Abstract—Wireless capsule endoscopy (WCE) allows medical doctors to examine the interior of the small intestine with a non-invasive procedure. This methodology is particularly important for Crohn’s disease (CD), where an early diagnosis improves treatment outcomes. However, the viewing and evaluation of WCE videos is a time-consuming process for the medical experts. In this work, we present a recurrent attention neural network for the detection in WCE images of CD lesions in the small bowel. Our classifier reaches 90.85% accuracy on our own dataset annotated by experts from the Hospital of Nantes. The model has also been tested on a public endoscopic dataset, the CAD-CAP database used for the GIANA competition, and achieves high performance on detection task with an accuracy of 99.67%. This automatic lesion classifier will greatly reduce the amount of time spent by gastroenterologists in reviewing WCE videos, which will likely foster the development of this technique and speed-up the diagnosis of CD.

Index Terms—Deep learning, recurrent attention model, Crohn’s disease, medical images classification

I. INTRODUCTION

Since the mid-1990s, the development of wireless capsule endoscopy (WCE) improves the diagnosis of the Crohn’s disease (CD) and its early treatment [1]. This minimally invasive technology offers significant diagnostic performance due to its ability to fully explore the 3 to 4 metres of the small bowel. It is now well accepted by the entire scientific community [2]. As angiodysplasia, its establishment is largely based on the detection of intestinal lesions that can be more easily detected with WCE aid. The diagnosis of CD is based on two scores: the Capsule Endoscopy Crohn’s Disease Activity Index (CECDAI) [3] and Lewis’ score [4]. These indicators depend on the number of lesions, their types and locations in the small bowel. As these scores are related to the number and precise identification of the lesions, it is necessary for gastroenterologists to view all 50,000 images generated by the WCE for each patient, which can be very time-consuming (30-60 minutes per read in most studies [5]).

Various systems have been developed to limit the time required for gastroenterologists to analyze data. Many efforts have been made to detect intestinal lesions from images obtained by

WCE. These works can be classified into two main categories: algorithms based on ad hoc techniques presented in section II-A and algorithms based on convolutional neural networks (CNN), presented in section II-B. These networks allow the automatic extraction of features that make them more resilient and accurate, but also more complex to train because of the large amount of labeled ground truth required to learn their parameters.

To gather enough data to train neural networks, we set up a collaboration between the Hospital of Nantes and the Digital laboratory of Nantes. 3128 labeled WCE images have been collected and will continue to be totted. The choice was therefore made to create a recurrent neural network with attention in the manner of Mnih et al. [6]. This network, rather than taking the entire image as an input, chooses several patches successively extracted from the original image through unsupervised learning that will allow a classification decision to be made after multiple views of the same image. We hypothesize this framework to be particularly efficient with WCE images.

II. RELATED WORKS

A. Ad hoc methods

The first category of algorithms, not based on deep learning, focuses on the extraction of features from WCE images. A classifier is trained to make the link between the characteristics and image classes. Yu et al. [7] use the Local Binary Pattern (LBP) descriptor and the Scale Invariant Feature Transform (SIFT) descriptor before classification using an SVM to detect images containing ulcers. Other algorithms, such as the one developed by Li et al. [8], are based on extracting the colors of the images based on the observation that the color of the ulcers is predominantly white/yellow, then using a network of multilayer perceptrons to perform the classification. There are also techniques based on texture extraction as in Chen et al. [9]. The problem with these approaches is that they are not very robust to variations in lighting, angle of view and often specific to a type of lesion, making it more difficult to apply in real situations.

B. Deep learning methods

Over the past 4 years, new algorithms based on deep neural networks have been developed to segment and detect lesions from WCE images. These networks stand out for their different architectures and the data used to train them. Aoki et al. propose a network based on an architecture called Single Shot multibox Detector [10]. This network learns to generate delimitation boxes around areas considered pathological. Fan et al. propose a detection algorithm using the AlexNet network [11] driven on their own database containing 8000 WCE images. There is also a deep neural network in the literature called TerausNetV2 [12], a network for image segmentation. This algorithm was applied to the segmentation of images from WCE [13] and was awarded first place in the GIANA competition. Since these different algorithms are tested on different databases, it is difficult to compare their performance.

