\text{TiO}_2 = 0.88$ wt% ; $\text{P}_2\text{O}_5 =$
77 0.13 wt% ; Loss On Ignition (LOI) = 0.44 wt% ; Ostapenko, 1970).

78 Kudryavy volcano is a place of great interest to study fumarolic activity because of the stability of the
79 activity (at least 30 years) and because of the extreme temperatures recorded (up to 940°C)
80 (Korzhinsky et al., 1994; Taran et al., 1995). The long term high temperature degassing is attributed to
81 a steady-state degassing, with volatiles rising continuously from the zones of arc-magma generation at
82 mantle-depth to the surface (Fischer et al., 1998).

83 The chemical composition of the high temperature Kudryavy gases ($T > 700^{\circ}\text{C}$) is $\text{H}_2\text{O}/\text{CO}_2 =$
84 40 - 70 (Fischer et al., 1998; Taran et al., 1995; Wahrenberger, 1997), $\text{CO}_2/\text{S}_{\text{total}} = 1 \pm 0.3$, $\text{S}_{\text{total}}/\text{Cl} = 4$
85 ± 1 (Fischer et al., 1998), $f_{\text{H}_2}/f_{\text{H}_2\text{O}} = 10^{-2.0}$ to $10^{-2.5}$ corresponding to an oxygen fugacity between the
86 fayalite-magnetite-quartz (FMQ) buffer and the nickel-nickel oxide (NNO) buffer (Taran et al., 1995).
87 The relative abundances of N_2 , Ar and He are typical of arc-type volcanic gases (Fischer et al., 1998).
88 The isotopic compositions are in the range of -4 to 8.9‰ for $\delta^{18}\text{O}$ with a value of $\delta^{18}\text{O} = 5 \pm 1$ ‰
89 (Taran et al., 1995) and $\delta\text{D} = -19 \pm 3$ ‰ (Goff and McMurtry, 2000) in the highest temperature gas
90 sampled (920°C).

91 Sublimates of Kudryavy fumaroles have been described by several authors (Africano, 2004;
92 Bykova et al., 1995; Korzhinsky et al., 1996, 1994; Kovalenker et al., 1993; Magazina et al., 1996;
93 Wahrenberger, 1997). The natural sublimates described in Kudryavy fumarolic rocks are formed by
94 various minerals including, hematite, magnetite, molybdenite, greenockite, wurtzite, cannizzarite,
95 cosalite, pyrite, halite, sylvite, rozenite, ilsemanite, tougarinovite, galena, tungstenite, thenardite and
96 aphtitalite (Africano, 2004).

97 The Kudryavy altered rocks present three main mineralogical assemblages of secondary
98 phases related to the temperatures of the fumaroles at which they were collected. In high temperature
99 assemblages (900 to 500°C) andradite ($\text{Ca}_3\text{Fe}_2\text{Si}_3\text{O}_{12}$), diopside ($\text{CaMgSi}_2\text{O}_6$), salite
100 ($\text{Ca}(\text{Mg},\text{Fe})\text{Si}_2\text{O}_6$), hedenbergite ($\text{CaFeSi}_2\text{O}_6$), wollastonite (CaSiO_3), sanidine (KAlSi_3O_8), albite
101 ($\text{NaAlSi}_3\text{O}_8$), Fe oxides, hercynite (FeAl_2O_4), cristobalite and tridymite (SiO_2) are documented
102 (Africano et al., 2003). These minerals are observed in the incrustations of the natural samples but do
103 not precipitate when sampling the gases in silica tubes, suggesting that their forming cations (Si, Ti,
104 Mg, Al, Ca) were not carried by the gases but were mobilized from the wallrock (Africano et al.,
105 2003). These minerals replace the primary minerals (pyroxene and plagioclase) in reaction to the
106 remobilization of the rock-bearing cations. Medium temperature (500 to 300°C) assemblages are
107 composed of anhydrite (CaSO_4), Al and Fe sulfates, Ti oxide, cristobalite, tridymite, quartz and pyrite
108 or hematite. Low temperatures ($< 200^{\circ}\text{C}$) rocks are completely silicified.

