36 **Abstract:**

37 The removal of black crusts decaying the surface of artworks is an important concern for the
38 conservation of cultural heritage. Nd:YAG laser cleaning of encrusted stones and plasters at 1064 nm is
39 widely recognized as an effective restoration technique, but induces a noticeable yellowing of the
40 surface. Several researches carried out on the effects of laser cleaning have been focused on the induced
41 yellowing and how to visually mitigate this phenomenon. To this end, UV-B radiations were
42 successfully used to lessen the laser-induced yellowing due to the removal of lamp black particles on
43 gypsum. The mechanism at play for both the formation of the compounds yellowing the surface and
44 their disappearance upon UV-B exposure remains, however, poorly understood. Within the frame of this
45 research, we apply surface-sensitive characterization techniques to analyze the yellowed surface
46 produced after Nd:YAG Q-Switched laser cleaning of lamp black deposit on a gypsum plate, and the
47 same surface after UV-B exposure. A combination of X-ray photoelectron spectroscopy and Fourier-
48 transformed infrared spectroscopy has been used to identify the residual carbon compounds responsible
49 for the yellow coloration of the substrate. A nanoscale structural description of the ejected particles
50 collected during the laser cleaning was finally performed with transmission electron microscopy. We
51 found that the yellowing is due to partially oxidized hydrocarbons compounds deposited at the surface
52 of the gypsum substrate. We propose that they form by reactions between carbon species emitted by the
53 vaporization of the carbon particles, with hydrogen and oxygen produced by the dissociation of water
54 molecules coming together from dehydration of the gypsum surface and from the water sprayed by the
55 operator during cleaning.

60

61 1. Introduction

62 Laser cleaning in restoration of artworks is a well-established and optimized technique [1,2].
63 Criticisms have, however, been expressed after its implementation due to the yellowish tint of the laser
64 cleaned surfaces [3]. The phenomenon thus became a controversial issue as it was unclear whether it
65 resulted from a specific side effect of laser cleaning [4] or from the revealing of a preexisting yellowish
66 layer [5,6]. Many scientific investigations recently evidenced laser irradiation as the cause of the
67 yellowing process and proposed ways to mitigate the discoloration pattern using poultices [7] or UV-B
68 irradiation [8]. Nevertheless, the chemical composition as well as the formation mechanism of the
69 compounds yellowing the surface remain enigmatic. As recently pointed out: “*the exact nature of the*
70 *material generated by laser treatment of black crust and contributing to the yellow color is still*
71 *unknown*” [9]. Several obstacles preclude the investigations. The material, phase or impurities at the
72 origin of the yellowing are invisible and hardly analyzable using conventional techniques on thin
73 sections. When analyses are carried out at the surface, only the substrate compounds are revealed
74 without recognition of any neoformed phases [1,2,9]. The phases induced by laser cleaning are therefore
75 assumed to be nano-sized and in a very low amount.

76 Black crusts forming at the interface between the substrate, the atmosphere and the polluted urban
77 or industrial environment, have very complex compositions ranging from nano to sand size particles,
78 minerals and organics, with a long list of chemical elements that are combined in various ways [5,10].
79 The interactions that may occur during a laser pulse are complex and the distinction between the initial
80 black crust compounds and neoformed phases resulting from laser irradiation is far from obvious. A
81 way to experimentally reproduce the phenomenon at play is (i) to make synthetic gypsum substrate,
82 close to the epigenic gypsum layer systematically found beneath the black crust on carbonate stone
83 surface [8,9], (ii) to artificially cover this substrate with a layer containing a single specie sensitive to
84 the laser, and (iii) to study the residues present on the yellowed surface after laser irradiation. Such
85 model systems have been investigated by various authors, using a multi-scale approach from optical to
86 electron microscopy coupled with energy-dispersed X-ray as well as electron energy loss spectroscopy
87 to study the morphological, mineralogical and chemical features that could be linked to the yellowing

88 phenomenon [8,9,11,12]. These studies brought new insights on the involvement of iron compounds
89 and fly ashes in the yellowing phenomenon. Researches also showed that black crusts can be mimicked
90 by lamp black nanoparticles, and that the laser-induced yellowing phenomenon is mitigated by UV-B
91 irradiation [8,11]. The different processes at play along these treatments of gypsum plates covered with
92 lamp black particles were carefully followed by spectrophotometry, but no information concerning the
93 composition of the laser-induced yellow surface were gained up until now. Following this work, we
94 have developed a specific analytical protocol capable of characterizing primary as well as neoformed
95 nano-sized phases of lamp black upon the different treatments. A combination of X-ray photoelectron
96 spectroscopy (XPS), Fourier-transform infrared spectroscopy (FTIR), scanning electron microscopy
97 (SEM), and transmission electron microscopy (TEM) was applied to follow the chemical and
98 morphological changes of a gypsum plate covered with lamp black, exposed to Nd:YAG Q-Switched
99 laser cleaning at 1064 nm followed by UV-B irradiation at 313 nm. These investigations bring new
100 insights on the nature and origin of the laser-induced yellowing phenomenon.

101

102 **2. Research aims**

103 Beside its unquestionable advantages, the Nd:YAG laser cleaning of artworks yields to the
104 yellowing of the treated surfaces. This study thus aims at understanding the mechanism at play in the
105 laser-induced yellowing phenomenon by providing morphological, chemical, and structural
106 characterizations of the primitive and the neo-formed carbon species on a model system. The ultimate
107 objective consists in providing physico-chemical justifications for the simultaneous or consecutive use
108 of UV-B exposure allowing for the progressive removal of the carbon compounds involved in the
109 yellowing phenomenon.

