#### 19 Abstract

20 In order to assess the genetic diversity and population structure of indigenous S. cerevisiae from Côte d'Ivoire, a total of 170 strains were isolated from four traditional alcoholic 21 beverages through nine regions. Microsatellite analysis performed at 12 loci revealed that 22 strains of palm oil and raffia wine were genetically related, unlike those of tchapalo and ron 23 wine which formed two distinct and homogeneous clusters. Furthermore, S. cerevisiae 24 isolates of traditional beverages from Côte d'Ivoire appear to be differentiated according to 25 26 the ecological niche. Indeed, a much higher heterozygosity was observed for isolates from ron wine and tchapalo beer, whereas isolates from palm oil wine and raffia wine were clearly 27 inbred. In comparison with the European, North American, Asian and others West African 28 populations, Ivorian population was well defined, although most of these strains were 29 admixed. Among these strains, only isolates from raffia wine appeared to have alleles in 30 common to all populations. 31

### 40 **1 Introduction**

Saccharomyces cerevisiae is one of the main actor involved in various biotechnology 41 processes. These last decades, several studies have been focused on genetic diversity and 42 biogeographical distribution of diverse S. cerevisiae strains. Molecular techniques used for 43 44 this purpose among many others are pulsed field gel electrophoresis (PFGE) (Vezinhet et al., 1990), restriction analysis of the mitochondrial DNA (mtDNA-RFLP) (Aigle et al., 1984; 45 Querol et al., 1992), amplified fragment length polymorphism (AFLP) (Azumi and Goto-46 Yamamoto., 2001), amplification of interdelta regions by PCR (Ness et al., 1993; Legras and 47 48 Karst 2003) and microsatellite markers (Techera et al., 2001; Legras et al., 2005). Microsatellite analyses have offered significant advances in understanding distribution and 49 50 dynamics of S. cerevisiae population from different terroirs. Thus, Viel et al. (2017) have detected specificities of S. cerevisiae at vineyard scale from the North-East of Italy, 51 suggesting a geographic differentiation according to the winemaking region with a 52 widespread dissemination of S. cerevisiae industrial strains that was very high in the areas 53 where the native strains abundance was low. Likewise, microsatellite analyses on S. 54 cerevisiae populations isolated from African traditional fermented foods allowed to highlight 55 the presence of an African phylogenetic branch separate from European (bread, wine, beer, 56 cheese) and Asian strains (sake) (Legras et al., 2007; Ezeronye and Legras, 2009; Tapsoba et 57 al., 2015), which was confirmed with recent genomic data (Liti et al., 2009; Peter et al., 58 2018). This suggests that African traditional fermented foods could be a reservoir of 59 genetically different strains of S. cerevisiae to be explored for applications such as food, 60 bioethanol production, biopreservation, biocontrol, etc. Most of S. cerevisiae commonly used 61 in biotechnology have been isolated from natural niches and have undergone various 62 63 domestication events that have resulted in the selection of strains adapted to human activities (technological strains, etc.). Although several studies have been performed on S. cerevisiae 64 65 isolated from some natural niches (Naumov et al., 1998; Sniegowski et al., 2002; Lorca et al.,

2018), it seems important to assess the structure, the genetic diversity and the distribution of 66 67 native S. cerevisiae obtained from African, and Ivoirian niches particularly, which has been very little studied so far. The characterization of these unexplored ecological niches may 68 provide new genotypes with beneficial properties for biotechnological applications. The aim 69 of this work was firstly to assess the genetic diversity of S. cerevisiae strains present in 70 traditional beverages from Côte d'Ivoire compared to other African beverages and then 71 72 characterize the population structure of the isolates of this species. For this purpose, this study focused on the yeast populations isolated from four fermented beverages obtained with 73 74 different vegetal material. These beverages were tchapalo beer produced from sorghum (Sorghum bicolor) and palm oil, raffia and ron wines respectively obtained from Elaeis 75 76 guineensis, Raphia hookeri and Borassus aethiopum sap fermentation.