III. NETWORK ARCHITECTURE

In this article, attention is considered as a sequential decision-making process of an agent interacting with a visual environment. The network is based on the one presented by Mnih et al. 2014 [6] and on the REINFORCE algorithm of Williams 1992 [14]. From this base network, the local features extraction of the *What? Network* has been improved thanks to a pre-trained VGG16. The memory process has also been upgraded by the addition of a Gated Recurrent Unit (GRU). The ability to control the patch size has been given to the network and is learned by reinforcement learning (RL).

A. Recurrent attention neural network

The global architecture of the network is described in Fig. 1. An endoscopic image X is provided as input to the network. The Glimpse Sensor will then extract a patch $\rho(X)$ from the original image according to $l_t = (x, y, z)$ where the coordinates x and y are normalized in the interval $[-1; 1]$, i.e. $(0, 0)$ is the center of the image, and z is a zoom coefficient between $]0; 1]$. With $s_x \times s_y$ the resolution of the original image, we get a resolution patch $(s_x \times z) \times (s_y \times z)$. This patch is then resized to keep a fixed size at the network input. The subnetwork *What? Network*, based on VGG16 [15] with batch normalization, pre-trained on ImageNet [16], allows to extract the characteristics of the patch $\rho(X)$. Only the 12 first layers of VGG16 and the first fully-connected layer have been preserved. In parallel, information about extracting the patch l_t crosses the *Where? Network* composed of 2 fully-connected layers, thus allowing the extraction of the characteristics relative to the extraction position of the patch $\rho(X)$. The two characteristic vectors produced by this network are of identical size and multiplied before being subjected to ReLU non-linearity. The new characteristic vector g_t at the output of the non-linearity then contains the ‘‘Where?’’ and ‘‘What?’’ information extracted by the *Glimpse Network* at time t . A Gated Recurrent Unit [17] (GRU) allows to merge the characteristics extracted at time t by the network with those extracted at the previous time contained in the previous internal state h_{t-1} of the GRU. This internal state of the GRU

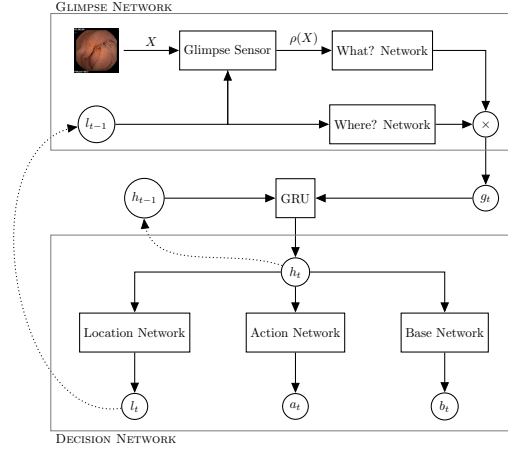

Fig. 1. **Architecture of the RANN** : At each time t , we provide the *Glimpse sensor* with an endoscopic image X and the location l_{t-1} of the patch to extract from the original image. Two independent neural networks, the *What? Network* and the *Where? Network*, will then extract information related to the content and location of the patch. A Gated Recurrent Unit (GRU) will then merge the characteristics previously extracted by the network to produce the current system state h_t . From this state, three subnets will independently produce l_t , the position of the next patch to extract, a_t , a vector containing a score associated with each class and b_t , the *baseline* from which is calculated the reward for RL.

will be reused at the next time step.

From the new internal state produced by the GRU, the *Action network* will produce a vector associating a score to each class. The *Baseline Network* will allow it to calculate the reward associated with a prediction so that it can train the *Location Network* by reinforcement. Learning by reinforcement is unsupervised and associates to each action of the network a reward that should be maximized by the network. Thus the network will increase the probability of locations maximizing the reward function. If the network classifies the image correctly, the reward is worth the number of views placed on the image minus the sum of baselines calculated by the network.

