HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

INVITATION LETTER

Dear Colleague,

You are invited to participate to the Special Issue (SI) on "Light-Assisted Catalysis for Water and Wastewater Treatment" (LACWWT) to be published in [Applied Catalysis B: Environmental](#) (IF 2016 =9.44) honoring the retirement of Professor César Pulgarin.

Remember that article title and authors MUST be that provided by you to the invited editors, or very similar. No other paper will be admitted.

The deadline for manuscript submission is **September 30, 2018 (NO EXTENSION WILL BE ALLOWED)**.

All the manuscripts should follow the guidelines of *Applied Catalysis B: Environmental*, will undergo the regular peer-review process and should meet the highest scientific quality standards of the journal. Manuscripts should be submitted online through EES system (<https://ees.elsevier.com/apcatb/>). You must choose Article Type as "Special issue - Honoring Cesar Pulgarin (LACWWT)" during the submission process. **Please include this "Invitation Letter" from the Guest Editors along with the manuscript.** For more general information please visit the online "Instructions for Authors" on: <https://www.elsevier.com/journals/applied-catalysis-b-environmental/0926-3373/guide-for-authors>.

SPECIFIC INSTRUCTIONS. The maximum length of each article is 8000 words equivalent (including abstract, text, figures, tables and references). A figure or table is equivalent to 400 words. Include in your COVER LETTER the contact e-mail of all co-authors and FOUR possible referees for your paper. Remember that perhaps you will be contacted by editors to actuate as referee of other papers of the SI.

This sentence should be added in the Acknowledgements section of their contributions stating: "This Special Issue is dedicated to honor the retirement of Prof. César Pulgarin at the Swiss Federal Institute of Technology (EPFL, Switzerland), a key figure in the area of Catalytic Advanced Oxidation Processes". As this SI is devoted to the closing of the career of Prof. Pulgarin, authors are also highly welcome to mention how their research and vision of AOPs has been affected by the works of Prof. Cesar Pulgarin.

Yours sincerely,

Abstract

In the present study, comparison of activation efficiencies of hydrogen peroxide (H₂O₂) and persulfate (PS, Na₂S₂O₈) induced by Fe(III)-Ethylenediamine-*N,N'*-disuccinic acid (EDDS) under polychromatic irradiation UVA and visible region at same conditions was studied for the first time. The effects of pH, Fe(III)-EDDS concentration, H₂O₂ and PS concentrations were investigated. *p*-hydroxyphenylacetic acid (*p*-HPA) was taken as a model pharmaceutical intermediate pollutant to estimate the oxidative process efficiency. In these two systems, the degradation rate of *p*-HPA increased (not linearly) using higher concentrated solution of H₂O₂ and Na₂S₂O₈. However, when

Fe(III)-EDDS concentration exceeding 250 μM , the degradation efficiency of *p*-HPA began to decrease. Surprisingly, results of pH effects showed that Fe(III)-EDDS/H₂O₂/UV system presents much higher degradation efficiency than Fe(III)-EDDS/PS/UV whatever the solution pH's, especially in neutral and alkaline solutions. In the Fe(III)-EDDS/H₂O₂/UV reaction, *p*-HPA degradation rate ($R_{p\text{-HPA}}$) increased fast from pH 2.5 to 7.5, then it began to decrease when pH increased to 9.0. While $R_{p\text{-HPA}}$ started to decrease with pH increase to 3.9 in Fe(III)-EDDS/PS/UV system. To explain this phenomenon, the second order constant of *p*-HPA (for both molecular and mono-anionic forms) with HO \bullet and SO₄ \bullet^- radicals were determined by laser flash photolysis (LFP) experiments for the first time. Results showed that $k_{p\text{-HPA},\text{HO}\bullet}$ was higher than $k_{p\text{-HPA},\text{SO}_4^{\bullet-}}$ for both anionic and molecular forms of pollutant. These results demonstrated that iron-complex induced photo-Fenton process is more efficient than activation of persulfate process, particularly at environmentally closed pH values and sun-simulated wavelengths ($\lambda > 300 \text{ nm}$).

Keywords

Advanced oxidation processes, iron-EDDS complexes, decontamination, wastewater

1. Introduction

Wastewater treatments based on advanced oxidation processes (AOPs), which mainly depend on the generation of free radical species, have been extensively studied in the last two decades [1, 2].