110

111 **3. Materials and methods**

112 *3.1 Sample preparation:* Synthetic samples were elaborated with gypsum plaster plates manually
113 covered with a thin layer of lamp black particles. The gypsum plates were made by hydration of pure

114 hemihydrate (97%, Acros organics) with distilled water (1/1 in mass). Windows (76 x 26 mm) were cut
115 in a dense foam template and glass microscope slides were placed at the bottom. The mixture
116 (hemihydrate + distilled water) was then applied on the slides until the windows were filled. The surface
117 was finally leveled with a spatula and the samples were left to dry for at least 24 hours. After demolding,
118 the surface was covered with lamp black pigment (noir de fumée ©) supplied by Artech. Fine-grained
119 black powder was applied dry with a brush to cover the gypsum plate with a black layer.

120 *3.2 Laser cleaning:* The plates were first cleaned with a Nd:YAG Q-Switched (QS) laser at 1064
121 nm (Thomson BM Industries NL201, 8 mm spot beam, 15 ns pulse duration, 10 Hz pulse frequency).
122 The laser fluence, expressed as an energy per unit area of the beam, ranged from 200 to 400 mJ/cm².
123 The irradiation conditions have been adjusted by an experienced restorer to optimize the cleaning result.
124 The surface of the samples was sprayed with water just before irradiation. Around a quarter of each
125 sample was preserved from laser cleaning and kept as a reference area (Area 1 in Fig. 1). A
126 complementary laser cleaning was carried out in the same conditions in order to collect the ablated
127 particles during laser irradiation. In this case, the sample was inclined at 45° in a box and small metal
128 grids used for transmission electronic microscope observation were held close to it during the cleaning
129 operation.

130 *3.3 UV-B exposure:* After laser cleaning, the plates were exposed to UV-B radiation (313 nm) in
131 an accelerated UV degradation chamber (Q-Panel LAB product) following previously optimized
132 conditions [8]: 90 hours at an irradiance of 1.42 W/m² reaching a total UV-B fluence of 46 J/cm². A
133 second quarter of the sample was protected with an aluminum foil to preserve the yellowed surface
134 obtained after laser cleaning (Area 2 in Fig. 1). The UV-B exposed surface represents the rest of the
135 sample (Area 3 in Fig. 1).

136 *3.4 Spectrocolorimetry:* Color measurements were carried out with a Hunterlab MiniScan XE
137 Plus System spectrophotometer with illuminant D65 using the 10° observer, equipped with a hand-held
138 positioning device [8], to evaluate the color variations after QS laser cleaning (Area 2 in Fig. 1) and UV-
139 B exposure versus time (Area 3 in Fig. 1). The evolution of the b* parameter, representative of the
140 chromaticity of interest, was specifically followed with respect to the gypsum reference surface.

Figure 1. a/ Macroscopic color changes of a gypsum plate covered with lamp black (Area 1) after Q-Switched laser cleaning (Area 2) and UV-B exposure (Area 3). The plate is 7.5 cm long. b/ Chromatic evolution of the Q-Switched laser cleaned area (b* value) as function of the cumulated UV-B fluence. The dashed blue line corresponds to the b* value measured on the reverse side of the gypsum plate.

141 3.5 *X-ray photoelectron spectroscopy*: XPS was recorded on Areas 1-3 to characterize the
 142 elemental composition and the chemical speciation of the surface species. Reference spectra were also
 143 acquired on a bare gypsum plate and on the lamp black powder for comparison purposes. The
 144 experiments were performed under ultra-high vacuum using a Resolve 120 hemispherical electron
 145 analyzer (PSP Vacuum) and a TX400 (PSP vacuum) unmonochromatized X-ray source (Mg K α at
 146 1253.6 eV) operated at 100 W. The information depth of XPS at this excitation energy and in the
 147 geometrical arrangement of the setup is typically 1 nm at the C1s line. Survey spectra were first collected
 148 at pass energy of 50 eV and an energy step of 0.2 eV, while the C1s lines were collected at 20 eV pass
 149 energy, and a step of 0.1 eV. The XPS lines were deconvoluted with the CasaXPS program, using
 150 Gaussian/Lorentzian profiles and after Shirley-type background subtraction. Elemental composition (in
 151 at. %) are obtained from the analysis of the survey spectra and after correction by the relative sensitivity
 152 factors provided in the program.

153 3.6 *Fourier-transform infrared spectroscopy*: the infrared spectra were recorded in attenuated
 154 total reflectance (ATR, germanium crystal) mode using a Bruker VERTEX70 mid-IR Fourier Transform

155 spectrometer equipped with a temperature-stabilized DLaTGS detector. All spectra were accumulated
156 on the surface of the different areas as well as the reference materials (bare gypsum plaster and lamp
157 black) in a spectral range of 650-4000 cm^{-1} by recording 200 scans at a resolution of 4 cm^{-1} . In this
158 energy domain, information depth in ATR is in the range of 0.2-1.4 μm for gypsum, i.e. 200-1400 times
159 deeper than XPS. The Opus software was used for the baseline correction, where a polynomial fit was
160 applied over the whole spectral range with a minimal number of anchor points (between 3 and 5,
161 typically). The characterization of the absorbance bands and the interpretation of their evolution with
162 the different treatments were carried out by a curve fitting procedure using the PeakFit software. We
163 have selected two regions of interests (ROIs) where specific spectral features of carbon are observed,
164 corresponding to the intervals between 1300 and 1600 cm^{-1} and between 2800 and 3100 cm^{-1} . The ROIs
165 were adjusted with several absorbance bands with Voigt profiles. Such profile is common in complex
166 condensed materials and corresponds to a convolution of Lorentzian and Gaussian profiles. The fitting
167 was achieved using a least-squares iterative procedure by varying the peak position, amplitude/area,
168 Gaussian and Lorentzian half-widths for all absorbance bands.