109

110 2. Methods

111 Samples were provided by Alain Bernard (ULB, Belgium): three rock samples associated with
112 the highest temperature fumarole (Fig. 1) were examined here (11, 15, and 21, see Fig. 2). They were
113 collected in August 1995 near active fumaroles at temperatures up to ~900°C. The depth of rock
114 sampling was 10 to 30 cm. For each sample we studied several polished sections oriented parallel to
115 the depth profile (e.g. 11A, 11B, 11C for sample 11). Despite some small discrepancies in their
116 mineralogical record (see next section), they were sampled at the same place.

117 We used a Scanning Electron Microscope (SEM) Philipps FEI XL30 ESEM LaB6 was equipped
118 with a BRUKER Quantax 655 detector, operated at 20 kV and 200 nA beam current at CEMEF-Mines
119 ParisTech in Sophia Antipolis (France). Energy-Dispersive X-ray spectroscopy (EDX) was used to
120 determine the mineral assemblages. Mineral analyses (Table 1) were acquired using Field Emission
121 Electron Probe Micro-Analyzer (EPMA) UH JEOL JXA-8500F operating at 20 kV accelerating voltage,
122 a 50 nA beam current, and 1 µm-sized beam at HIGP, University of Hawai'i at Manoa. Fluorescence
123 was calibrated to the K-lines of Mg in SC olivine (using a TAP crystal), Si in Rockport fayalite (TAP),
124 Cr on magnesio-chromite (LiFH), Fe in fayalite (LiF), Mn in Verma garnet (LiF), and Ni in NiO (LiF).
125 Standardization was made for Fe and Si on Rockport fayalite ($\text{Fe}_{1.9}\text{Mn}_{0.1}\text{SiO}_4$; USNM85276); Mg and
126 Ni on SC olivine ($\text{Mg}_{1.8}\text{-Fe}_{0.2}\text{SiO}_4$; NMNH111312); Mn on Verma garnet ($\text{Fe}_{1.2}\text{Mn}_{1.7}\text{Al}_2\text{Si}_3\text{O}_{12}$), and Cr
127 on magnesio-chromite ($\text{Mg}_{0.7}\text{Fe}_{0.4}\text{Cr}_{1.6}\text{Al}_{0.4}\text{O}_4$; NMNH117075), with counting times on peak (and each
128 background) as follows: 90 s (45 s) for Mg, Cr, and Si, 30 s (15 s) for Ni and Mn, and 20 s (10 s) for Fe.
129 The background fitted to the trace elements magnesium and chromium was an exponential function
130 defined by Probe for EPMA v.929. ZAF matrix corrections (Armstrong, 1988) were applied. The
131 detection limits were 0.02 wt% for FeO and 0.01 wt% for all other oxides.

132 Thermodynamic analyses and equilibrium phase assemblage diagrams were computed using
133 the Domino program from the Theriak-Domino software (De Capitani and Petrakakis, 2010) and the
134 internally consistent thermodynamic data sets from Holland and Powell (2011) extended with
135 kirschsteinite properties (as explained in Ganino and Libourel, 2017). In such modeling, the calculated
136 stable mineral assemblage is a combined function of the selected bulk chemical composition (X) of a
137 given volume and the prevailing conditions (P, T) during crystallization.

138

139

140 3. Results

141

142 3.1. Petrography of the host-rock and of the incrustations

143

144 The fumaroles are located in basaltic andesite flows with a porphyritic-aphanitic texture
145 (Fig. 2) and composed of phenocrystals of olivine (FO_{78}), orthopyroxene (hypersthene), clinopyroxene
146 (augite), plagioclase (ranging from labradorite to bytownite) and titanomagnetite. The aphanitic
147 groundmass displays a similar primary mineralogy. Our survey of fumarolic rocks confirm (Africano,
148 2004) that secondary minerals occur as incrustations in pores and alteration veins of primary
149 pyroxenes and plagioclase.