The reaction between H₂O₂ and Fe(II)/Fe(III) is a well-known method for the generation of hydroxyl radicals (HO \bullet), including Fenton (Fe(II)/H₂O₂) [3, 4], Fenton-like (Fe(III)/H₂O₂) [5] and photo-Fenton (UV/Fe(III)/H₂O₂) processes [6-10]. With high oxidation abilities, HO \bullet ($E^0 = 2.8 \text{ V}$)

has a wide application for removing environmental contaminants like endocrine disruptors, chlorophenols, dyes, pharmaceuticals and pesticides [4, 11-13]. However, in recent years, studies on sulfate radical ($\text{SO}_4^{\bullet-}$) have proved that this radical is outstanding in degrading recalcitrant organic pollutants ascribing to its similar oxidation-reduction potential ($E^0 = 2.6\text{-}3.2\text{ V}$) [14], much longer half-life time and more selective reactivity compared with HO^\bullet . From previously reported literature data, the generation of $\text{SO}_4^{\bullet-}$ usually derives from the activation of persulfate (PS) by heat [15], UV or transition metals [16-18]. Among these activation processes, methods involved Fe^0 , Fe^{2+} or Fe^{3+} with or without UV are efficient, energy-saving and relatively nontoxic [18]. The main formations of HO^\bullet and $\text{SO}_4^{\bullet-}$, from iron activation routes, are shown below [19-21]:

The generation of HO^\bullet and $\text{SO}_4^{\bullet-}$ based on iron mediated activation, mainly combined with UV irradiation, has played predominant roles in advanced oxidation processes. However, there are several defects in these activation methods. The most predominant drawback is the Fe^{2+} natural oxidation into Fe^{3+} in water due to the oxygen presence and Fe^{3+} ions precipitation at pH higher than 4.0. Therefore, most of the iron species present in natural and slightly basic solutions, exist in the form of insoluble ferric oxides and (hydr)oxides. Due to these physicochemical properties of iron in water, the activation of persulfate by $\text{Fe}^{2+}/\text{Fe}^0$ is more favorable in acidic solution than in neutral and alkaline pH [18].

For these reasons, the development of Fe(III)/Fe(II) organic complexes is essential to improve the removal efficiencies under environmentally relevant pH values. Polycarboxylate acids like citric,

oxalic and aminopolycarboxylic acids like ethylenediaminetetraacetic acid (EDTA) can form stable water soluble complexes with iron in neutral and slightly basic pH solutions, enhancing the dissolution of iron in natural water. Moreover, these complexes are photochemically active and efficient leading, by photoredox process, to the production of oxidative species like hydroxyl radicals [13, 22, 23]. However, EDTA is toxic and hard to be removed from aqueous solution by traditional chemical and biological water treatments and so it is always found in considerable concentration in rivers [24]. Compared to EDTA, ethylenediamine-N,N'-disuccinic acid (EDDS), which is a structural isomer of EDTA, has been recognized to be more easily biodegraded and more environmental friendly [25]. Photo-induced production of HO^\bullet and $\text{SO}_4^{\bullet-}$ based on Fe(II)/Fe(III)-EDDS complexes has been widely studied in recent years, showing excellent efficiency in removing organic pollutants in water and soil near neutral pH [5, 7, 9, 26-33]. Huang et al. demonstrated that in homogeneous Fenton-like process (Fe(III)-EDDS/ H_2O_2), Fe(III)-EDDS (molar ratio 1:1) shows better removal efficiency of bisphenol A (BPA) in alkaline solution than in acidic one [34]. At the same time, Wu and coworkers reported that under UV radiation, photo-Fenton process (Fe(III)-EDDS/ H_2O_2 /UV) has much higher efficiency in removing 4-tert-Butylphenol (4tBP) than Fenton process. This result can be ascribed to the rapid generation of Fe(II) under irradiation [9]. In the presence of PS with Fe(III)-EDDS/UV, rapid oxidation of 4-terbutylphenol (4tBP) is observed due to the formation of $\text{SO}_4^{\bullet-}$. In neutral and basic pH conditions, the efficiency of 4tBP degradation is much higher with Fe(III)-EDDS than with Fe(III) aquacomplexes [14]. So, the use of Fe(III)-EDDS complexes leads to efficient oxidation processes whatever the sources of radical species (HO^\bullet or $\text{SO}_4^{\bullet-}$). However, the comparison between Fe(III)-EDDS/ H_2O_2 /UV and Fe(III)-EDDS/PS/UV systems under same conditions including the

effects of pH, Fe(III)-EDDS concentration, H₂O₂ and PS concentrations has never been investigated before. The main goal of this paper is to compare these two processes using *p*-hydroxyphenylacetic acid (*p*-HPA) as a model pollutant. *p*-HPA is one of the pharmaceutical intermediates and also widely used in the synthesis of pesticides and commonly detected in olive oil wastewaters [35, 36]. The aim of this study is to quantify the different activation efficiency of H₂O₂ and PS by Fe(III)-EDDS under irradiation in the same experimental conditions and to correlate the efficiency with the production of HO[•] and SO₄^{•-} radicals. Especially, to reach this goal and understand the different mechanisms, the second order rate constants of *p*-HPA with HO[•] and SO₄^{•-} are determined by laser flash photolysis (LFP) for the first time.

