ABSTRACT After a period of operation, the mechanical properties of ship-to-shore (STS) cranes can change. It is necessary to analyze the strength of the main structural component in STS cranes under dynamic load to assess their safety. This case study was conducted on a 28-ton capacity STS crane. A testing system with signal sensing, conditioning, acquiring, and analysis was established. After on-site testing, all of the stresses of the test positions were calculated and determined to be in the allowable range. As a result of this study, a systematic approach to analyze the strength of the main structural component in STS cranes under dynamic load is proposed.

INDEX TERMS ship-to-shore cranes, dynamic load, Kalman filters

I. INTRODUCTION

S HIP-to-shore (STS) cranes are used in ports and termi-nals to transfer containerized cargo to and from ships 2 з [1]. Since its inception more than 50 years ago (the first quayside container crane was built in January 1959 [2]), the 5 container industry has made remarkable progress. The typical 6 elements of an STS crane include a combination of two sets 7 of ten rail wheels mounted to the bottom of the vertical 8 frame and braced system; a structurally designed system 9 of beams assembled to support the boom, cabin, operating 10 machinery, and the cargo being lifted; crane boom; hook; 11 operating cabin; and storage equipment. The crane is driven 12 by a specially trained operator who sits in a cabin attached to 13 the trolley suspended from the beam. The trolley runs along 14 rails located on the top or sides of the boom and girder. The 15 operator runs the trolley over the ship to lift the cargo, usually 16 containers. Once the spreader locks onto the container, the 17 container is lifted, moved over the dock, and placed on a truck 18 chassis (trailer) to be taken to the storage yard. The crane also 19 lifts containers from the chassis on the dock to load them onto 20 the ship. 21

STS cranes are mostly used for a long duration. Prolonged use affects the mechanical properties of STS cranes. If an accident occurs, the economic losses can be enormous, and thus, safety assessments are necessary. There are many performance indicators related to STS crane safety, including structure strength, dynamic stiffness, and fatigue strength. The main objective of this paper is to study the strength of the main structural component in STS cranes under dynamic load.

28

29

30

There are many studies on machines under dynamic load. 31 For example, a simple experimental technique employing 32 wire strain gauges for measuring dynamic loads and stresses 33 in operating gear systems has been described in [3]. Others 34 have applied simple rigid-plastic methods to analyze plastic 35 failure of ductile beams loaded dynamically, as N Jones in 36 [4]. JA Laman et al. [5] have calculated the dynamic load 37 allowance in steel through-truss bridges. PS Shenoy et al. [6] 38 have performed quasi-dynamic finite element analysis (FEA) 39 for a typical connecting rod to capture stress variations over 40 a cycle of operation. ES Hwang et al. [7] have analyzed the 41 simulation of dynamic loads in bridges. VA Kopnov [8] has 42 predicted the fatigue life of the metalwork of a travelling 43 gantry crane. Some experiments on a welded steel frame 44 exposed to fatigue loading, and on wire ropes damaged by 45 saw cuts have been conducted in [9]. Research about the 46 sensitivity of some sources of uncertainty in the seismic 47 response of a Korean container crane structure has been 48 reported in [10]. A comparative study of nonlinear static 49 and time history analyses of typical Korean STS container 50 cranes has been described in [11]. Furthermore, there are 51 some published books about the impact strength of materials 52 [12] and introductions to examples of structural computation 53 of machine components [13]. However, in the existing litera-54 ture, we have not found a systematic testing approach applied
to STS cranes under dynamic load. However, all the previous
studies lack of systematic approach in analyzing the strength
of the main structure component in STS crane under dynamic
load.

In this paper, the dynamic load strength test is designed 60 to determine whether the main structural component of an 61 STS crane can withstand transient impact stresses caused by 62 preset loads and changes in the trolley position. Simulating 63 the worst working conditions allow us to determine whether 64 the structure meets strength requirements. In this paper, a 65 study on an STS crane with 28-ton capacity and 18 years of 66 service has been conducted with on-site testing. We have not 67 conduct field tests under strong wind conditions because of 68 the safety concerns [14]. 69

The remainder of the paper is organized as follows. In section II, we introduce the test method, including the principles of the testing system, the location of measuring points to find the loading, and the conditions. In section III, we summarize the data and analyze it with Kalman filters, showing the maximum value of stress at each measuring point. In section IV, we present our conclusions.