B. Loss function

The network cost function is a sum of three cost sub-functions \mathcal{L}_a , \mathcal{L}_b and \mathcal{L}_r . First, the cross entropy function \mathcal{L}_a computes the network classification error at the last glance at the image with the network prediction \hat{Y}_i and the ground truth Y_i :

$$\mathcal{L}_a = -\frac{1}{n} \sum_{i=1}^n Y_i \log(\hat{Y}_i). \quad (1)$$

Then, function \mathcal{L}_b calculates the mean square error between the R_t^i reward and the b_t baseline established by the network (2). The reward is equal to the number of glances placed on the image if the latter has been correctly classified, 0 otherwise. This *baseline*, depending on the present and past contexts, allows the reward to be adjusted in order to push the network to improve on its previous results.

TABLE I
CONFUSION MATRIX ON CAP-CAD TEST DATASET PROVIDED BY GIANA ORGANIZERS.

	Non-pathological	Pathological	
	Normal	Inflammatory-lesions	Vascular-lesions
Normal	289	0	3
Inflammatory-lesions	0	297	25
Vascular-lesions	0	28	258

TABLE II
NEURAL NETWORK PERFORMANCE EVALUATION ON GIANA AND CROHN-IPI DATASETS.

Dataset	3 classes	2 classes				
	Accuracy	Accuracy	Specificity	Sensitivity	F1	F2
GIANA	93.78%	99.67%	100.00%	98.97%	99.24%	99.51%
CROHN-IPI	-	90.85%	91.47%	90.22%	90.44%	90.67%

$$\mathcal{L}_b = \frac{1}{n} \sum_{i=1}^n \sum_{t=1}^T (b_t - R_t^i)^2 \quad (2)$$

Function \mathcal{L}_r allows to set up the unsupervised RL (3). The principle is as follows: a strategy $\pi(\tau^j; \theta)$, depending on the network parameters θ associates a probability to the path τ^j . A path is a succession of actions u_t , in our case the change of the location of the patch extraction. Each action results in a new state s_t , in our case a new patch at the system input. This new state then influences the system that will produce a new action that will lead to a new state. The objective of the reinforcement algorithm is to maximize the probability of trajectories that maximize the reward ($R_t - b_t$) and *a contrario* to decrease the probability of trajectories leading to a low reward. We use Monte Carlo methods to estimate the expected return from a state by averaging the return from M multiple rollouts of a policy.

$$\mathcal{L}_r = -\frac{1}{n} \frac{1}{M} \sum_{i=1}^n \sum_{j=1}^M \sum_{t=1}^T \log \pi(u_t^j | s_{i:t}^j; \theta) (R_t^j - b_t) \quad (3)$$

IV. EXPERIMENTAL RESULTS AND DISCUSSIONS

The different medical image segmentation and detection algorithms mentioned in above were each tested on different databases, not all containing the same types of lesions. Currently, results of the different methods presented during the Giana competition on the CAP-CAD database [18] are not available but will be published shortly.

A. Results on GIANA

The training dataset contains 1800 images obtained by WCE divided into 3 classes: 600 images with vascular lesions, 600 with inflammatory lesions and 600 containing no pathology. The images of the training base undergo random transformations (rotations, y-mirroring and elastic distortion) during training in order to increase the diversity of examples, thus making it easier for the network to generalize its knowledge. 80% of the images in the database are used to train the network and 20% for validation. The confusion matrix presented in

table III-A show results obtained on the test dataset of the GIANA competition that contains 900 images.

An accuracy of 93.78% is obtained for the three-class classification task (inflammatory lesion, vascular and normal). Since our problem deals with the detection of lesions, the classes vascular-lesions and inflammatory-lesions have been grouped into a “pathological” class. The maximum accuracy on the two-class classification task (pathological, non-pathological) is 99.67%, *i.e.*, about one error for 300 images. Table III-A summarizes different metrics evaluations.