2. Materials and methods

2.1 Irradiation setup and experimental procedure

List of chemicals used in this work is reported in the Supporting Information. For the control experiment in the dark, reactions are performed in a brown bottle with continuous magnetic stirring at room temperature. The reactions start from the addition of H₂O₂ or Na₂S₂O₈ to the solution. For the degradation of *p*-HPA under irradiation, the experiments are performed in a home-made photoreactor placed in a cylindrical stainless steel container. Four fluorescent light bulb lamps (Philips TL D 15 W/05) were separately placed in four different axes. Meanwhile, the photoreactor, which is a water-jacketed Pyrex tube with 2.8 cm internal diameter, was placed at the center of the setup. The emission spectrum (Fig.S1) was determined using an optical fiber coupled with a CCD spectrophotometer (Ocean Optics USD 2000+UV-vis) and energy has been normalized to the actinometry results using paranitroanisole (PNA)/pyridine method [37]. A total

flux of 1451 W m^{-2} reaching the solution was determined between 300–500 nm. Solutions are magnetically stirred with a magnetic bar during the reaction and total volume was 100 mL. All the experiments are carried out at room temperature ($293 \pm 2 \text{ K}$), controlled by a circulating cooling water system. The initial concentration of *p*-HPA is $50 \text{ }\mu\text{M}$ in all experiments, and samples are taken from the reaction tube at fixed interval times. In order to stop the Fenton reaction after the samples taken from the photoreactor, $20 \text{ }\mu\text{L}$ IPA were added immediately after withdrawn.

2.2 p-HPA quantification and degradation rate

The concentration of the *p*-HPA remaining in the aqueous solution is determined with an Alliance high performance liquid chromatography (HPLC) equipped with a photodiode array detector (Waters 2998, USA) and Waters 2695 separations module. The experiments are performed by UV detection at 274 nm. The flow rate is 0.15 mL min^{-1} , the injection volume is $50 \text{ }\mu\text{L}$ and the mobile phase is a mixture of water (with 0.1% H_3PO_4) and methanol (65/35, v/v). The column is a Nucleodur 100-3 C18 of $150 \times 2.0 \text{ mm}$, particle size $3 \text{ }\mu\text{m}$. In these conditions, the retention time of *p*-HPA is 6.7 min. The initial degradation rate of *p*-HPA is $R_{p\text{-HPA}} (\text{M s}^{-1}) = k_{\text{app}} \times [p\text{-HPA}]_0$ with $[p\text{-HPA}]_0$ the initial concentration of *p*-HPA, k_{app} the pseudo-first-order apparent rate constant (s^{-1}). The error is $\pm 3\sigma$, obtained from the scattering of the experimental data.

2.3 Laser Flash Photolysis

Experiments are carried out using the fourth harmonic ($\lambda_{\text{exc}} = 266 \text{ nm}$) of a Quanta Ray GCR 130-01 Nd: YAG laser system instrument and the energy is set at 45 mJ/pulse . Other conditions are kept the same to those described in previous articles [14, 38]. Conditions and chemicals used for the determination of reactivity constants are reported in the Supplementary Information.

3. Results and Discussion

3.1 Evaluation of the second order rate constants

p-HPA has two pKa (4.5 and 10.5) corresponding to the carbonyl and alcoholic functions.

Considering that the typical pH range of natural and sewage treatment plan waters is from 4 to 8,

the second second-order rate constant was determined at pH 2.5 (molecular form) and pH 8.5

(mono-anionic form). At 266 nm laser excitation no transient species are detected when only

p-HPA is present in solution. The determination of the second order rate constant between *p*-HPA

and HO• ($k_{p\text{-HPA},HO^\bullet}$) is determined by using chemical competition kinetics with thiocyanate

anions (SCN⁻) as reported in equations R4-R7 and Scheme S1. $k_{p\text{-HPA},HO^\bullet}$ is obtained by

following the absorbance of SCN₂^{•-} in the presence of different *p*-HPA concentrations. The

absorbance of SCN₂^{•-} species decreases when the concentration of *p*-HPA increases due to the

competition with SCN⁻ for the reaction of HO•. The slope of the linear fit of Abs₀/Abs vs *p*-HPA

concentration is used to determine the second order rate constant $k_{p\text{-HPA},HO^\bullet}$ (Table 1). Details

concerning the second-order rate constant determination are reported in Fig. S2A.