150 In sample 11 (section 11C shown in Fig. 3), an altered clinopyroxene hosts a pore, probably
151 resulting from acidizing leaching (Fig. 3a), that contains euhedral andradite ($Ca_3Fe_2Si_3O_{12}$). Andradite
152 displays a pronounced oscillatory zoning associated with varying grossular content or Al/Fe ratio (Fig
153 3b). Veins of Ca-Fe-Mg -rich minerals (hedenbergite $CaFeSi_2O_6$, diopside $CaMgSi_2O_6$) are also
154 present within the K-Feldspars (Fig. 3c). Larger pores show a zonation at their peripheries (Fig. 3d),
155 including hercynite associated to davyne ($(Na,K)_6Ca_2Si_6Al_6O_{24}SO_4Cl_2$), albite ($NaAlSi_3O_8$), sodalite
156 ($Na_8Al_6Si_6O_{24}Cl_2$), nepheline ($(Na,K)AlSiO_4$) assemblages (Fig. 3e and 3f). Area exhibiting the shape
157 of nearly euhedral porphyric primary pyroxene now totally replaced by hedenbergite are cross-cutted
158 by veins of sodalite and K-feldspar (Fig. 3g and 3h). The two main types of secondary silicates (Ca-
159 Fe- rich and Na-Al- rich) are frequently observed in association (Fig. 3i). Gypsum (Fig. 3j, 3k and 3l)
160 is also present enclosing euhedral andradite or hedenbergite.

161 Sample 21 (section 21B shown in Fig. 4) displays very similar pattern and assemblage with altered
162 porphyric primary minerals (Fig. 4a). Here pores are incrustated from the periphery to the center with
163 anorthite-hedenbergite-andradite (Fig. 4b, 4c, 4d 4e, 4f, 4g). Albite is the unique Na-Al -rich silicate
164 we observed. Magnetite, wollastonite and hercynite are also present, with wollastonite being
165 frequently associated with andradite and magnetite (Fig. 4c, 4g and 4i).

166 Secondary phases in sample 15 (section 15C shown in Fig. 5) are hedenbergite (Fig. 5a), andradite
167 (Fig. 5d), quartz (or other SiO₂ minerals; Fig. 5b), and nearly euhedral magnetite (Fig. 5c and 5e) in
168 some places covered with hercynite (Fig. 5f).

169

170 **3.2. Mineral composition**

171

172 In addition to SEM-EDX identification, the compositions of the secondary phases were
173 analyzed using Field Emission Electron Probe Micro-Analyzer and reported in Table 1. Within the
174 secondary phases, we confirm the observation from Africano et al. (2003) that the secondary pyroxene
175 are present with very contrasted compositions. They consist generally in salite (pyroxene with various
176 Ca-Fe-Mg contents) but some compositions are close to the end-member diopside
177 ($\text{Mg}_{0.96}\text{Ca}_{0.96}\text{Fe}_{0.08}\text{Si}_2\text{O}_6$), hedenbergite ($\text{Mg}_{0.02}\text{Ca}_{0.98}\text{Fe}_1\text{Si}_2\text{O}_6$) and wollastonite ($\text{Ca}_{0.98}\text{Fe}_{0.02}\text{SiO}_3$).

178 The chemical composition of wollastonite varies from nearly pure wollastonite to iron-rich
179 wollastonite ($\text{Ca}_{0.82-0.79}\text{Fe}_{0.18-0.21}\text{SiO}_3$). There is a large gap between the composition of the
180 hedenbergite and the iron-rich wollastonite. Contrary to the large diversity in pyroxenes composition,
181 garnets are present only as andradite. As already shown by Africano (2004), the oscillatory zoning in
182 andradite (Fig. 3b) is linked to the Al/Fe ratio, with composition varying from Gr_{69.8} (light gray in
183 Back Scattered Electron (BSE) Image) to Gr_{61.2} (darker gray). Although not characterized with EPMA,
184 we used EDX-SEM to analyze the composition of nepheline, sodalite and davyne (Table 2).