169 *3.7 Scanning electron microscopy and transmission electron microscopy:* SEM was used to study
170 the morphology of the lamp black particles, the gypsum plaster substrate, and the treated areas at a
171 micron and sub-micron scale. The SEM observations were performed with a JEOL 6320F operated at
172 15kV. Samples were coated with titanium prior to being placed in the SEM chamber. TEM was
173 performed to characterize the nanoscale morphology and internal structure of the particles composing
174 the lamp black and the ablated particles collected on the grids during cleaning tests. TEM observations
175 were carried out on a JEOL JEM 2011 operated at 200kV. Bright field TEM micrographs were acquired
176 with a CCD camera (GATAN, Ultrascan® 1000XP) assisted by the Digital Micrograph software
177 (GATAN).

178

179 **4. Results**

180 Visual observation (Fig. 1a) allows an easy distinction of the three different areas (Area 1/lamp
181 black crust, Area 2/after Q-Switched laser cleaning, and Area 3/after 90 hours of UV-B exposure). After

182 laser cleaning, Area 2 has a yellowish aspect, with a b^* value of about 7 in term of chromaticity. It
183 corresponds to the b^* value at zero UV-B fluence (Fig. 1b). The evolution of b^* indicates the
184 colorimetric changes induced by UV-B exposure of Area 3. Colorimetric measurements were made
185 repetitively on this area after 15, 40, 50, 70, and 90 hours of exposure. The decrease of b^* highlights the
186 progressive de-yellowing phenomenon previously described [8,11]. However, b^* does not reach the
187 reference value of 0.99 (dashed line in Fig. 1b) within the considered exposure time, indicating that UV-
188 B exposure does not fully reveal the original color of the gypsum plate.

189 The deconvoluted C1s XPS spectra recorded on Areas 1-3 are shown in Fig. 2a (the C1s and O1s
190 spectra, including those of the bare gypsum plate and the lamp black particles are presented and further
191 discussed in the supplementary material S1). The black crust of Area 1 (Fig. 2a, bottom) presents a main
192 peak located at a binding energy of 284.8 eV corresponding to the lamp black particles, and typical of
193 graphitic materials [13]. The second peak at 288.2 eV is related to carbonate CO_3 , likely in the form of
194 calcium carbonate CaCO_3 [14] contaminating the gypsum plate surface, a contamination of unknown
195 origin. It is already present on the bare gypsum spectrum (see supplementary material S1) and is detected
196 in Area 1 as the substrate is not perfectly covered by the carbon crust (see below, SEM results, Fig.5a).
197 The lamp black peak contributes to 49 at. % to the elemental surface composition of Area 1 (Fig. 2b).
198 After laser cleaning (Area 2) the carbonate peak at 288.2 eV has increased relatively to the other
199 contributions (Fig. 2a, middle). The residual carbon peak, now shifted at 285.5 eV, represents only 4 at.
200 % of the elemental composition of Area 2 (Fig. 2b). This + 0.7 eV shift indicates that this residual carbon
201 is not of the same kind than the initial lamp black particles. Binding energies of 285.5 eV correspond to
202 aliphatic hydrocarbons [15], which therefore dominate the composition of the residual carbon layer. A
203 further C1s peak at 291.6 eV appears, typical of CO_2 [16]. We assume that a part of the CaCO_3 species
204 located at the very surface (typically 1 nm in depth) have been decomposed in $\text{CaO} + \text{CO}_2$ [17] under
205 the laser beam. CO_2 remains trapped in the subsurface region, perhaps through chemical complexation
206 or in nano-bubbles. As this reaction takes place at $T > 800^\circ\text{C}$, it allows setting at 800°C the lower
207 temperature experienced by the first atomic layers of the gypsum surface during the laser treatment.

208 After UV-B exposure (Area 3, Fig. 2a top), the residual carbon peak at 285.5 eV has almost totally
 209 disappeared. The remaining signal represents only 0.75 ± 0.15 at. % (rounded at 1 at. % Fig.2b) of the
 210 elemental composition of Area 3 (Fig. 2b), while the CaCO_3 and the CO_2 peaks are still present. UV-B
 211 induces the removal of the residual carbon compounds, which eventually whitens the gypsum surface
 212 [8,11]. We suppose that this 1 at. % of remaining carbon precludes the full recovery of the original
 213 chromaticity of the gypsum plate (Fig. 1b).

Figure 2. a/ Deconvoluted C1s XPS lines of Areas 1-3. b/ Contributions to the total surface composition (in at. %) of the lamp black (LB) C1s line in Area 1, and of the residual carbon (RC) C1s lines in Area 2 and 3.

214 The FTIR spectra of the gypsum substrate and those of Areas 1-3 are displayed in Fig. 3, after baseline
 215 subtraction and normalization by their integrated area. The most intense absorption bands come from
 216 the bending (δ) and stretching (ν) vibration of gypsum, located at 1010 ($\nu_1 \text{ SO}_4$), 1150 ($\nu_3 \text{ SO}_4$), 1620

217 (δ O-H \cdots O), 1680 (δ O-H \cdots O), 3240 (ν O-H \cdots O), 3410 (ν O-H \cdots O), and 3550 cm^{-1} (ν O-H \cdots O) [18].
 218 Very weak bands coming from CH and CC vibrations are also present but barely distinguishable on Fig.
 219 3.