77

#### 78 2 Material and Methods

#### 79 2.1 Sample collection and yeast isolation

80 Samples of palm wine (raffia, palm oil and ron wines) were collected during ten sampling campaigns in different regions of Côte d'Ivoire. Sampling areas for raffia wine were located 81 82 at Grand-Lahou, Alepé, Adzopé and Abengourou; those for palm oil wine were located at Bingerville, Bonoua, Grand-Lahou, Alépé and Attinguié while those for ron wine were 83 located at Toumodi. Sorghum beer or tchapalo samples were collected during four sampling 84 85 campaigns at Abidjan and Bingerville. These sampling areas were located in south-eastern and middle of Côte d'Ivoire as indicated by the sample map (Figure 1). Distance between the 86 sampling areas and the city of Abidjan as well as their geographical coordinates are shown in 87 the Table 1. Local producers in 26 different sites were contacted and sampling was carried out 88 from September 2014 to January 2015 and from August 2016 to September 2016. Sampling 89 was twice a day (morning and evening) done at weekly intervals, to collect samples of 9 to 90 91 15hr fermentation duration. Samples were collected into pre-sterilized 250 ml Plexiglas containers, and immediately immersed in an isothermal box containing dry ice, and brought to 92 93 the laboratory within 3 h.

Total titratable acidity (TTA), pH, and total soluble sugars (TSS) for each sample were determined as previously described (Tra Bi *et al.*, 2016). For yeast isolation, each beverage sample (1 mL) was directly diluted in tenfold series in buffered peptoned water (BIO-RAD, France) and aliquots (0.1 mL) were plated in duplicate on Yeast Extract Peptone Dextrose (YPD) agar. After incubation at 30°C for 3-5 days, ten yeast colonies were randomly selected from each sample and purified by streaking two times on YPD agar. *Saccharomyces* yeasts were presumptively isolated by cultivation of purified colonies on lysine agar medium
(Sigma-Aldrich, France). Thus, a total of 262 isolates were selected for molecular
identification and maintained at -80°C in YPD broth containing 20% (v/v) glycerol (Merck,
France).

Variance analysis (ANOVA) and Tukey HSD tests (Honestly Significant Difference) with R
statistical software v3.4.1 (R Core Team, 2017) were used to compare the physicochemical
and microbiological characteristics of each beverage taken from the different sampling areas.
Differences were considered significant for values of P <0.05.</li>

108

#### 109 2.2 Molecular identification of *Saccharomyces* species

110 The species level identity of Saccharomyces strains was checked initially by non-transcribed spacer PCR-Restriction Fragment Length Polymorphism (NTS2 PCR-RFLP) analysis using 111 112 AluI and **BanI** enzymes in comparison with reference strains. From strains showing S. cerevisiae NTS2 PCR-RFLP profile (Nguyen and Gaillardin, 1997), thirty representative 113 114 strains were selected for D1/D2 region sequencing (Kurtzman and Robnett, 1998). The D1/D2 region of 26S rRNA gene was amplified with the primer pair NL-1 (5-115 116 GCATATCAATAAGCGGAGGAAAAG-3) and NL-4 (5-GGTCCGTGTTTCAAGACGG-3) (Kurtzman and Robnett, 1998). Reactions were performed in an automatic thermal cycler 117 (Gene Amp PCR System 2700, Thermo Fisher Scientific) under the following conditions: 118 initial denaturation at 94°C for 4 min followed by 30 cycles of denaturation at 94°C for 30 s, 119 primer annealing at 54°C for 40 s and DNA extension at 72°C for 1 min 30 s. A final 120 extension was completed at 72°C for 7 min. Amplicons were visualized on 0.8% agarose gel. 121 Finally, 20 µL of PCR products were sequenced on both strands with the primers used for the 122 PCR amplification (Eurofins, Germany). Assembly of both strands sequences was performed 123 using the phred/phrap/consed suite (Gordon et al., 1998). Identification queries were fulfilled 124 by a BLAST search of the National Center for Biotechnology Information database (NCBI, 125 Bethesda, USA) and the YeastIP databases (http://genome.jouy.inra.fr/yeastip/). 126