185

186

187 **4. Discussion**

188

189 **4.1. Formation of secondary minerals in fumarolic rocks interpreted as a metamorphic 190 process**

191 The formation of secondary phases is clearly a complex process involving the diverse
192 interactions between the ascending fumarolic gases and the wallrock. Condensation, sublimation,
193 dissolution and precipitation may play a role as well, resulting in the observed textures. The

194 composition of the volcanic vapor was determined (Taran et al., 1995) and it has been shown that the
195 elements necessary for the formation of the secondary phases are mobilized in-situ from the altered
196 minerals (Africano, 2004). Following this idea, we attribute the formation of Ca-Fe silicates to various
197 reactions involving the wallrock “primary” mineralogy. With this scenario, we developed a simplistic
198 modeling using Gibbs energy minimization to calculate the stable mineral assemblages. Stability can
199 be expected in such a system characterized by high temperature and the presence of an activating fluid
200 phase.

201

202 **4.2. Secondary high-temperature minerals assemblages and composition and implications on** 203 **the forming process**

204 **4.2.1. Andradite and hederbergite assemblages**

205 Mineral assemblages of the altered rocks collected at the Kudryavy high temperature
206 fumaroles are characterized by the presence of andradite. This mineral was already described in the
207 literature (e.g. Africano et al., 2003), and we confirm here its presence in all our samples. Andradite
208 typically occurs in skarns (Murad, 1976; Zharikov et al., 1991) and is associated with hedenbergite
209 and magnetite in Fe-rich skarns (Einaudi, 1981; Meinert, 1982). It is also present in the calcic
210 metasomatism of igneous rocks (Firman, 1957). Varet (1970, 1969) reported andradite crystals in lava
211 fractures where fumarolic gases at ~700°C circulated. The andradite–grossular series is widespread in
212 basalts metamorphosed even under low grade (prehnite–pumpellyite and pumpellyite–actinolite facies,
213 possibly extending into the zeolite facies) conditions (Coombs et al., 1977) and may form below
214 200°C (Gutzmer et al., 2001). In conclusion, andradite alone does not bring much information about
215 temperature.

216 In Kudryavy, andradite is systematically associated with hedenbergite. The association $adr + hd$ is
217 also very common and does not provide any information about temperature (e.g. Gustafson, 1974).
218 Nevertheless, the stability field is restricted to ± 2 log unit of the Fayalite-Magnetite-Quartz (FMQ)
219 oxygen buffer (Fig. 6a) if $a_{SiO_2} = 1$.

220

221 **4.2.2. Andradite destabilization into wollastonite and magnetite**

222 We documented the occurrence of andradite assemblages with magnetite and wollastonite
223 (Fig. 4c, 4g and 4i). This assemblage is an evidence of the following equilibrium (Moecher and Chou,
224 1990):

225

227

228 Such an equilibrium requires $T > 750^\circ\text{C}$ (Fig. 6a) and can be used as a diagnostic of “high”
229 temperature. Here the first “secondary” mineral to form is andradite that is later replaced by a new
230 assemblage (wo + mt). Such replacement suggests an increase in the temperature during the fumarolic
231 activity. The hydrothermal activity may have been continued but with varying temperature driving this
232 destabilization. It is worth noticing that the conditions we described (equilibrium $\text{hd} + \text{adr}$ and
233 $\text{adr} = \text{wo} + \text{mt}$; highlighted in green in Fig. 6a) fit perfectly the conditions independently described by
234 Taran et al. (1995) (indicated by the orange stars in Fig. 6a).

235

236 **4.2.3. Nepheline, Sodalite and the effect of aSiO₂ on the stability of Ca-Fe- minerals**

237 Nepheline is abundant in sample 11. This mineral displays textural features of other secondary
238 minerals as it is found as incrustation. Its presence in a magmatic rock saturated with respect to SiO₂
239 confirm its formation as a secondary mineral.