77 II. TESTING METHOD

78 A. TESTING SYSTEM

The dynamic load test assesses the dynamic loading stresses 79 in the main girder carrying the member system, rod system, 80 and gantry system. Tensile stress is expressed as positive 81 while compressive stress is negative. Figure 1 shows a 82 schematic structure of our dynamic load strength test and 83 analysis. It includes strain measuring points, signal sensing 84 and conditioning, signal analysis, and output. The signals 85 enter a 14-channel strain gauge signal conditioner to be 86 processed and amplified. One of the advantages of this testing 87 system is that it can produce a stable gauge output signal. 88 Using the on-site data acquisition system, the parameters of 89 the dynamic load working condition can be obtained. These 90 data and synchronously processed signals will be stored in 91 the specified virtual instrument memory for the secondary 92 processing. 93

Dynamic load stress testing and analysis of the main equipment will use the following instruments and sensors:

- ⁹⁶ 1) electrical resistance strain gauges,
- 97 2) quad strain adapter, and

100

101

102

103

104

105

- 3) crane status monitoring and evaluation system, which
 mainly includes
 - a) workstation,
 - b) signal channel expansion box,
 - c) signal conditioning apparatus,
 - d) data collector,
 - e) visualization software, and
 - f) data management and analysis software.

106 B. MEASURING POINTS

The beam of an STS crane is primarily subjected to trans verse and axial loads. When we analyze the strength of the

main structural component, we ignore axial loads. Consider 109 a beam that is simply-supported at E and K, and subjected to 110 three concentrated loads and two distributed loads as shown 111 in Figure 2. F_x is the dynamic load acting on the beam; the 112 location of X can be changed along the beam. The transverse 113 loads cause internal shear forces and bending moments, 114 which in turn cause axial stresses and shear stresses in the 115 cross section. Considering the reactions as plane stress states, 116 we obtain the following empirical equation for calculating 117 the total stress [15]: 118

$$\sigma = \sqrt{\sigma_1^2 + \sigma_m^2 - \sigma_1 \sigma_m + 3\tau^2} \tag{1}$$

where σ_1 is the longitudinal axial stress caused by the bending moment, σ_m is the compressive stress caused by the concentrated load, and τ is the shear stress. The simple theory of elastic bending states that

$$\sigma_1 = \frac{M_{max}}{Z} \tag{2}$$

where M_{max} is the maximum bending moment for the beam and Z is the section modulus. If the force is evenly distributed across the cross section, the internal forces can be approximated as uniform, and the beam is subjected to a uniform normal stress, defined as

$$\sigma_m = \frac{P}{\delta C} \tag{3}$$

with P the concentrated load, δ the width (depth) of the 128 concentrated load, and C the length of the concentrated load. 129

When the beam is subjected to a set of equal and opposite transverse forces, there is a tendency to failure caused by stratification of the material. If this failure is restricted, then a shear stress τ is generated, defined as

$$\tau = \frac{QA_r}{I\sum\delta} \tag{4}$$

with I the moment of inertia, Q the shear force, A_r the area of the cross section, and \sum the summation. To calculate these parameters, it is necessary to analyze the cross section of the beam, which is a rectangular tube, as shown in Figure 3. Assuming that the beam is symmetric about the neutral axis passing through its centroid, we can calculate the relevant geometric parameters as

$$\begin{cases} A_r = ab - a_1b_1 \\ I = \frac{ab^3 - a_1b_1^3}{12} \\ Z = \frac{ab^3 - a_1b_1^3}{6b} \\ e = \frac{b}{2} \\ i = \sqrt{\frac{ab^3 - a_1b_1^3}{12(ab - a_1b_1)}} \end{cases}$$
(5)

where a and b are the length and width of the cross section, respectively; a_1 and b_1 are the internal length and width of