127

#### 128 2.3 Microsatellite analysis

The genomic DNA extraction of isolates was performed following the procedure described by Hoffman and Winston (1987), based on a mechanical grinding of cells in presence of detergent, followed by several steps of protein and RNA removal from a 24 hour yeast culture in YPD broth. Microsatellite loci analysis was performed according to Legras *et al.* (2007). Amplification was performed at 12 loci combined in two multiplex of 6 loci (Table S1 in the supplemental material), and the size of fluorescent amplicons was measured on an ABI3100
(Applied Biosystems) capillary electrophoresis device, using Gene Scan HD400Rox size
standard (Applied Biosystems). These genotypes were compared to data obtained in previous
work on strains from other origins.

138

#### 139 **2.4 Population analysis**

The evaluation of relationships between S. cerevisiae strains was carried out from the genetic 140 relative dissimilarity distance which reflects the number of alleles differing between two 141 individuals, and calculated with the library POPPR (v2.5.0) under R statistical software v3.4.1 142 143 (R Core Team, 2017). Trees were obtained from distance matrices with R library ape v5.0, 144 and drawn using R library ggtree v1.10.5 (Yu et al., 2017). In order to assess genetic structure in S. cerevisiae populations, two different approaches were used. The first one was Bayesian 145 146 clustering analysis implemented with InStruct 2.3.4 software (Gao et al., 2007) to identify the most likely number of genetic clusters or 'populations' (denoted by K) and assign individuals 147 148 to their most likely cluster. In order to deduce ancestry on that set of strains, 8 runs were performed with Instruct for values from K = 2 to 17, and 8 additional runs for values from K 149 150 = 14 to 16. The most likely K value was identified as the value giving the lowest mean value of Deviance Information Criterion (DIC) of the different runs. The results of the 16 runs of 151 the best value of K were combined with CLUMPAK (Kopelman et al., 2015) according to the 152 LargeK Greedy method. The second was a multivariate method based on discriminant 153 analysis in principal components (DAPC) (Jombart et al., 2010) and implemented with the R 154 Adegenet package v2.1.0 (Jombart, 2008) in R v3.4.1 (R Core Team, 2017). DAPC identified 155 clusters of genetically related organisms by partitioning genetic variability into clusters that 156 maximize between-group and minimize within-group differentiation. This approach was an 157 ideal clustering algorithm for datasets that does not followed Hardy-Weinberg equilibrium. 158 Analysis was performed taking into account alpha score function to choose the optimal 159 number of principal components for the analysis of dataset (López-Uribe et al., 2016) due to 160 161 the changes of the individual membership probability according to the number of PCA axes retained. Population analyses were performed using the hierfstat v0.04-22 R package (Goudet, 162 2005) for Nei (1973) estimates of effect of subpopulations compared to the total population 163 (Fst). Population differentiation according to sampling area was tested with OBSTRUCT 164 (Gayevskiy et al., 2014). The inbreeding coefficient of an individual relative to the 165 subpopulation (Fis) was estimated with hierfstat. Average selfing rates were estimated as 1 -166 167 o, where o the outcrossing rate is o = (1-Fis)/(1+Fis)

168

#### 169 **3 Results**

#### 170 **3.1 Characteristics of beverages**

The global characteristics of the four different beverages from which strains were isolated in 171 this study were presented in Table 2. It appeared from this investigation that these four 172 beverages had in general a similar acidic pH and a Total Titratable Acidity (TTA) varying 173 between 0.47 and 1.35. The soluble sugars content varied from one beverage to another with 174 the highest content in tchapalo. The yeast load observed in the Ivorian beverages sampled was 175 generally of the same order. Average values were  $1.1 \times 10^8$  CFU/mL in ron wine,  $1.7 \times 10^7$ 176 CFU/mL in tchapalo beer, 1.4×10<sup>7</sup> CFU/mL in palm oil wine and 1.3×10<sup>7</sup> CFU/mL in raffia 177 178 wine (Table 2).