240

241 The reaction involved here is the hydrothermal alteration of albite associated to the leaching of SiO₂ as
242 follows:

243

245

246 This reaction does not provide much information on the temperature, but the nepheline can occur as
247 three different polymorphs (alpha, beta and gamma) that could be used as thermometers: alpha-
248 nepheline (25-194°C), beta-nepheline (194-907°C), gamma-nepheline (907-1257°C) (Kelley et al.,
249 1953). If most nepheline is the beta polymorph here, we were close to the stability field of gamma-

250 nepheline and this polymorph would be expected in the very hot fumarole where the samples were
251 collected (T~900°C).

252 The abundant sodalite also described here can be derived from nepheline (Sharp et al., 1989) or
253 directly from albite (Drüppel and Wirth, 2018) according to the following reaction:

254

256

258

259 Here again, sodalite does not provide much information on the temperature. Its formation requires a
260 high chlorine content of the fluid phase that interacted with the fumarolic rock in agreement with the
261 composition described by Taran et al. (1995). Strictly speaking, salinity of the magmatic vapor is quite
262 low (with Na content <41.2 ppm) but chlorine content is high (up to 15380 ppm) leading us to propose
263 that the chlorine involved in the formation of sodalite may come from HCl rather than from NaCl as
264 proposed in reaction (3) and (4).

265 The stability field of nepheline and sodalite clearly depend on the aSiO₂ as it is also the case for the
266 stability of most secondary minerals. Indeed, if we examine andradite in a Ca-Fe-Si-O system, its
267 stability relative to hedenbergite is governed by the reaction

268

270

271 In a silica-saturated system involving pure phases, this equilibrium lies between the Hematite-
272 Magnetite and FMQ buffers at FMQ ±2 log units (Fig. 6b). In a silica-undersaturated system with pure
273 phases, the equilibrium constant for reaction (5) is

274

$$275 \quad \log K_{(5)} = 2 \log f\text{O}_2 - 9 \log a\text{SiO}_2 \quad (6)$$

276

277 Solving for log fO₂ gives

278

279 $\log fO_2 = 1/2 \log K_{(5)} - 9/2 \log aSiO_2$ (7)

280

281 and the shift in the equilibrium $\log fO_2$ due to the degree of silica undersaturation is

282

283 $\Delta K_{(5)} \log fO_2 = 9/2 \log aSiO_2$ (8)

284

285 Changes in silica undersaturation that cause the term $\log aSiO_2$ to be negative would then
286 shift then significantly ($-4.5 \log$ units fO_2 shift per order of magnitude of $aSiO_2$) the equilibrium
287 location of reaction (3). Thus, the effect of the silica activity is significant and should have profound
288 implications on the phase relationships (see also Ganino and Libourel, 2017). To consider the effect of
289 silica activity, we calculated isothermal stable mineral assemblages as a function of $aSiO_2$ and fO_2 for
290 the chemical system Ca-Fe-Mg-Si-O (corresponding to the major components in the primary
291 pyroxenes) at $T=800^\circ\text{C}$ and $P=1$ bar (Fig. 6b). In this system, the equilibrium assemblages observed in
292 Kudryavy high-temperature ($700\text{-}900^\circ\text{C}$) fumarolic rocks are di-hd, di-wo-mt and adr di-mt
293 (equilibrium lines highlighted in green in Fig. 6b). These equilibria are compatible with $\log(aSiO_2)$, in
294 the range -1 to 0 and $\log fO_2$ in the range -17 to -12. More specifically, if we consider the equilibrium
295 $\text{adr} = \text{wo} + \text{mt}$ (green line between fields di-wo-mt and adr-di-mt in Fig. 6b) the fO_2 is fixed at $\log fO_2$
296 $= -13.5$, a value that falls perfectly into the range estimated by Taran et al. (1995) and those measured
297 in Kudryavy fumaroles by Rosen et al. (1993) and Osadchii et al. (1997). This good agreement
298 supports the relevance of our simple thermodynamic approach.