For sulfate radical reactivity, the decay of SO₄^{•-} was followed at 450 nm. To obtain $k_{p\text{-HPA},SO_4^{\bullet-}}$,

the pseudo-first order constant decay of SO₄^{•-} ($k'_{SO_4^{\bullet-}}$) in the presence of different *p*-HPA

concentrations was fit with a linear equation. The slope was the $k_{p\text{-HPA},SO_4^{\bullet-}}$ value [14]. At pH 2.5,

a decrease of the SO₄^{•-} was observed with a pseudo-first order constant $k'_{SO_4^{\bullet-}}$ of $4.29 \times 10^4 \text{ s}^{-1}$.

After the addition of *p*-HPA (3.33×10^{-4} M), the transient decay increases to $1.58 \times 10^6 \text{ s}^{-1}$ due to the quenching of $\text{SO}_4^{\bullet-}$ by *p*-HPA (Fig. S2B). The same method was used at pH 8.5 for the reactivity of mono-anionic form of *p*-HPA and the results are reported in Table 1. In acidic solution (molecular form of *p*-HPA) the reactivity between *p*-HPA and photogenerated radicals results higher than at alkaline pH (mono-anionic form of *p*-HPA). This effect is more pronounced with HO^\bullet where $k_{p\text{-HPA},\text{HO}^\bullet}$ is 3 times higher at pH 2.5 than at pH 8.5, while for $\text{SO}_4^{\bullet-}$ an increase of about 1.3 times is determined.

3.2 Effect of UV and Fe(III)-EDDS complex

In the dark, *p*-HPA is stable in aqueous solution even in the presence of Fe(III)-EDDS and no direct photolysis was observed under adopted irradiation conditions. As a contrary, under adopted UVA polychromatic irradiation, H_2O_2 and $\text{Na}_2\text{S}_2\text{O}_8$ can produce HO^\bullet (R4) and $\text{SO}_4^{\bullet-}$ (R8).

However, *p*-HPA has a relatively low degradation rate in the presence of H_2O_2 (1 mM) or $\text{Na}_2\text{S}_2\text{O}_8$ (1 mM) alone under UV, achieving 10% and 30% removal respectively, after 120 min of irradiation (Fig. S3 and S4). In fact, the quantum yield of HO^\bullet generation is very low at wavelengths longer than 300 nm. In terms of pH effect, faster *p*-HPA degradation is observed at pH 3.0 or 4.5 than at pH 9.4 in agreement with the evaluated second order rate constants as a function of pH (Table 1).

Fig.1A shows the degradation of *p*-HPA with Fe(III)-EDDS (100 μM) at two different H_2O_2

concentrations (100 and 500 μM) in the dark or under irradiation. The disappearance of *p*-HPA is much faster in the photo-Fenton system (Fe(III)-EDDS/H₂O₂/UV) than in Fenton-like process (Fe(III)-EDDS/H₂O₂) [34]. According to the summarized mechanism (see before), the production of HO[•] was correlated with the formation of Fe(II) (R9, R10) [9, 34] and then with the oxidation of target compound. Under irradiation, UVA light significantly enhances the generation of Fe(II), improving the degradation of *p*-HPA in the first 10 min through the Fenton process (R1) [7, 9]. At higher H₂O₂ concentration (500 μM) added into the solution, *p*-HPA can be removed completely in 60 min in Fenton-like process and in 10 min in photo-Fenton system. At lower concentration of H₂O₂ (100 μM) *p*-HPA is not completely removed with or without UV irradiation. These results corroborate that H₂O₂ concentration is a crucial and a limiting parameter in the oxidation process.

With Na₂S₂O₈, the pH and the different concentrations are kept the same of the H₂O₂ system. The different degradation kinetics are shown in Fig.1B. Although some previous papers reported that Fe(III) can activate persulfate to produce SO₄^{•-} in the dark, it was not the case in our system. In fact, much higher concentration of Fe(III) species and persulfate seem needed to do this activation [39]. Under irradiation, Fe(III)-EDDS/Na₂S₂O₈ system shows a good efficiency for *p*-HPA degradation but much lower compared to the system with H₂O₂. Different reasons can explain the lower efficiency of this system. First of all, it is important to mention that the formation of Fe(II) *via* reaction R10 is one of the crucial step to active S₂O₈²⁻ or H₂O₂ to produce oxidative species through reactions R1 and R3, which are identified and evaluated in terms of relative importance in the following part of this paper. The lower efficiency can be due to the fact that the second order rate constant of the activation of S₂O₈²⁻ ($k_{\text{S}_2\text{O}_8^{2-}, \text{Fe}^{2+}} = 20\text{-}27 \text{ M}^{-1} \text{ s}^{-1}$) is more than three times smaller than the one with H₂O₂ ($k_{\text{H}_2\text{O}_2, \text{Fe}^{2+}} = 76 \text{ M}^{-1} \text{ s}^{-1}$). In addition, the lower efficiency of