Figure 3. Baseline corrected ATR-FTIR spectra obtained on the reference gypsum plate and areas 1-3.

220 The CH and CC vibrations can be studied on the two ROIs (1300-1600 cm^{-1} and 2800-3100 cm^{-1})
 221 presented Fig. 4a and 4b where the spectral intensities have been renormalized to the gypsum bands
 222 at 1680 cm^{-1} (Fig. 4a) and 3410 cm^{-1} (Fig. 4b). In the 1300-1600 cm^{-1} region (Fig. 4a), these bands are
 223 assigned to the C-H bending bands of aliphatic compounds (δ CH₃ sym. \sim 1390 cm^{-1} ; δ CH₂ \sim 1430 cm^{-1} ;
 224 δ CH₃ asym. \sim 1470 cm^{-1}) and to the stretching bands of aromatic rings (ν C=C \sim 1540 and 1600 cm^{-1})
 225 [19]. In the 2800-3100 cm^{-1} region (Fig. 4b), the absorption bands are assigned to the C-H stretching
 226 bands of aliphatic and aromatic compounds (ν CH₂ bridges \sim 2825 cm^{-1} ; ν CH₂ sym. \sim 2850 cm^{-1} ; ν CH₃
 227 sym. \sim 2875 cm^{-1} ; ν CH \sim 2895 cm^{-1} ; ν CH₂ asym. \sim 2920 cm^{-1} ; ν CH₃ asym. \sim 2960 cm^{-1} , ν CH aromatic
 228 at 3030 cm^{-1}) [19,20]. These organic compounds are present in the lamp black particles, made of a
 229 mixture of small bent graphitic crystallites (see below, TEM results) and matrix-bonded hydrocarbons.
 230 Assuming that the substrate bands remain unaltered by the different treatments on the depth probed by
 231 the ATR technique, the normalization allows estimating the relative changes in the carbon coverages

232 with the different treatments. A spectral deconvolution of the FTIR signal is therefore presented in Fig.
 233 4 for the two ROIs.

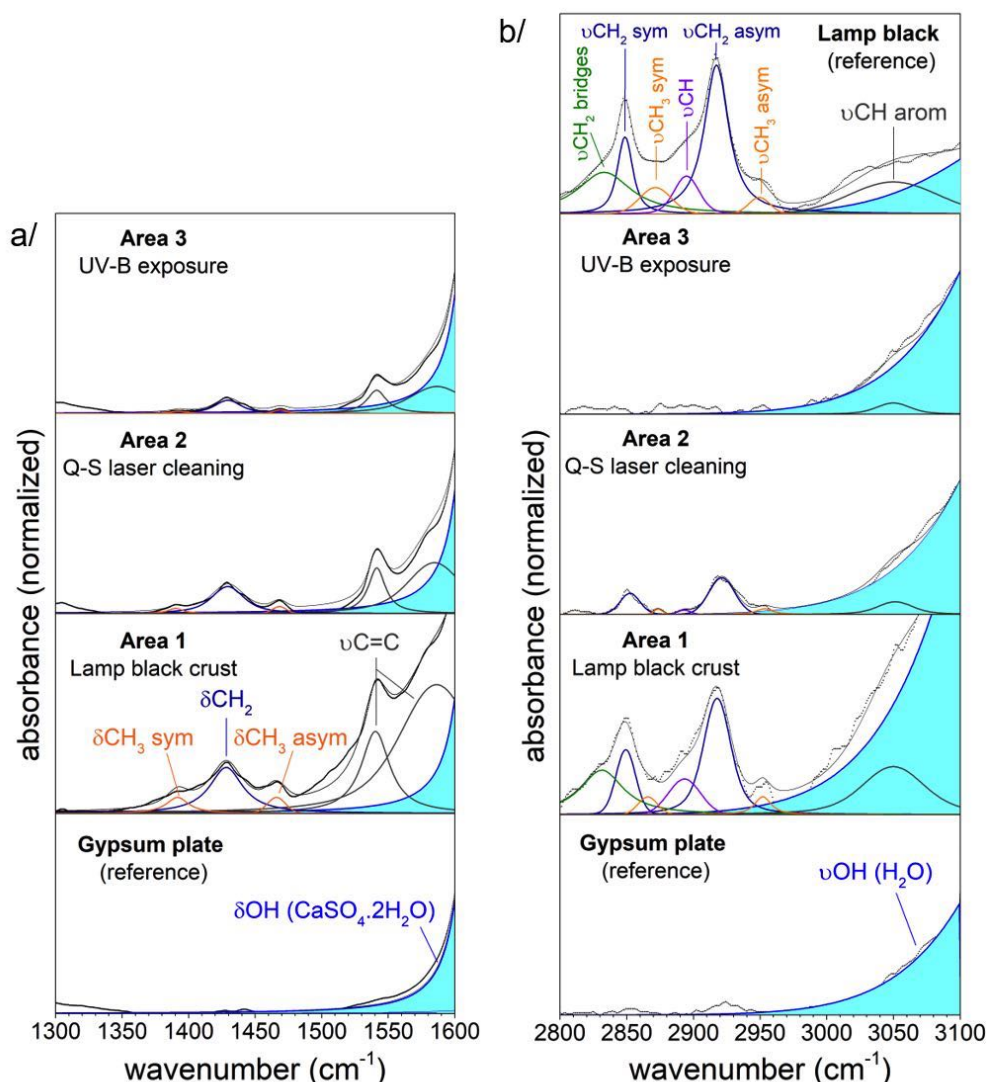

Figure 4. Contribution of the different vibrational modes on the curve fitting analysis of regions a/ 1300-1600 cm⁻¹ and b/ 2800-3100 cm⁻¹. The reference spectrum of the lamp black powder was also fitted in the 2800-3100 cm⁻¹ domain for comparison.