179

#### 180 **3.2** Assessment of *Saccharomyces cerevisiae* diversity

A total of 170 isolates from Côte d'Ivoire traditional beverages (Table S2 in the supplemental 181 182 material) were identified as belonging to the species S. cerevisiae by using molecular methods. Indeed, the RFLP of NTS2 PCR products showed 2 bands for AluI (1500 and 200 183 184 pb) and 3 bands for BanI (660, 450 and 220 pb) typical to S. cerevisiae strains (Nguyen and Gaillardin, 1997). Then, the sequencing of the D1/D2 domains of the 26S rDNA confirmed 185 the identity of some strains tested as S. cerevisiae with a little sequence divergence of 1 to 4 186 bp for 16 strains and 100% identity for 14 strains (Table S3 in the supplemental material). 187 Sequence divergence of 3 to 4 bp was already observed from S. cerevisiae strains isolated 188 from tchapalo (N'Guessan et al., 2011). The 170 isolates derived from four ecological niches 189 sampled at 26 different sites from 9 regions (south-eastern and middle) of Côte d'Ivoire. 190 Among them, 58 have been isolated from ron wine, 64 from raffia wine, 29 from palm oil 191 wine and 19 from tchapalo beer. These isolates were subjected to a microsatellite analysis 192 193 which allowed to generate genotypic data. In order to compare the populations between the different type of beverages, Fst statistics between isolates from tchapalo beer, palm oil, raffia 194 195 and ron wines were calculated with these data. Population comparisons indicated significant differences between all populations (P< 0.01). Fst data showed weak values ranging from 0-196 0.107 (Table 3a), indicating a little genetic differentiation between the significantly different 197 beverage isolates. The smallest differentiation was observed between palm oil wine and raffia 198 wine strains, and in contrast, tchapalo was the most differentiated population from other 199 populations. Ron wine population presented a moderate differentiation from tchapalo and 200 201 raffia wine.

Impact of geographical origin on S. cerevisiae diversity was studied for isolates from palm oil 202 wine, raffia wine and tchapalo beer. Ron wine with only one sampling area was not 203 considered for this study. The Nei pairwise Fst distances matrix for the two sampling areas of 204 tchapalo beer (Abidjan and Bingerville) showed low Fst values and non-significant 205 206 differentiation. In contrast the four sampling areas of raffia wine (Grand-Lahou, Alépé, Adzopé and Abengourou) and most of the five sampling areas of palm oil wine showed low 207 Fst values and significant differentiation between sites (Table 3). Furthermore, pairwise Fst 208 statistic values for all sampling areas demonstrated no correlation to geographical distance, 209 210 suggesting that diversity of S. cerevisiae was not related to geographical origin. Although isolates of palm oil and raffia wines were genetically related, S. cerevisiae isolates from Côte 211 212 d'Ivoire traditional beverages appeared to be differentiated according to the ecological niche.

The Fis values evaluated for each population were 0.603 and 0.544, respectively, for 213 214 individuals from palm oil wine and raffia wine, 0.234 and 0.138 for individuals from ron wine and tchapalo beer that contained strains not corresponding to one specific fermentation (Table 215 216 4). Such high values of Fis which indicate a low outcrossing rate (and a high mean inbreeding rate) as well as the high observed homozygosity of strains isolated from palm oil wine and 217 218 raffia wine (26 and 25 % of observed sites are heterozygotes), suggest that palm oil wine and 219 raffia wine are inbred. In contrast, the low Fis values which indicate a high outcrossing rate (and a low mean selfing rate) as well as the high observed heterozygosity (52 and 76 % of 220 221 observed sites are heterozygotes) for isolates from ron wine and tchapalo beer suggest more 222 outbred populations.