Na₂S₂O₈ can be also due to the second order rate constants between *p*-HPA with HO[•] or SO₄^{•-}, $k_{p\text{-HPA},HO^{\bullet}}$ is 4.6 times higher than $k_{p\text{-HPA},SO_4^{\bullet-}}$ in acidic solutions (Table 1). As a contrary, the photolysis of H₂O₂ and Na₂S₂O₈ are not responsible for this effect at the concentration and light irradiation wavelengths used in this process.

3.3 Effects of H₂O₂ and Na₂S₂O₈ concentrations

Initial degradation rate of *p*-HPA ($R_{p\text{-HPA}}$) is used to evaluate the degradation efficiency of the reaction process. $R_{p\text{-HPA}}$ is evaluated from the first 5 min of irradiation, because during this period pH of the solution kept stable, and the degradation can be well fitted by pseudo first order kinetics. Fig.2 shows the initial degradation rate of *p*-HPA with different H₂O₂ concentrations in photo-Fenton process. $R_{p\text{-HPA}}$ increases from 1.50×10^{-7} to 3.80×10^{-7} M s⁻¹ when H₂O₂ concentrations increases from 50 μM to 1 mM. The observed increase of *p*-HPA degradation when the concentration of H₂O₂ increased is obvious considering that H₂O₂ is one of the two compounds generating HO[•] in the Fenton process. In fact, as described in Fig.1A, H₂O₂ concentration was the limiting parameter. However, H₂O₂ is also a scavenger of HO[•] ($k_{H_2O_2,HO^{\bullet}} = 2.7 \times 10^7$ M⁻¹ s⁻¹) and so too high concentration of H₂O₂ will lead to a decrease of the organic compound degradation rate [7]. Due to the much higher rate constant of HO[•] reaction on *p*-HPA ($k_{p\text{-HPA},HO^{\bullet}} = 2.2 \times 10^{10}$ M⁻¹ s⁻¹) the decrease of the *p*-HPA degradation is not observed in our experimental conditions. In fact at highest H₂O₂ concentration used (1 mM) 90% of HO[•] are still consumed by *p*-HPA. For this reason, it was only observed that the increase rate slowed down when H₂O₂ increased from 250 μM to 1 mM. Moreover, at this concentration the contribution to the degradation of *p*-HPA from the direct photolysis of H₂O₂ is still negligible (Fig. S3).

The effect of $\text{Na}_2\text{S}_2\text{O}_8$ concentration is shown in Fig.2. Similar to H_2O_2 , the degradation rate is always increasing when $\text{Na}_2\text{S}_2\text{O}_8$ concentration increases. In fact $\text{S}_2\text{O}_8^{2-}$ is the source of radical species and the negative effect of $\text{Na}_2\text{S}_2\text{O}_8$, in terms of radical species scavenger probably $\text{SO}_4^{\bullet-}$ in this case ($k_{\text{S}_2\text{O}_8^{2-}, \text{SO}_4^{\bullet-}} = 6.1 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$) [40], is much slower than in the case with H_2O_2 ($k_{\text{H}_2\text{O}_2, \text{HO}^{\bullet}} = 2.7 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$). In fact, under our experimental conditions ($[\text{Na}_2\text{S}_2\text{O}_8^{2-}] \leq 1 \text{ mM}$) a constant increase of the degradation rate of *p*-HPA with the increase of persulfate concentration is observed.