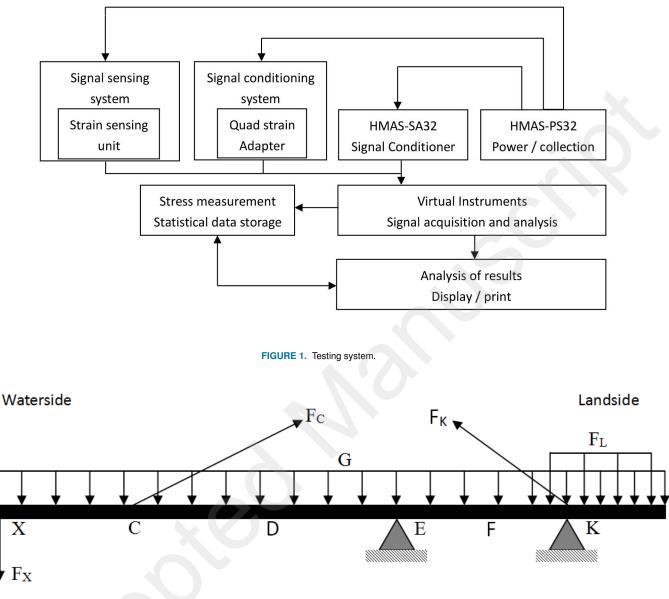

FIGURE 2. Reaction for the beam.

 F_X : Dynamic load (Self-weight of trolley and hopper, and test load); F_C : Force of the diagonal link reaction on point C; F_L : Weight of the house (Machinery house, electric room, power station and so on); G : Self-weight of the beam; D : Center between C and E; F : Center between E and K. F_K : Force of the diagonal link reaction on point K.

the cross section, respectively; e is the extreme point; and i is the radius of gyration [15].

By calculating σ , we find that the maximum σ must appear 145 at points C, D, E, F, or K (as shown in Figure 2). These 146 sensors will be placed at these positions. Theoretically, the 147 diagonal link connects with the beam at point C. However, in 148 practice, the diagonal link connects with the beam at points 149 A and B by lugs, so the sensors are set at the points A and 150 B instead of point C. All of the measurement points are 151 shown in Figure 4. To reduce the number of sensors to 14, 152 U_1, U_3, U_5 , and U_7 (see Figure 4) are considered to have 153

the same mechanical properties. Similarly, D_1 , D_3 , D_5 , and 154 D_7 are considered the same. The same applies to M_1 and 155 M_5 , and M_2 and M_6 . Therefore U_5 and D_7 are chosen as 156 measurement points at A, B, D, and F; and M_1 and M_6 are 157 chosen as measurement points at E and K. In addition, U_3 158 and U_7 are measured at point D to improve measurement 159 accuracy. These points have been labeled AU5, AD7, BU5, 160 BD7, DU5, DU7, DD7, DU3, EM1, EM6, FU5, FD7, KM1, 161 and KM6. 162

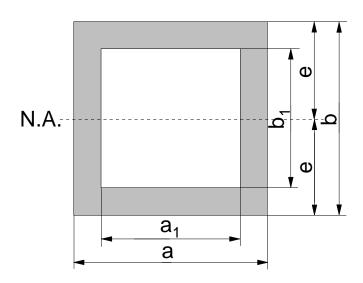

FIGURE 3. Cross section of the beam (view from waterside to landside).

C. LOADING AND CONDITION 163

Main structure testing with dynamic load stress is based 164 on a static stress test. With static stress tests, including 165 quantitative distributions and static load waveforms [16], 166 we can analyze the features of large static stress points in 167 both amplitude and frequency domains, and then check the 168 strength of the structure with a dynamic load. 169

The positions with different loading and conditions are 170 shown in Figure 5. The test load is 25 tons (nominal load of 171 28 tons). The wind scale was 3 and the environmental tem-172 perature was 25°C. We have conducted a total of 10 cyclic 173 experiments from testing condition 0 to testing condition 4, 174 and calculated the average cycle time, which was 200 s. The 175 on-site test conditions (TC - Testing Condition) are: 176