223

#### **3.3 Genetic relationship among strains**

The phylogenetic relationships among Ivorian strains of *S. cerevisiae* were highlighted by a phylogenetic tree (Figure 2a). This dendrogram showed that strains of tchapalo (in green) and ron wine (in blue) formed two distinct and homogeneous clusters, unlike those of palm oil (in brown) and raffia wines (in red). Strains of the latter two groups appeared mixed in the remaining clusters.

To further detect the specificities of these Ivorian *S. cerevisiae* populations in comparison to populations from other African countries, and in comparison to well characterized populations such as those from wine, sake, and bread, we built a tree including the 170 Ivorian strains and 214 strains from multiple African countries or other origins (Figure 2b) analysed in a previous work (Tapsoba *et al.*, 2015). This consensus neighbour-joining tree was obtained from a pairwise individual distance matrix calculated with relative dissimilarity distance. It showed

several clusters of different genetic origin closely related to geographic origin. Thus, there 236 was a cluster formed from European strains: wine and bread strains. Five clusters of strains 237 originated from African substrates, one of which consists of tchapalo and millet beer 238 (different shades of green) and the four others of different types of palm wine. The last two 239 clusters encompassed Asian and North American strains. Ivorian strains are mainly 240 encountered as sub groups inside the main clusters. In contrast to sorghum beer strains, ron 241 wine strains from Côte d'Ivoire are found in two main clusters, one close to Burkina Faso ron 242 243 wine strains, and in a second different cluster. A similar situation can be observed for raffia 244 wine strains: one group of strains is detected close to Nigerian raffia wine strains, whereas the 245 second group is different.

246

#### 247 **3.4 Population structure**

Population structure was inferred with the Bayesian clustering software InStruct which does not assume Hardy-Weinberg equilibrium, but instead assigns individuals proportional membership coefficients in different populations based on inbreeding rates, which is well suited for *S. cerevisiae* population analysis (Gao *et al.*, 2007; Martiniuk *et al.*, 2016). Deviance information criterion indicated the most likely ancestral population number to be K = 15.

Each population was labelled by the geographic location and/or substrate from which the 254 strains were isolated (Figure 3). The 15 populations included 11 African beverage populations 255 among them, five originated from Côte d'Ivoire, two from European wine and bread 256 populations, one from the Asian sake population and one from the North American oak 257 population. The InStruct inferences revealed that most strains were assigned to a single 258 ancestry cluster although admixtures were observed. About 8 out of 18 clusters were 259 composed of individuals with one ancestral cluster membership coefficients higher than 0.80. 260 The 10 other clusters (bread, sake from Japan, oak from North-America, laboratory, Bertram 261 palm from Malaysia, various origins from Africa, Hyphaene thebaica from Djibouti, raffia, 262 263 palm oil and ron wines from Côte d'Ivoire) appeared as admixtures. A small number of individuals within ron (Borassus aethiopum) wine strains had alleles common with those of 264 ron strains from Burkina Faso, raffia and palm oil wines from Côte d'Ivoire. Strains of palm 265 oil wine have some alleles in common with strains from Djibouti, Ghana (bili), Burkina Faso 266 (dolo), other strains from Côte d'Ivoire (tchapalo and millet beer) and European wine strains. 267 Strains of raffia wine appeared to have alleles in common with all populations, but in small 268 269 proportion (Table S2 in the supplemental material).