3.4 Effects of Fe(III)-EDDS concentrations

Fig.3 shows the removal percentage of *p*-HPA with different Fe(III)-EDDS concentrations after 5 min of irradiation in the presence of 100 μM of H_2O_2 . The removal percentage of *p*-HPA increases when Fe(III)-EDDS concentration increases from 50 to 250 μM and a decrease at higher Fe(III)-EDDS concentration up to 1 mM is observed. Higher concentration of Fe(III)-EDDS produces larger amount of Fe(II) under irradiation followed with higher concentration of HO^{\bullet} through Fenton process. However, EDDS is able to interact with this process. Compared with H_2O_2 , EDDS has an almost 100 times higher second order rate constant with HO^{\bullet} ($k_{\text{EDDS}, \text{HO}^{\bullet}} = 2.48 \pm 0.43 \times 10^9 \text{ M}^{-1} \text{ s}^{-1} \gg k_{\text{H}_2\text{O}_2, \text{HO}^{\bullet}}$) [41]. Moreover, by similarity of the results published by Di Somma et al. [42] on Cu(II)-EDDS complex, Fe(III)-EDDS could be also a significant trap of hydroxyl radicals. So, EDDS, its photo-induced by-products and Fe(III)-EDDS complex can compete more strongly with *p*-HPA molecules. Another reason can explain the inhibition at higher Fe(III)-EDDS concentration. In fact, Fe(III)-EDDS is decomposed very fast under irradiation [17, 30], and the high concentration of Fe(II) produced is able to react with HO^{\bullet}

with a high reaction rate (R11) [43]. Furthermore, the formed Fe(III) species are spontaneously precipitated at the used pH (7.5). Thus the formed colloid or precipitation can be responsible for the inhibition of the penetration of photons in the solution.

In Fe(III)-EDDS/Na₂S₂O₈/UV system, Na₂S₂O₈ is set as 500 μM, because at lower concentration (100 μM), it is difficult to differentiate the effect of Fe(III)-EDDS concentration due to relatively low degradation percentages. From Fig.3, a similar trend can be observed compared to H₂O₂, so EDDS and its by-product also act as scavengers of SO₄^{•-} ($k_{EDDS,SO_4^{\bullet-}} = 6.21 \times 10^9 \text{ M}^{-1}\text{s}^{-1}$) [14]. Moreover, higher concentration of Fe(III)-EDDS can produce high concentration of Fe(II) in solution at the initial stage, while too much Fe(II) also can compete reacting with SO₄^{•-} with high rate constant (R12) [16].

3.5 Effects of pH

In the Fe(III) (photo)-induced activation reactions, pH always plays a significant role during the whole process. Firstly, in the *p*-HPA/Fe(III)-EDDS/UV system, pH effects are investigated, as shown in the insert of Fig.4. Under polychromatic irradiation, Fe(III)-EDDS can produce HO[•] through a complex photoinduced mechanism as described in different studies [17, 44]. However, if we compare with the photo-Fenton process, the photo-production of HO[•] was very limited without H₂O₂. (Fig.1). When the pH increases from 3.0 to 4.7, the removal efficiency increases very fast, while with pH further increase up to 9.4, degradation percentage continues to increase but much more slowly. The constant increase of the *p*-HPA removal with the increase of pH is due

to the higher HO[•] formation quantum yield when the pH increases [17]. However, according to our previous results by Wu et al. [14, 30], Fe(III)-EDDS showed different predominant species with respect to pH and the complex Fe(OH)EDDS formed at pH higher than 6.0 can also explain the higher efficiency at higher pH in terms of HO[•] formation. However, the slower increase observed at pH higher than 4.7, can be attributed to the lower reactivity (three times lower) of HO[•] on the mono-anionic form of *p*-HPA. The rate constants have been evaluated for the first time during this study and are presented in Table 1.

The pH effect on the Fe(III)-EDDS/H₂O₂/UV and Fe(III)-EDDS/Na₂S₂O₈/UV processes during the initial stage (first 5 min of irradiation) are shown in Fig.4. The trend of pH effects is different from Fe(III)-EDDS/UV system and is also quite different although the experimental conditions are similar but the oxidation species used (H₂O₂ and Na₂S₂O₈) are different. So, the activation mechanisms of these two different processes are not exactly the same.

In the Fe(III)-EDDS/H₂O₂/UV reaction, *p*-HPA degradation efficiency increases fast from pH 2.5 to 7.5, then it begins to decrease when pH increases to 9.0. As explained with the system Fe(III)-EDDS/UV (insert Fig.4), in general, the increase of efficiency with the increase of pH is mainly due to the increased HO[•] formation quantum yield and chemical speciation of Fe(III)-EDDS complexes vs pH possessing different photoactive abilities. However, in the photo-Fenton process HO[•] generation is mainly due to the Fenton process and so to the photo-generation of Fe(II) which is correlated with the first photochemical step, the photoredox process from the complex Fe(III)-EDDS leading to the formation EDDS[•] and Fe(II). To compare and understand well this mechanism, Fe³⁺ is introduced instead of Fe(III)-EDDS, see Fig.S5. In order to keep Fe³⁺ soluble in the solution, a very acidic pH is selected (pH = 2.0) although the