1) TC0 (from position 0 to position 1): In this zero state 177 condition, the test load is located in the hopper, and the 178 grab bucket rests on the test load. The rope is loosened 179 until there is no force between the trolley and the grab 180 bucket. 181

2) TC1 (from position 1 to position 2): First, the trolley 182 runs at full speed to the limit position of the front 183 beam and the grab bucket begins to free fall. Then, 184 the control wire rope makes the bucket stop for 10 185 seconds, after which the bucket grabs the test load, and 186 it begins to rise at full speed. Finally, the control wire 187 rope makes the grab bucket stop. 188

3) TC2 (from position 2 to position 3): First, the trolley 189 runs to the middle position of the front beam and the 190 grab bucket begins to free fall with the test load. Then, 191 the control wire rope makes the bucket stop for 10 192 seconds, after which it begins to rise at full speed. 193 Finally, the control wire rope makes the grab bucket 194 stop. 195

4) TC3 (from position 3 to position 4): First, the trolley 196 runs to the position of the back beam and the grab 197

bucket begins free fall with the test load. Then, the 198 control wire rope makes the bucket stop for 10 seconds, 199 after which it begins to rise at full speed. Finally, the 200 control wire rope makes the grab bucket stop.

5) TC4 (from position 4 to position 0): The trolley runs back to the zero position of the beam. The grab bucket 203 lays down the test load. The system goes back to zero 204 and checks the zero drift of the test system. 205

III. RESULTS AND ANALYSIS

A. DATA COLLECTION

As described previously, data are collected from 14 sensitive points at varying positions along the beam and around the 209 beam cross-section.

B. KALMAN FILTERING

The sampling rate of the signal voltages is 2500Hz. How-212 ever, the field environment is complex, causing noise that 213 interferes with the signal. To improve the efficiency of data 214 analysis, it is necessary to process the data with a Kalman 215 filter. The general linear discrete system can be expressed as 216

$$\begin{cases} X(k) = A(k)X(k-1) + B(k)U(k) + w(k) \\ Z(k) = H(k)X(k) + v(k) \end{cases}$$
(6)

where X(k) is the *n*-dimensional state vector; U(k) is the 217 system control vector; w(k) is the *n*-dimensional system 218 noise vector; A(k) is the state transition matrix from k-1219 to k; B(k) is the excitation transfer matrix from k - 1 to k; 220 Z(k) is the *m*-dimensional observation vector; H(k) is the 221 predictive output transfer matrix for time k; and v(k) is the 222 m-dimensional observation noise vector [17]. The Kalman 223 filter is applied to data prediction, which requires the use of 224 predictive derivation equations as follows: 225

$$\begin{cases} X(k|k-1) = A(k)X(k-1|k-1) + B(k)U(k) \\ P(k|k-1) = A(k)P(k-1|k-1)A(k)^{T} + Q \\ X(k|k) = X(k|k-1) + Kg(k)(Z(k) - H(k)X(k|k-1)) \\ Kg(k) = P(k|k-1)H(k)^{T}/(H(k)P(k|k-1)H(k)^{T} + R) \\ P(k|k) = (I - Kg(k)H(k)P(k|k-1)) \end{cases}$$
(7)

where X(k|k-1) is the result of the prediction using the 226 previous state of the system; X(k-1|k-1) is the optimal 227 result of the previous state of the system; P(k|k-1) is the 228 corresponding covariance of X(k|k-1); P(k-1|k-1)229 is the corresponding covariance of X(k-1|k-1); A^T is 230 the transpose of matrix A; Q(k) is the covariance matrix 231 of w(k); Kg(k) is the Kalman gain at time k; R(k) is the 232 covariance matrix of v(k); and I is the unit matrix [18]. 233 In this system, x(k) represents the system status at time k, 234 and Z(k) represents the pressure measurement at time k, 235 so n = m = 1, and the state transition matrix B(k) is a 236 zero matrix. We used Gaussian white noise as our model to 237 better simulate unknown real noise, which is often caused 238 by a combination of many different sources of noise. If we 239 increase the system noise, the Kalman gain will also increase, 240