299 We computed equilibrium assemblages in presence of water for FMQ-buffered conditions at 1
300 bar, for the system Ca-Fe-Mg-Si-O-H and Ca-Na-Al-Si-O-H that may correspond respectively to the
301 hydrothermal alteration of primary pyroxene and plagioclase (Fig. 7). Fig. 6a shows that adr-hd and
302 hd-wo are stable in a large temperature range but are restricted to $aSiO_2 \sim 10^{-0.5}$. On the other hand, the
303 equilibrium $\text{adr} = \text{wo} + \text{mt}$ requires $T \sim 750^\circ\text{C}$. Fig. 7b suggests a similar silica activity for the
304 equilibrium ab-ne ($aSiO_2 \sim 10^{-0.5}$) with little influence of the temperature. In terms of temperature, the
305 rarity of hydrous minerals implies $T > 220^\circ\text{C}$ for the Ca-Fe-Mg-Si-O-H system and $T > 400^\circ\text{C}$ for the

306 Ca-Na-Al-Si-O-H system. The relatively low silica activity recorded here during the high temperature
307 phase contrasts with the documented presence of secondary silica ($a_{\text{SiO}_2} > 1$). We follow the idea of
308 Africano (2004) of a late and low temperature phase: silica was leached at high temperature and
309 precipitated in pores when the temperature of the fumarolic gases decreased.

310 Probably because of the high-temperature and the presence of a fluid phase helping the
311 attainment of equilibrium, the mineralogical signature of the fumarolic rocks in Kudryavy can be
312 modelled accurately using a simple thermodynamic equilibrium in a metamorphic process. Solid-solid
313 reactions typical of metamorphic processes are particularly clear when observing the destabilization of
314 andradite into wollastonite and magnetite (reaction 1) or the equilibrium between andradite and
315 hedenbergite (reaction 5). Dissolution may be involved (decrease of a_{SiO_2} / leaching of SiO_2) and
316 condensation may also occur (pores filled with SiO_2), but most silicates we documented have not been
317 formed by condensation. The textural relationships including pores filled with those minerals, suggest
318 a mobility (fluid phase) rather than a simple replacement. The extremely simple explanation proposed
319 here with secondary phases directly deriving from the primary minerals provide key parameters for the
320 phase stability, but fails to explain their mode of occurrence.

321

322 **4.2.4. Davyne**

323 Thermodynamic data are not available for davyne in the database from Holland and Powell
324 (2011) and the lack of experimental data on this mineral prevents to implement it into the database.
325 For this reason, even though this mineral is important, we were not able to model its stability and it
326 does not provide precision on extensive parameters (temperature, a_{SiO_2} , f_{O_2}). Nevertheless, the
327 occurrence of davyne is not surprising because this mineral is found typically in metasomatized and
328 hydrothermally altered lavas (e.g. Bonaccorsi et al., 1994). Its presence documented in other areas
329 where only moderate temperature fumarolic gases are recorded (e.g. Vesuvius, highest temperature in
330 the range 360-445°C, (Chiodini et al., 2001)) makes us propose that davyne alone is not an indicator
331 of high temperature.

332

333 **4.2.5. Ferro-wollastonite**

334 The mineral composition of the wollastonite-hedenbergite group brings additional information
335 to characterize high-temperature mineralogy: experimental data show a miscibility gap between
336 hedenbergite and wollastonite above about 800° C (Rutstein, 1971 and Fig. 8). The chemical
337 compositions of iron-rich wollastonite in Kudryavy fumarolic rocks fall in the immiscibility gap. With
338 decreasing temperature, iron-rich wollastonite should transform to hedenbergite + wollastonite. Here
339 we assume that the cooling rate was too high for a complete transformation of Fe-rich wollastonite into
340 hd+wo. In summary, the occurrence of iron-rich wollastonite provides an evidence of high-
341 temperature (>800°C) crystallization.