234 In Area 1 the prevalence of the two absorption bands at 2850 and 2925 cm⁻¹ (CH₂ symmetric
 235 and asymmetric stretching modes, in blue lines on Fig. 4b) with respect to those of the CH₃ groups
 236 terminating the aliphatic chains (in orange lines) indicates that these chains are long. The band at 2895
 237 cm⁻¹ (in purple line on Fig. 4b) is related to C-H stretching of tertiary carbon atom at branching points
 238 of the aliphatic chains [20]. The absorption band at 2825 cm⁻¹ is assigned to CH₂ groups located near
 239 sp²-hybridized carbon (in green on Fig. 4b), for instance in aliphatic species bonded to (or binding) the
 240 edge(s) of the graphitic crystallites [20]. This band is not detected anymore in the spectrum of Area 2,
 241 indicating that these peripheral CH₂ groups have disappeared after the laser impact. This is a further

242 evidence, with XPS, that the structure of the residual carbon compounds is different from the initial
243 lamp black particles. Yet, the C-H stretching bands of aliphatic chains (2850 and 2925 cm^{-1}), the
244 stretching bands of aromatic rings ($\nu \text{C}=\text{C} \sim 1540$ and 1600 cm^{-1}), and aromatic C-H stretching (νCH
245 aromatic at 3030 cm^{-1}) are still observed, with a different intensity balance. If the residual carbon
246 compounds are dominated by aliphatic species, they also contain aromatic hydrocarbons. The layer of
247 organic carbon after laser cleaning is also thinner, since all the infrared bands have strongly decreased
248 in intensity. Molecular organic compounds were also identified recently by Papanikolaou et al. [21]
249 through their fluorescence contribution to the Raman signal of laser-cleaned marbles. These compounds
250 are eventually bleached upon UV-B exposure, as barely no corresponding absorbance bands are detected
251 in Area 3 (Fig. 4b). They are likely below the detection limit, as some remaining signal of the
252 corresponding C-H groups is observed in the $1300\text{-}1600 \text{ cm}^{-1}$ region of Area 3 (Fig. 4a). In this spectral
253 region, a decrease of the infrared signal is also observed with the treatments, but less markedly than in
254 the C-H stretching region.

255 The SEM observation of Area 1 reveals that the gypsum plate is made of a mixture of prismatic,
256 lamellar to acicular crystals with sharp edges entangled together (Fig. 5a). The lamp black particles lie
257 on the crystals and consist of aggregates of submicronic spherical particles (Fig. 5a and b). Some parts
258 of the substrate remain uncovered, as already inferred from the XPS data (Fig. 2a, Area 1). On the laser
259 cleaned surface (Area 2), the same mixture of prismatic, lamellar and acicular gypsum crystals is
260 observed (Fig. 5c), but the lamp black aggregates have disappeared. Single submicronic round particles
261 are sometimes detected (Fig. 5d, arrow), in rare places where the surface of the gypsum crystals is
262 altered. This occurs probably when the crystals are not covered with lamp black particles, and
263 consequently absorb all the laser energy.

Figure 5. SEM micrographs of gypsum covered with lamp black before (Area 1) and after Q-S laser cleaning (Area 2) obtained in secondary electron mode. a/ Surface of the plaster plate showing gypsum crystals covered with aggregates of lamp black particles (Area 1). b/ Aggregates of lamp black particles of spherical shapes (Area 1). c/ Surface of the plate after Q-S laser cleaning (Area 2). d/ Details of the gypsum crystal where some alterations are observed (Area 2).

264 TEM micrographs show that the lamp black particles consist of primary spherical nanoparticles
 265 arranged in aggregates (Fig. 6a). The diameter of the primary nanoparticles ranges from 50 to 200 nm
 266 (Fig. 6a and b). Higher magnification (Fig. 6c) reveals their inner structure: the dark fringes correspond
 267 to small bent graphitic layers, concentrically arranged in an onion-like structure typical of soot particles
 268 [22]. After laser treatment the ejected particles have been also analyzed at high magnification. Some of
 269 them retain this initial structure (Fig. 6d), but new kinds of particles are observed. Figs. 6e-f show a
 270 class of particles with concentric multifaceted stacks of graphitic layers (white arrow on Fig. 6f)
 271 wrapping voids. A second type of particles displays evidences of a partial destruction (Fig. 6g), where
 272 graphitic stacks (Fig. 6h and i, white arrow) coexist with an amorphous carbon phase (Fig. 6g, black
 273 arrow), and where the concentric organization is lost. These images correspond well to the observed
 274 structural and chemical changes of carbon nanoparticles upon laser annealing [23,24], which
 275 simultaneously induces the crystallization of a part of the particles and the vaporization of another part,

276 followed by the formation of a condensed amorphous carbon phase from the carbon evaporated in the
 277 gas phase [23].