optimal pH is 2.8 to better generate the most light absorbing iron complex with water molecules. Fe(III)-EDDS shows faster degradation efficiency than Fe^{3+} in the initial stage, ascribing to the higher photochemical activity of the complex Fe(III)-EDDS than the ion Fe^{3+} . As for Fe(III)-EDDS, the degradation is also very fast in the first 10 minutes and after slows down. In $\text{Fe}^{3+}/\text{H}_2\text{O}_2/\text{UV}$ system, the degradation is nearly stopped after about 30 minutes of irradiation. This important slow down and then complete stop of the reaction is due to the almost total consumption of H_2O_2 . The higher final removal percentage observed with Fe^{3+} than with Fe(III)-EDDS is due to the presence of EDDS which can consume also $\text{HO}\cdot$ and so decrease the reactivity efficiency on *p*-HPA.

As a contrary of this rapid initial degradation observed with H_2O_2 , in the Fe(III)-EDDS/ $\text{Na}_2\text{S}_2\text{O}_8/\text{UV}$ system, a gradual degradation during the irradiation process is observed (Fig.1). Fe(III)-EDDS is decomposed fast almost in the first 10 min by photoredox process, into Fe(II) and $\text{EDDS}\cdot$, whatever the species present in the solution [14, 30]. In the Fe(III)-EDDS/ $\text{Na}_2\text{S}_2\text{O}_8/\text{UV}$ system $R_{p\text{-HPA}}$ slightly increases until pH 4.0 and then decreases when the pH increases (Fig 4). The pH effect is not exactly the same with H_2O_2 (an increase is observed until around pH 7.5). This difference of pH effect could be due to the interaction of $\text{S}_2\text{O}_8^{2-}$ in the radical processes. Indeed, $\text{S}_2\text{O}_8^{2-}$ can react with the first radical generated by the photoredox process on EDDS (R10) and then avoid the reaction with O_2 leading to the formation of $\text{HO}_2\cdot/\text{O}_2^{\bullet-}$ [44]. This hypothesis was deduced from the literature (Miralles-Cuevas et al. 2014) [12], $\text{EDDS}\cdot$ can react with hydroxide anions or persulfate in aqueous solution to form related radicals (i.e. hydroxyl and sulfate radicals). Furthermore, $\text{S}_2\text{O}_8^{2-}$ can consume electrons and $\text{O}_2^{\bullet-}$ to form sulfate radicals [45, 46]. While it's well known that $\text{HO}_2\cdot/\text{O}_2^{\bullet-}$ are particularly important

because they can modify the Fe(III)/Fe(II) cycle and so the reactivity [34]. Moreover, the degradation efficiency is mainly affected by the photochemical activation abilities of different formed of Fe(III)-EDDS complex and the soluble Fe(III) concentrations in solution [30]. With pH increase, the precipitation of Fe(III) in aqueous solution is became a main limiting step. For another non-negligible reason, it's well known that Fe(II) can be easily oxidized to Fe(III) by the dissolved oxygen in water, and this effect is accelerated when solution pH is higher than 4 [47]. So, the soluble Fe(II) undergoes competitive reaction with $H_2O_2/S_2O_8^{2-}$ or dissolved oxygen. From R1 and R3, $k_{S_2O_8^{2-}, Fe^{2+}}$ is smaller than $k_{H_2O_2, Fe^{2+}}$, and we argue that in the competing reactions, high amount of Fe(II) can be consumed by oxygen in Fe(III)-EDDS/ $Na_2S_2O_8$ /UV systems at higher pH's solutions. This reactivity can explain the decreased degradation rate when the pH increases. Comparison between Fe^{3+} and Fe(III)-EDDS also was conducted, as shown in Fig.S5. At pH 2.0, $Fe^{3+}/Na_2S_2O_8$ (500 μ M)/UV system shows a fast and gradual degradation of *p*-HPA, and *p*-HPA can be removed completely in 45 min.

3.6 Identification of active species at pH 3.9

In order to determine the radicals involved in the degradation of *p*-HPA in the different processes, IPA and TBA are used as scavengers of radicals and so added in the solution (Fig.5). In fact, at adopted concentrations, IPA (10 or 20 mM) was considered to quench efficiently both generated $SO_4^{\bullet-}$ and HO^{\bullet} , considering the second order rate constants of $k_{IPA, SO_4^{\bullet-}} = 7.42 \times 10^7 M^{-1} s^{-1}$ and $k_{IPA, HO^{\bullet}} = 1.9 \times 10^9 M^{-1} s^{-1}$, while TBA (1 or 2 mM) can be considered to be more selective toward HO^{\bullet} ($k_{TBA, HO^{\bullet}} = 6.0 \times 10^8 M^{-1} s^{-1}$) than with $SO_4^{\bullet-}$ ($k_{TBA, SO_4^{\bullet-}} = 8.31 \times 10^5 M^{-1} s^{-1}$) [39]. From Fig.5A, 20 mM of IPA can almost completely inhibit the degradation of *p*-HPA. At this

concentration, 97 % of HO[•] is consumed by IPA and only 3% was consumed by *p*-HPA. At lower concentration of IPA (1 mM) only 63% of HO[•] can react with IPA and so a degradation of *p*-HPA was still observed and corresponds to almost 30% of removal. So, HO[•] radical is identified as the active species responsible of *p*-HPA transformation in the system with H₂O₂.