342 What is remarkable about the secondary phase assemblages observed here is that they are
343 precisely what is predicted from high-temperature alteration of the primary magmatic minerals. No
344 hydration or reverse (low-temperature) metamorphism has altered this high-temperature signature.
345

346 **4.3. A guideline to ancient or planetary fumarolic environment.**

347 Fumarolic activity at the Kudryavy volcano is peculiar because of the high temperature
348 measured, well above most other fumarole fields. Igneous activity and hydrothermal circulation have
349 been present throughout Earth history. The Earth has always recycled buried volatiles including
350 carbon and water back to the surface. During the early Earth's history (e.g. Archean Eon the mantle
351 temperature and surface heat flow would presumably be higher than resulting in a primitive plate
352 tectonics that is different from that of the present (more plate boundaries i.e. more volcanic margins,
353 e.g. Hargraves, 1986) and a widespread high-temperature volcanic activity (komatiites e.g. Arndt et
354 al., 2008). These two aspects lead us to propose that Kudryavy-like hot volcanic fumaroles might have
355 been more widespread in the early Earth history than now. The mineralogical features we identified
356 here provide a guidance for recognizing high-temperature fumaroles in the rock record. These features
357 (assemblages adr-wo-mt, iron content of wollastonite) are particularly efficient because they formed
358 from the fumarolic alteration of common primary phases as pyroxenes and plagioclase which are very
359 frequent and widespread in most volcanic rocks. The unique limitations are the paucity of Archean
360 outcrops and the possible late retrograde alteration to low-temperature hydrated assemblages that
361 could have affected and erased the high-temperature assemblages.

362 In a planetary science perspective, our observation could be used to identify ancient high-
363 temperature hydrothermal activity on other planetary bodies. For the case of Mars, several ancient
364 Martian volcanoes display pyroclastic rocks, such as Elysium Mons and Hadriaca Mons. Thus
365 suggests the possibility of high volatile abundances during the earliest period of volcanic activity, and
366 possibly Kudryavy-like hot-temperature hydrothermal system with volcanic vapors. The Kudryavy
367 volcano provides a high-temperature analog with respect to Jaroso hydrothermal system in Spain
368 already proposed as an analog for martian low-temperature hydrothermal field (e.g. Martínez-Frías et
369 al., 2007).

370

371 **Conclusion**

372 This work characterizes the phase assemblages and mineral compositions that are indicative of
373 high temperature hydrothermal systems. It confirms the presence of hedenbergite, andradite,
374 wollastonite, magnetite, hercynite (Ca-Fe--rich secondary minerals) and shows that a second type of
375 secondary minerals (Na-Al -rich) are also present: nepheline, sodalite and davyne. Some of these
376 minerals do not provide much information on the thermo-chemical conditions, but others can be used
377 as sensors. The best piece of evidences for high-temperatures are the assemblages adr-wo-mt
378 (associated with a $>750^{\circ}\text{C}$ equilibrium), and the iron content of wollastonite (iron-wollastonite stable
379 above 800°C). As a result of the high-temperatures and the presence of a fluid phase helping the
380 completion of equilibrium, a simple modelling of thermodynamic equilibria provides an accurate
381 mineralogical signature of the fumarolic rocks after replacement of the primary minerals. Similar
382 mineralogical features could be of importance when looking at the properties of old extinct
383 hydrothermal systems. Such high-temperature fumarolic fields are rare today, but could have been
384 more frequent in the early history of Earth. High-temperature fumarolic rocks could be widespread in
385 Archean outcrops if late retrograde alteration to low-temperature hydrated assemblage had not affected
386 and erased the high-temperature assemblages. .Our results provide also a guidance for characterizing
387 high-temperature hydrothermal systems on other planets and in particular on Mars.

565 Acknowledgements: This study was supported by grants from the COMUE Université de la Côte
566 d'Azur (Idex Academie 3) and BQR Géoazur. We thank Kazuhide Nagashima and Alexander T.
567 Krot for fruitful discussions and Suzanne Jacomet and Olivier Tottereau for their technical
568 support. We gratefully acknowledge reviews by Y. Taran and an anonymous reviewer and the
569 careful reading from M. Wieczorek, which have substantially improved the quality of this
570 manuscript.