278

 280 lamp black particles before (a to c) and after Q-S laser cleaning (d to i). a/ to c/ aggregate composed of
 281 spherical nanoparticles, made of small graphitic planes (dark fringes) concentrically arranged. d/ to f/
 282 aggregate of particles after laser irradiation showing alternating graphitic stacks (white arrow) and voids.
 283 g/ to i/ ablated particles with elongated and/or folded ribbon structures (white arrow) mixed with an
 284 amorphous carbon phase (black arrow).

285

286 5. Discussion

287 The TEM observations of the ejected particles indicate that the lamp black aggregates have been
 288 processed at very high temperatures under the laser beam. Indeed, since the thermal diffusion length is

289 $(4D\tau)^{1/2}$ where D is the thermal diffusivity of the material and τ the laser pulse duration [25], the energy
290 of short laser pulses is mainly absorbed in a small thickness [2]. As reported by Abrahamson et al. [23],
291 annealed particles like those of Fig. 6e readily form after a single pulse at 50 mJ/cm^2 of a same Nd:YAG
292 Q-switched laser at 1064 nm, corresponding to an equivalent temperature of 2850°C . This induces the
293 stacking, the growth and the de-winkling of the graphitic planes [26], accompanied by the increase of
294 the graphitic character of the considered particles [24]. At increased number of pulses, Abrahamson et
295 al. measured a maximum temperature of 4180°C (> 4 pulses or 300 mJ/cm^2) and starts detecting C_2
296 (ethene) and C_3 (propadiene) radicals in the incandescence signal of the laser plume. However, carbon
297 vaporization already starts below 4 pulses (at 3500°C), as the authors observed solidified carbon material
298 formed by nucleation of vaporized carbon [24]. In our case, laser cleaning is achieved at pulse frequency
299 (10 Hz) and fluence ($200 - 400 \text{ mJ/cm}^2$) conditions where both graphitization and vaporization occur.
300 This leads to various forms of the ejected carbon particles observed by TEM: multifaceted annealed
301 particles (Fig. 6e), partially annealed unstructured particles mixed with an amorphous carbon phase (Fig.
302 6g), and finally intact particles (Fig 6b).

303 On the substrate side, we have seen that within the 1 nm in depth probed by XPS, the laser treatment
304 has increased the surface temperature to a minimum of 800°C , as indicated by the decomposition of
305 calcite (Fig. 2). At such temperature, dehydration of the surface of gypsum crystals certainly occurs, as
306 this process starts around 120°C . Yet, the Ca 2p line (not shown) remains unchanged after the laser
307 treatment. In particular, no CaO species are detected, and therefore anhydrous gypsum has not thermally
308 decomposed into $\text{CaO} + \text{SO}_2 + \frac{1}{2} \text{O}_2$ [27]. Since this reaction starts around 1200°C , it allows estimating
309 the maximum surface temperature at 1200°C . Note however that the melting point of CaSO_4 is not far
310 above, at 1460°C . If the surface temperature gets close to 1460°C at some places, it is not surprising to
311 observe some altered gypsum crystals and round particles (Fig. 5d) resulting from the (partial) melting
312 of gypsum. However, since the gypsum bands in the infrared spectra remain unchanged (Fig. 3) upon
313 the laser treatment, no thermal alteration of the bulk of the gypsum substrate has occurred. This is
314 consistent with the limited thermal diffusion length of the laser pulse into the substrate (28 nm).

315 The SEM observations clearly indicate that no lamp black aggregates remain after laser cleaning.
316 Therefore, the residual carbon results from the deposition of volatile carbon species at the surface of the
317 gypsum substrate. At the laser impact, the lamp black particles explode, are vaporized, chemical bonds
318 are broken, producing a plasma mixing atoms, molecules, and ions, where gas-phase chemical reactions
319 occur. A fraction of the formed products can condense on the gypsum substrate. The resulting organic
320 compounds are not visible by SEM, but they yellow the substrate. FTIR and XPS indicate that the
321 residual carbon is made of hydrocarbon dominated by aliphatic species, mixed with few aromatic
322 species. Their organic nature is essential for the facile degradation by UV-B radiation, through
323 photooxidation of linear or cyclic aliphatic [28] and aromatic hydrocarbons [29], that would not take
324 place if they were highly graphitic or made of residual black lamp particles [30]. Literature indicates
325 that laser ablation/vaporization of carbon particles produces small gas-phase carbon clusters [31] at
326 $T < 3500^{\circ}\text{C}$, and carbenes C_2 and C_3 at $T > 4180^{\circ}\text{C}$ (and this is probably not limited to these species)
327 [24]. In any case, the formation of hydrocarbons requires both the catenation (polymerization) of carbene
328 - a facile reaction-, and a further hydrogen addition to the formed carbon chains. Hydrogen is provided
329 by the laser dissociation of water molecules coming both from dehydration of the gypsum surface and
330 from the water sprayed by the operator before the laser cleaning. Indeed, in presence of nanoparticles,
331 water radiolysis and breakdown are caused by the secondary electrons flux generated by the visible/IR
332 laser irradiations [32,33]. Water dissociation also provides O and OH radicals allowing for oxidation
333 and hydroxylation of the carbon precursors. Since the residual carbon compounds yellow the surface,
334 they include specific species not absorbing in the 560-590 nm wavelength range. A possible candidate
335 is the carbonyl group $-\text{C}=\text{O}$, which causes the yellowing of organic polymers [34]. Similar to the
336 hydrogenation reactions, $-\text{C}=\text{O}$ groups can form by oxidation of the carbon precursors. Their probable
337 low concentration makes them difficult to detect with infrared spectroscopy, and, furthermore, their
338 typical bands ($1670\text{-}1820\text{ cm}^{-1}$) are hidden by the bending OH vibrations of the gypsum substrate. XPS
339 would be more sensitive, but the $\text{C}=\text{O}$ groups also lie close in energy to the CO_3 group of the calcium
340 carbonate, making their detection difficult.