In order to improve the detection of population structure of this study, a discriminant principal 270 component analysis (Jombart et al., 2010) based on 80 % of the global variation obtained 271 from the 50 first PCA axis was conducted (Figure 4). The first two axes enabled 272 differentiation of sorghum and millet beers strains (different shades of pink in the lower part 273 of Figure 4a) from Burkina Faso ron wines strains (shade of brown), Côte d'Ivoire (coral) and 274 275 miscellaneous African strains (magenta) in the upper part of Figure 4a. Genetic differentiation between African strains following some of their ecological niche was observed in the second 276 277 axis: strains from the sap of Arecaceae family plants of the (palm oil palm, raffia palm, 278 Borassus palm...) in the upper quadrant of Figure 4a were distinguished from those Poaceae 279 family (millet and sorghum) in the lower part. The cluster strains corresponding to Ivorian 280 tchapalo beer isolates were colocalized with Burkina Faso dolo beer isolates and Côte d'Ivoire millet beer strains. As for axes 3 and 4 (Figure 4b), they highlighted the differentiation 281 282 between North-America populations and Ghana cocoa strains from that of the rest of the world, and the axis 4 differentiate Nigeria palm strains (and to a lower extent sake strains) 283 284 from other strains. The two plots (Figure 4) showed that palm oil, raffia and ron wines from Côte d'Ivoire were also clustered but these clusters overlapped with clusters strains from 285 286 Djibouti palm, Nigeria raffia wine, Burkina Faso ron wine and African miscellaneous origins. 287 This clustering was also in agreement with the clustering obtained at K = 15 for InStruct.

Obstruct tests were performed to evaluate if the population structure revealed in Bayesian 288 ancestry profiles obtained from Instruct was correlated with the geography and confirmed of 289 Nei pairwise Fst distance. For this analyse, only palm oil and raffia wines isolates, which had 290 more than two sampling areas were considered. Obstruct analysis and canonical discriminant 291 analysis clearly showed that the differences between isolates for most sampling areas of palm 292 oil wine (Attinguié, Grand-Lahou, Alépé, Bingerville and Bonoua) were significant (Figure 5, 293 Table S4a in the supplemental material). Strains isolated from Bonoua and Grand-Lahou were 294 very different from the others. For strains from sampling areas of raffia wine, the differences 295 between populations were also significant with the isolates from Alépé and Grand-Lahou and 296 297 very different from the others isolates (Figure 5, Table S4b in the supplemental material).

298

#### 299 4 Discussion

This study was centered on the genetic diversity and population structure of indigenous *S*. *cerevisiae* from Cote d'Ivoire, as well as the factors that may explain the structure of the resulting populations. For this purpose, four traditional alcoholic beverages (raffia wine, palm oil wine, ron wine and tchapalo beer) collected in nine regions of Côte d'Ivoire were studied.

The pH of these beverages, which fluctuated between 3 and 5, were similar to those reported 304 by several authors in palm wines after the first day of tapping (Amoa-Awua et al., 2007; 305 Karamoko et al., 2012) and in tchapalo beer produced by traditional brewers (Aka et al., 306 307 2008). These ranges of pH could be a major advantage for the bio-preservation of these beverages by protecting them from the development of some pathogenic flora (Aka et al., 308 2008; Yao et al., 2009). The Total Titratable Acidity (TTA) and Total Soluble Sugars (TSS) 309 contents were variable from one beverage to another, while the yeast average load was around 310  $10^7$  to  $10^8$  CFU /mL in the four beverages. The low TSS contents observed in beverages of 311 this study could be related to the high yeast load, but also to the rest of the microbiota of these 312 313 beverages. TTA rates observed in beverages could be due to the production of a variety of 314 organic acids by yeasts and bacteria (N'guessan et al., 2008; Karamoko et al., 2012). Yeast loads found in this study could probably be due to the sum of various physical, chemical, and 315 316 biotic factors such as temperature, humidity, presence of nutrients, such as sugars (Santiago-Urbina et al., 2015). Similar yeast loads were reported in traditional fermented beverages 317 318 produced in Africa (Aka et al., 2008; Stringini et al., 2009; Karamoko et al., 2012). Diversity analysis indicated that ecological niche had a major influence on S. cerevisiae population's 319 320 native of Côte d'Ivoire. Fis values of palm oil and raffia wines strains (0.603 and 0.544) 321 revealed an excess of homozygote individuals which is very likely due to high inbreeding within each population rather than to population differentiation (Albertin et al., 2014). 322 Schuller and Casal (2007) also observed a significant excess of homozygotes in their study on 323 three vineyards located in the northwest of Portugal. These authors explained this fact by 324 asexual reproduction with some cycles of homothallic self-mating (genome renewal). 325 Moreover, these authors proposed as an alternative explanation that a mitotic recombination 326 or gene conversion during asexual reproduction may generate such a low of heterozygosity. 327 The high degree of homozygosity would point to the existence of genetically isolated clonal 328 subpopulations of S. cerevisiae strains with distinct genetic constitution. However, the 329 microsatellite loci analyzed here represent only a tiny fraction of the genome and provide an 330 331 indication of the mean heterozygosity. The heterozygosity detected at these microsatellite loci was found in good agreement with genomic data (i.e. Legras et al., 2007; 2018) but other loci 332 in the genome including those with technological relevance can present at different 333 heterozygosity status. 334