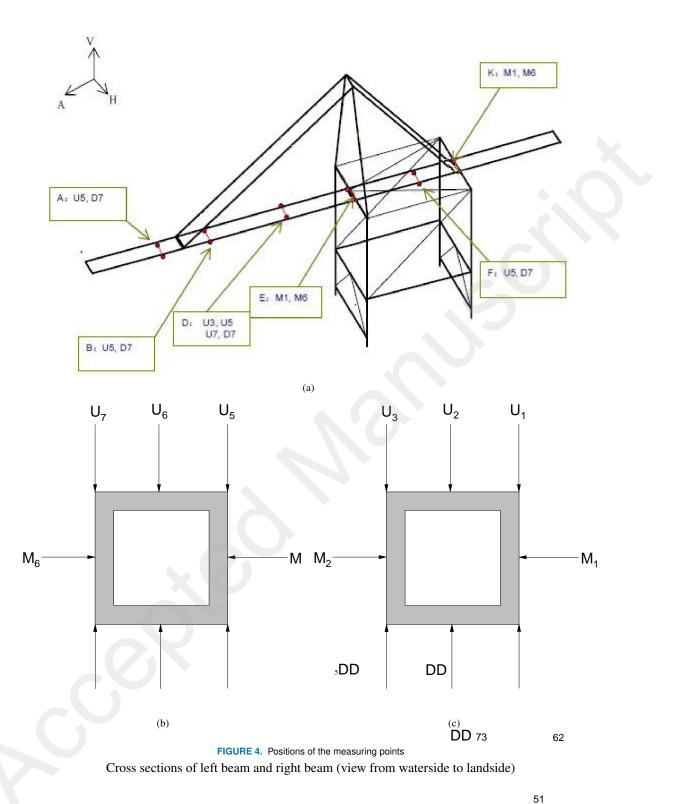

201 202

206

207

208

210

making the initial value more reliable; if we increase the
measured noise, the Kalman gain will decrease, making the
theoretical value become more reliable.

The data processed by Kalman filtering is shown in Figure 6. The horizontal axis is time in seconds, and the vertical axis is stress measured at positions DU3 and DD7 after filtering. We also label the maximum and minimum values

after filtering. 2169-3536 (c) 2018 IEEE. Translations and content mining are permitted for academic research only. Personal use is

C. CALCULATE THE MEASURED POINT STRESS

From the filtered signal, we can obtain the maximum value of stress at each stress measurement point and analyze the corresponding test condition. The calculation results for each measurement point are given in Table 1. The results show that 253

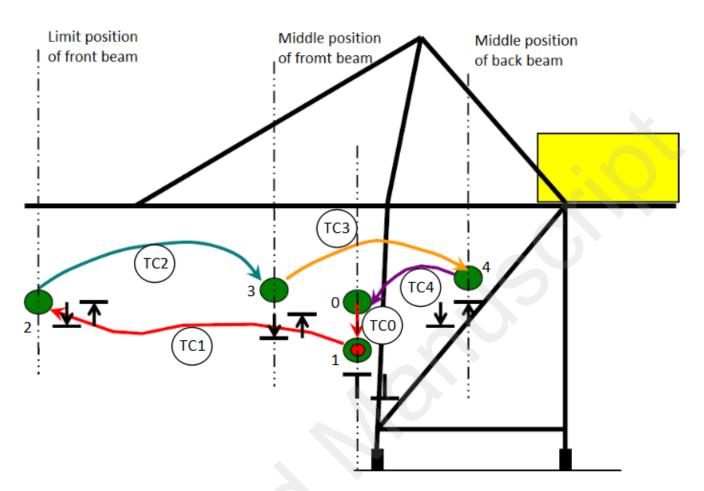

FIGURE 5. Schematic view of the positions with different loading and conditions.