341 This study evidences, on a model system, the contribution of hydrocarbons stemming from the
342 laser annealing of the lamp black particles. In the actual conditions of black crust soiling artworks, this
343 process will add to the other causes of yellowing reported in the literature so far, such as the diffusion
344 of soluble organic compounds [5,35], and the chemical transformations of iron oxides [12].

345

346 **6. Summary and conclusions**

347 Black crust frequently covers stones and plaster of artworks in urban environments. The Nd:YAG
348 Q-Switched laser cleaning of the soiled surfaces at 1064 nm induces however a noticeable yellowing.
349 While this phenomenon is now mitigated by the simultaneous [21] or consecutive use of UV-B [8,11],
350 the nature of the yellowing compounds remains unknown. The present study shows, on a model system,
351 that the initial lamp black crust is composed of aggregates of graphitic spherical nanoparticles with
352 matrix-bonded organic species. The Nd:YAG Q-Switched laser provokes the ablation/vaporization of
353 these particles. Some of the ejected particles seem intact, others show signs of annealing at very high
354 temperature, such as partial graphitization or partial destruction accompanied by amorphization. A part
355 of the laser energy is transferred to the top surface of the gypsum substrate, causing the dissociation of
356 the calcium carbonate contaminating the substrate, within a depth of 1 nm probed by XPS. The laser
357 ablation of the carbon nanoparticles produces a plasma plume where carbon species can polymerize and
358 react with hydrogen and oxygen produced by the dissociation of water, emitted by both the gypsum
359 surface and spread by the operator. This leads to the formation of hydrocarbon chains and few aromatic
360 species which redeposit on the substrate. The yellow color could be due to the presence of some carbonyl
361 groups (C=O) attached to the polymeric chains. The organic nature of this residual carbon allows for its
362 facile photooxidation under the subsequent UV-B exposure.

363 In the light of these results, could laser cleaning be improved? The fluence and frequency of the
364 laser pulse are set just at the ablation threshold to allow for the removal of the particles. Yet, their
365 vaporization occurs despite this minimum deposited energy. The water sprayed before cleaning strongly
366 enhances the process [25], but hydrogen and oxygen radicals provided by water favor the conversion of

367 vaporized carbon into hydrocarbon species, and their oxidation is at the origin of the yellow color. Even
368 at 25°C and a typical 40% relative humidity, the partial pressure of atmospheric water (9.6 Torr) might
369 provide enough water molecules ($3.1 \cdot 10^{17}$ molecules.cm⁻³) for these reactions to occur if no water is
370 sprayed by the operator. From all these considerations, avoiding the formation of such a yellowish
371 residual hydrocarbon film after laser cleaning seems rather difficult. It makes the subsequent UV-B
372 exposure mandatory [8,11,21].

373

374 **Acknowledgments**

375 The authors would like to thank Cecile de Oliveira and Veronique Vergès-Belmin (LRMH-USR 3224,
376 Champs-sur-Marne, France) for their help and careful advices, and Agata Dmochowska-Brasseur
377 (Ateliers Bouvier, Les Angles, France) for the laser cleaning of the studied samples.

S1. C1s and O1s XPS

Fig. S1 presents the C1s (left panel) and O1s (right panel) data of the bare gypsum plate (bottom), the lamp black particles (top), and those of Areas 1-3 (covered with lamp black; after laser cleaning; after laser cleaning + UV), whose C1s data are shown also Fig. 2 of the article.