Evaluation of genetic diversity of Ivorian strains only revealed that isolates sharing the same micro-environment would be genetically similar to each other, regardless of their geographical origin, implying that ecological origin is the main factor responsible for the

close phylogenetic relationship between S. cerevisiae strains. Impact of geographical origin 338 on genetic diversity evaluated with Obstruct showed a difference between most of strains 339 population according to sampling area, which was in accordance with Nei Fst pairwise 340 distance. However these genetic distances remained low. Phylogenetic tree, Instruct and 341 Discriminant Analysis of Principal Components (DAPC), considering only African strains, 342 presented that subgroups appeared to be formed by differentiation according to ecological 343 origin. One of the possible explanations is that at a relative close geographical distance, 344 insects like bees, wasps, and fruit flies, as well as birds, which are known to be vectors for 345 346 yeasts, could have homogenized these yeast populations. Also, Human activities (sharing seasonal staff and equipment during the harvest and fermentation periods) could influence the 347 348 yeast population structure and promote dispersal (Börlin et al., 2016). Although strains of palm oil wine, raffia wine and ron wine were isolated in Côte d'Ivoire, they have been 349 350 associated to the same cluster containing the strains of other African countries which derived also of plant sap from the Arecaceae family (Elaeis guineensis, Raphia hookeri, Borassus 351 352 aethiopum, Borassus akeassii and Hyphaene thebaica). The clustering of strains from different traditional beers, notably tchapalo in Côte d'Ivoire, dolo in Burkina Faso and bili bili 353 354 in Ghana in the same cluster would reflect the history of the inoculum used. In Côte d'Ivoire, 355 sorghum beer was initially produced by populations living in the North and North-East of the country (Djè et al., 2008; N'guessan et al., 2010). Inocula found in Southern and Eastern Côte 356 357 d'Ivoire may have been introduced by traditional producers from North and North East of Côte d'Ivoire and those of Burkina Faso, Mali and Ghana. An exception to this distribution of 358 strains according to their geographical origin was the genetic affiliation of strains from Asia 359 (Japanese sake, Malaysian palm wine), and from North America (oak) of some Ivorian 360 strains, a result in agreement with those of Liti et al. (2009). Strains from palm oil, raffia 361 wines and tchapalo beer had common alleles with those of European wine, suggesting that 362 these strains could have a hybrid origin as reported by Ezeronye and Legras (2009). This 363 origin could always be explained by the fact that the European colonization of Africa would 364 365 have led to the introduction of S. cerevisiae in the same way, as cachaça strains in Brazil (Barbosa et al., 2018). This particular ecological situation, where African and European wine 366 or bread species are present in the same environment, may have provided the opportunity for 367 cross-breeding (Legras et al., 2007). Our results confirm that the beverage production areas 368 represent a reservoir of indigenous strains with a particular genotypic profile, selected by 369 interactions between yeasts and their environment, as suggested by Martínez et al. (2007). 370

The presence of few European wine and bread strains alleles, in low proportions among Ivorian strains would have provided them with some genes of interest, expressing phenotypic characteristics which could be interesting to exploit in fermentation processes. However, a thorough analysis of the biotechnological properties of these strains will be necessary to confirm this idea.