In the presence of persulfate (500 μM), 20 mM of IPA can react with 86% SO₄^{•-} when *p*-HPA is present at 50 μM, so higher concentrated IPA is needed if SO₄^{•-} want to be completely inhibited. HO[•] radical is mainly generated from two routes. Firstly, it is generated from the photolysis of Fe(III)-EDDS complex. Secondly, SO₄^{•-} can also react with hydroxyl anion or water molecule to produce HO[•] (R13-14) [17, 48, 49]. To evaluate the relative significance of the two radicals (sulfate and hydroxyl) in this system, experiments are also performed with TBA acting specifically as a trap for hydroxyl radical. When the concentration of TBA increases from 1 to 2 mM the decrease of *p*-HPA concentration near 60% is the same (Fig. 5B). So, it is possible to conclude both radicals are involved in the system Fe(III)-EDDS/Na₂S₂O₈/UV with a specific percentage respectively near 20% for HO[•] and 80% for SO₄^{•-}.

4 Conclusion : comparison of H₂O₂ and S₂O₈²⁻ efficiency

In general, the *p*-HPA degradation efficiency is much higher with Fe(III)-EDDS/H₂O₂/UV system than with Fe(III)-EDDS/Na₂S₂O₈/UV system whatever the solution pH's. Firstly, this difference can be explained considering the second order rate constants $k_{p\text{-HPA}, \text{HO}^{\bullet}}$ and $k_{p\text{-HPA}, \text{SO}_4^{\bullet-}}$ (Table 1). The value of $k_{p\text{-HPA}, \text{HO}^{\bullet}}$ is higher than $k_{p\text{-HPA}, \text{SO}_4^{\bullet-}}$ both at pH 2.5 (4.6

times) and 8.5 (2.1 times). Secondly, the rate constants of the key reactions generating the radical species is more than 3 times higher for the Fenton process (R1) than for the activation of persulfate with Fe(II) (R3). However, at pH 2.5, the ratio of the rate constants between radical species and *p*-HPA $k_{p\text{-HPA},HO^\bullet} / k_{p\text{-HPA},SO_4^{\bullet-}}$ equal to 4.6 and the ratio of *p*-HPA disappearance rate in the two systems $R_{p\text{-HPA}}(H_2O_2) / R_{p\text{-HPA}}(Na_2S_2O_8)$ equal to 5.2 are similar. It is slightly higher for the *p*-HPA disappearance rate which is coherent with the two reasons mentioned at the beginning of this paragraph. As a contrary the difference between these two ratios is much higher at pH 8.5, $R_{p\text{-HPA}}(H_2O_2) / R_{p\text{-HPA}}(Na_2S_2O_8)$ equal to 16.7 is eight times higher than $k_{p\text{-HPA},HO^\bullet} / k_{p\text{-HPA},SO_4^{\bullet-}}$ equal to 2.1. So, as previously demonstrated, the Fenton process, involving Fe(III)-EDDS complex, is higher at near neutral pH than in acidic pH [34]. This significant result in terms of environmental aquatic compartments seems not present for the activation of persulfate to generate $SO_4^{\bullet-}$ radical. Indeed, in this case a dramatic decrease of the efficiency is observed. So, in this particular study, with *p*-HPA used as organic pollutant and UV/Fe(III)EDDS as source of Fe(II), we clearly demonstrated that the Fenton process is more efficient than activation of persulfate process and more particularly at environmentally closed pH values.

In the future, the application of such AOP's using Fe(III)EDDS complexes could be also studied in real water matrix such as sewage treatment plant (STP) waters. However, it is very well known that the presence of naturally occurring inorganic ions and organic matter can play very often an inhibition role on the pollutant degradation. In fact, as recently demonstrated in STP waters, the formation of secondary radicals such as carbonate ($CO_3^{\bullet-}$) and chloride derivative (Cl^\bullet , $Cl_2^{\bullet-}$, ...) can strongly modify the oxidative process and as consequence the pollutant degradation [39, 50].