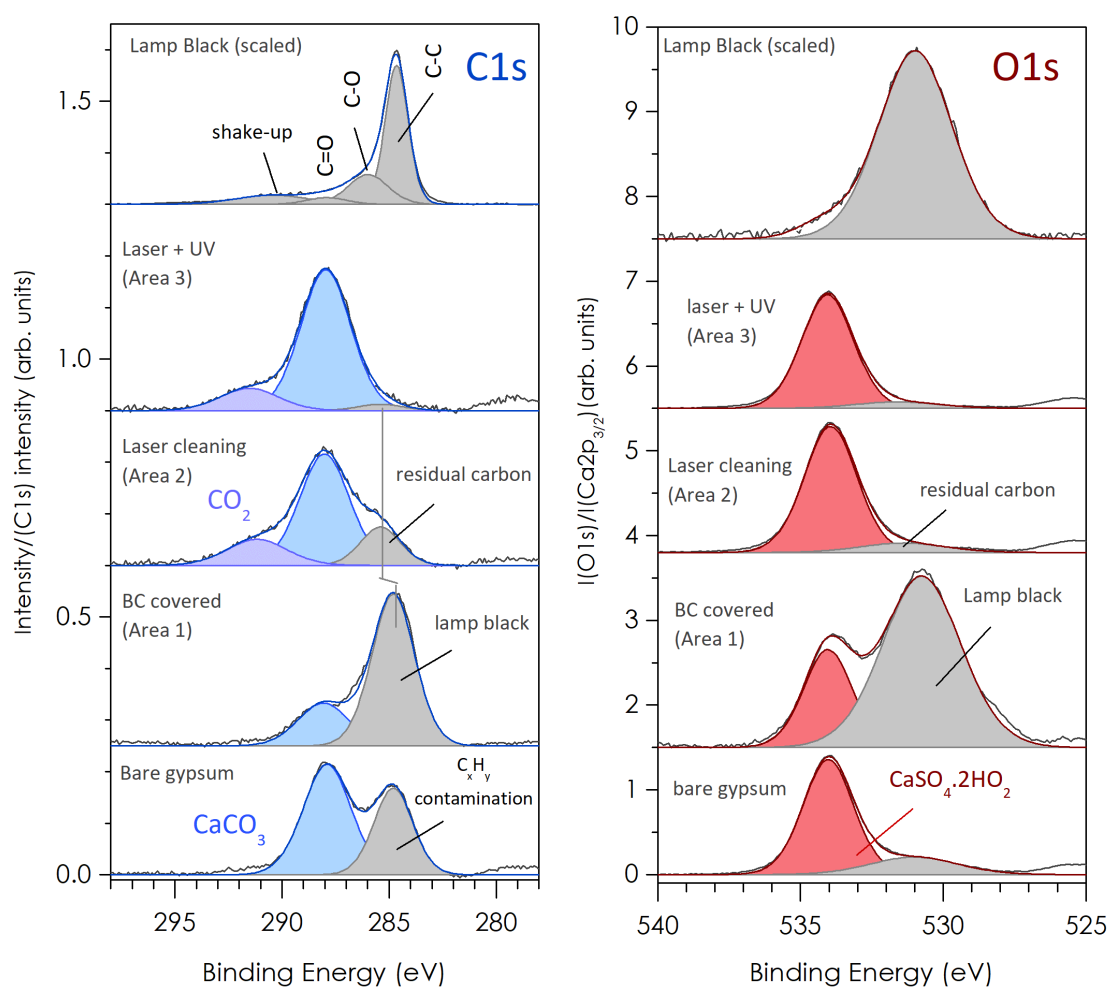

Figure S1. Deconvoluted C1s (left) and O1s (right) XPS lines of bare gypsum (bottom), of Areas 1-3 and lamp black (top).

a/ C1s XPS spectra

The C1s spectra are normalized to their integrated intensity to allow for their comparison.

-The C1s spectrum of the lamp black particles is scaled for display (left panel, top). It is deconvoluted in 4 components [1] : the most intense peak at 284.8 eV is related to C-C bonds of the graphitic layers of the primary particles. The shake-up (or plasmon) peak at 290.3 eV results from this graphitic nature. The lamp black particles are also oxidized, as shown by the two contributions of oxidized carbon at 286.0 eV (C-O) and 287.9 eV (C=O).

- The C1s spectrum of the bare gypsum plate (left panel, bottom) presents a peak at 284.8 eV, typical of adventitious hydrocarbons C_xH_y , and a second one at 288.0 eV assigned to $CaCO_3$ [2,3] contaminating the gypsum plate. This peak could hide some oxidized groups belonging to the adventitious carbon species, if any.

- The C1s spectrum of Area 1 is made of two peaks. The one at 288.0 eV is assigned to $CaCO_3$ visible through holes in the lamp black crust, and the second at 284.8 eV assigned to the lamp black peak. This peak certainly contains a (attenuated) contribution of the adventitious carbon detected on the bare gypsum plate (284.8 eV), which will also be visible through these holes. The C1s peak at 284.8 eV is fitted with a broad single component, and therefore the slight oxidized part of the lamp black spectrum is not simulated.

- The C1s spectra of Area 2 and 3 are made of three peaks. The most intense peak at 288.0 eV is the $CaCO_3$ peaks, which increases relatively to the lamp black contribution after laser cleaning (Area 2) as the particles are ablated, and after UV exposure (Area 3). As explained in the article, the second peak at 285.5 eV is assigned to the neo-formed phase of carbon that redeposits after laser ablation/vaporization (residual carbon, Area 2). The UV exposure makes it almost completely disappear (Area 3). The CO_2 peak at 291.6 eV is a side effect, due to the laser decomposition of $CaCO_3$ (see main text).

b/ O1s XPS spectra

The O1s spectra are normalized to the integrated intensity of the $Ca2p_{3/2}$ peak (except for lamp black) to allow for their comparison. The raw O1s spectrum of lamp black is scaled for display.

-The O1s spectrum of the lamp black particles (right panel, top) is a single peak at 530.8 eV, which includes the two contributions of the oxidized carbon groups (C=O and C-O) [4].

- The O1s spectrum of the bare gypsum plate (right panel, bottom) presents a main peak at 533.9 eV assigned to gypsum $CaSO_4 \cdot 2H_2O$, that might include a weak contribution of $CaCO_3$

(energy calibration differs from [5]), and a broad one at 530.8 eV related to the oxidized carbon groups of the adventitious carbon species contaminating the gypsum plate.

- The O1s spectrum of Area 1 presents a substrate peak ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) - pointing out from the holes of the lamp black particles-, and a contribution of the oxidized carbon groups of lamp black at 530.8 eV.

- The O1s spectra of Area 2 and 3 are made of two peaks. The most intense peak at 533.9 eV is that of gypsum $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$. The peak at 530.8 eV strongly decreases after laser ablation/vaporization (Area 2). We assign it as mainly due to the oxidized part of the neo-formed phase (labelled “residual carbon”), eventually bleached after the UV treatment (Area 3).

The O1s evolution of the carbon oxide peaks from Area 1 to Area 3 is fully consistent with that of the C1s peak at 284.8 eV related to the lamp black particles contribution before/after ablation/vaporization and the subsequent UV exposure.