Figure 1: Map of Côte d'Ivoire showing the areas from where samples were collected.

## Population source

- Palm oil wine
- Ron wine
- Raffia wine
- Tchapalo beer

**Figure 2a**: Phylogenetic tree among Ivorian *S. cerevisiae* strains. The tree is drawn according to neighbour-joining method from a pairwise individual distance matrix calculated with relative dissimilarity distance between 170 strains and based on the polymorphism at 12 loci.

**Figure 2b**: Phylogenetic tree among *S. cerevisiae* strains of diverse geographical origins and substrates. The tree is drawn according to the neighbour-joining method from a pairwise individual distance matrix calculated with relative dissimilarity distance between the 284 strains (from 18 different ecological niches) and based on the polymorphism at 12 loci.

Inference of each population ancestry with InStruct

**Figure 3**: Inferred population structure using InStruct program on the 384 *S. cerevisiae* strains. Deviance information criterion indicated the most likely population number to be K = 15. *S. cerevisiae* populations are delimited vertically according to their ecological origin. Colours represent the different alleles that constitute each population.

(b)

**Figure 4:** Discriminant principal component analysis (DPCA) (a): Plot showing representation of the different clusters according to axes 1 and 2; (b) plot showing representation of the different clusters according to axes 3 and 4. Clusters are shown by different colours and inertia ellipses, while dots represent individuals.

**Figure 5**: Canonical discriminant analysis of the ancestry obtained for palm oil wine (a) and raffia wine (b) isolates from Côte d'Ivoire with OBSTRUCT, after removal of strains from other countries. The outer blue ellipsoid labelled group reflects the variation of the group means around the grand mean while the red circle reflects the pooled within-group dispersion and covariation. The black points indicate predefined populations while numbers at the arrows indicate inferred populations.

	Maximum	$3.91 \pm 0.21$	$1.00 \pm 0.14$	$5.80 \pm 0.30$	$2.6 \pm 0.6 \times 10^8$
Tchapalo beer	Average	$3.46 \pm 0.13^*$	$0.93 \pm 0.03^{\ddagger}$	$7.70 \pm 1.04^{\ddagger}$	$1.7 \pm 0.1 \times 10^{7*}$
	Minimum	$3.38 \pm 0.1$	$0.92 \pm 0.02$	$5.81 \pm 0.57$	$1.2 \pm 0.1 \times 10^7$
	Maximum	$3.5 \pm 0.14$	$0.94 \pm 0.04$	$10.87 \pm 2.0$	$2.4 \pm 0.1 \times 10^7$

Table 2: Physico-chemical characteristics and yeast count of alcoholic beverages of the study

The values expressed are the average of three measurements. On the same column, mean values with the same symbol are not significantly different (Tukey HSD test range at P < 0.05).

**Table 3a:** Pairwise Fst distance matrix between populations isolated from different beverages. Fst is calculated according to Nei (1973). Fst values are given in the lower matrix and upper matrix indicates P-value estimated from 1000 permutations of the genotypes dataset.

	Palm oil wine	Raffia wine	Ron wine	Tchapalo beer
Palm oil wine	0.000	0.008	0.001	0.001
Raffia wine	0.021	0.000	0.001	0.001
Ron wine	0.061	0.069	0.000	0.001
Tchapalo beer	0.107	0.074	0.073	0.000

**Table 3b**: Pairwise Fst distance matrix between sampling areas. Fst is calculated according to Nei (1973). Fst values are given in the lower matrix and upper matrix indicates P-value estimated from 1000 permutations of the genotypes dataset.