B. Results on CROHN-IPI

The CROHN-IPI (CI) database includes 3218 images divided into 7 different classes, 6 corresponding to different types of pathological lesions (aphtoid ulceration, ulceration from 3 to 10 mm, ulceration greater than 10 mm, edema, stenosis, erythema) and a class containing images of non-pathological intestines. These data have been annotated by two gastroenterologists and come from 39 different patients. The dataset contains 1590 pathological images and 1628 non-pathological ones. 70% of the images in the database are used to train the network, 10% for validation and 20% for evaluation. The results obtained are grouped in table III-A. An average accuracy of 89.26% is obtained after 10 cross-validations, for an architecture using 4 views of resolution 80×80 on the images from WCE and 7 rollouts network from Monte-Carlo sampling.

C. Discussion

The results obtained are inferior on the CI database than on the GIANA database (one error every 10 images on CI versus one error every 300 images on GIANA). There are several reasons for this discrepancy. First, vascular lesions in angiodysplasia are significantly easier to recognize by their bright red color than lesions in Crohn’s disease. Secondly, the GIANA dataset includes 600 images of each of the lesions and 600 non-pathological images, allowing the network to train on 300 examples before being tested. For CI, some classes of lesions such as stenosis or erythema are under-represented (less than 70 examples). Then, it can also be explained by the

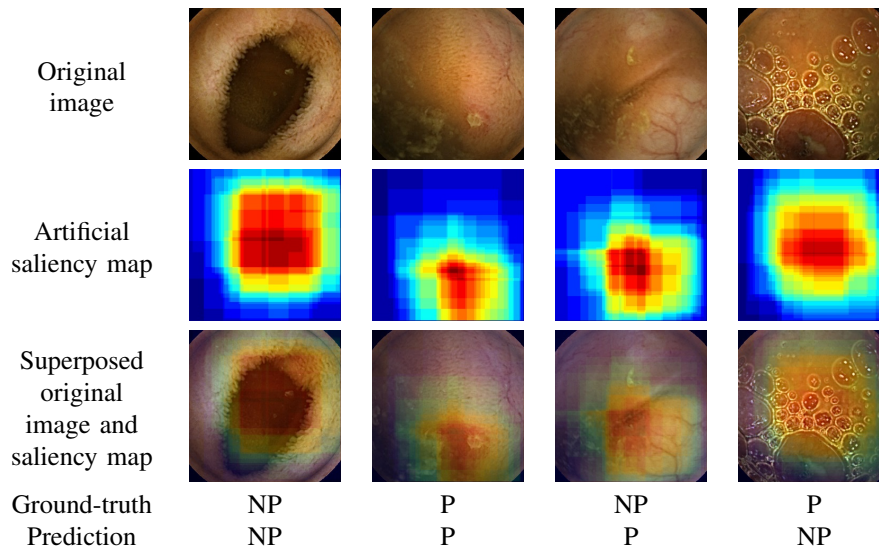

Fig. 2. Examples of artificial saliency maps according to the detection result (with P for the pathological class and NP for the non-pathological one).

way GIANA's images were chosen compared to those of CI. GIANA images seem much cleaner, containing less image noise (blurred, low light) and intestinal activity noise (fewer bubbles on the images).

As we can see in Fig. 2, the network looks at relevant parts of the image to make the classification decision. These artificial saliency maps are generated by plotting the 4 glimpses for the 7 rollouts networks from Monte-Carlo sampling.

V. CONCLUSION

This article presents the implementation of a recurrent attention neural network architecture. It was trained and tested on two different datasets: GIANA and CI obtaining an accuracy of 99.78% and 90.85% respectively.

The prediction on CI, the dataset built in partnership with the Hospital of Nantes, are less accurate due to the number of complex and more realistic images it contains. The addition of new examples to this database, selected thanks to the understanding of where the network focuses, should allow the network to integrate new cases and thus improve results.