| Point | Max(MPa) | Time(s) | Min(MPa) | Time(s) |
|-------|----------|---------|----------|---------|
| AU5 | 0 | 0 | -40.09 | 159 |
| AD7 | 17.34 | 41 | 0 | 0 |
| BU5 | 0 | 0 | -40.38 | 78 |
| BD7 | 17.16 | 39 | 0 | 0 |
| DU5 | 0.05 | 3 | -82.60 | 84 |
| DU7 | 0.55 | 2 | -82.75 | 100 |
| DD7 | 59.90 | 100 | 0 | 0 |
| DU3 | 1.68 | 1 | -88.49 | 100 |
| EM1 | 8.39 | 91 | -0.51 | 1 |
| EM6 | 6.10 | 100 | 0 | 0 |
| FU5 | 36.68 | 137 | -4.40 | 35 |
| FD7 | 0.01 | 4 | -19.87 | 62 |
| KM1 | 0 | 0 | -4.63 | 62 |
| KM6 | 2.67 | 159 | -3.27 | 62 |

TABLE 1. Structural dynamic load strength (MPa)

the maximum compressive stress occurs in condition TC2 (when the trolley runs to the middle position of the front beam), at DU3. The corresponding value is:

$$\sigma_{max}^{(DU3)} = -88.49 \quad (MPa)$$

The maximum tensile stress occurs also in condition TC2, at DD7. The corresponding value is: 258

$$\sigma_{max}^{(DD7)} = 59.90 \quad (MPa)$$

The STS crane beam is made of steel Q345 (Chinese criterion, similar to S355 in the European criterion, with the same dynamic safety factor), so the allowable stress is given by [15]: 262

$$[\sigma] = \sigma_y/n = 345/1.5 = 230$$
 (MPa)

where σ_y is the yield limit and n is the safety factor for the load. All of the measurement points with dynamic load stress should satisfy the strength requirements: 265

$$\sigma|_{max} < [\sigma]$$

In field strength testing, the maximum tensile stress occurs at DD7, with a value of 59.90 MPa; the maximum dynamic load stress occurs at DU3 with a -88.49 MPa. These values meet the strength requirements. 269

IV. CONCLUSION

This paper introduces a systematic approach to analyzing the 271 strength of the main structural component in an STS crane 272

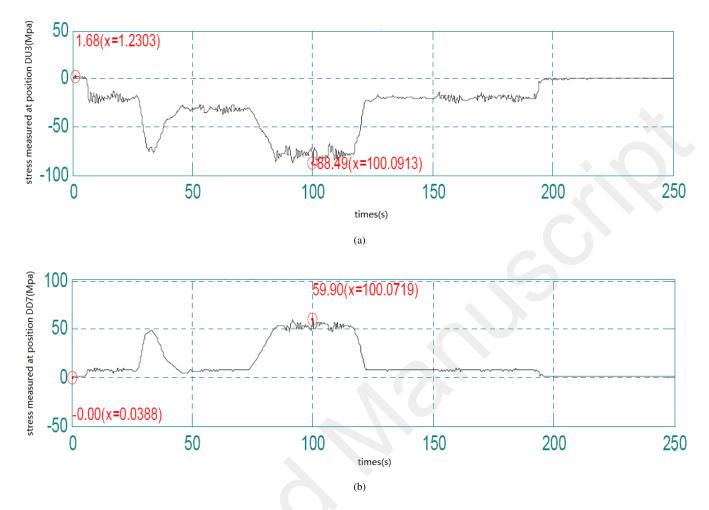

FIGURE 6. Time-domain curves of stress in maximum stress points

under dynamic load. First, we established a testing system for 273 the main structural component in STS cranes, including sig-274 nal sensing, conditioning, acquisition, and analysis. Second, 275 we identified dangerous positions at which maximum stress 276 may occur and arranged sensors in these positions. Third, we 277 designed the on-site test conditions, and acquired signals and 278 processed them with Kalman filters. Fourth, we calculated 279 the stresses of the test positions under various test conditions. 280

However, there are some limitations of our method. Due 281 to safety concerns, we have not conducted field tests un-282 der strong wind conditions. When strong winds occur, the 283 structural connections of the crane (such as the connection 284 between the legs and the main beam and the connection 285 between the legs and the lower cross beam) can produce large 286 eddy currents. Large negative pressures will be generated in 287 this zone, creating a strong turbulent flow zone between the 288 two main beams and producing a negative wind pressure. 289
