17
18 **ABSTRACT**

19 In this study, the degradation of four emerging contaminants (losartan potassium
20 (LP), furosemide (FRSM), caffeine (CAF), and carbendazim (CBZ) under UV-C,
21 UV-C/H₂O₂, and UV-C/S₂O₈²⁻ was investigated. A comparative evaluation of the
22 efficiency of UV-C/H₂O₂ and UV-C/S₂O₈²⁻ in the degradation of these target CECs
23 has not yet been reported. Moreover, target compounds were submitted to UV-
24 C/AOPs individually in pure water and their simultaneous degradation was
25 investigated in real surface water. Evolution of the acute toxicity of each
26 compound during treatment was evaluated using *Alivibrio fischeri*. Quantum
27 yields were determined for LP (0.011 to 0.016), FRSM (0.024 to 0.092), CAF
28 (0.0007 to 0.0009), and CBZ (0.0016 to 0.0036) at different pH values. UV-
29 C/H₂O₂ and UV-C/S₂O₈²⁻ achieved more than 98% removal of all compounds
30 within 600 mJ cm⁻², and pseudo-first-order kinetic constants (k'_{app}) for the

31 degradation reactions were up to seven times higher in the presence of these
32 oxidants when compared to k'_{app} values obtained for UV-C photolysis. k'_{app}
33 measured for UV-C/H₂O₂ were higher than those calculated for UV-C/S₂O₈²⁻
34 except in the case of LP. Acute toxicity analysis suggested the formation of toxic
35 intermediates during the UV-C photolysis of LP and FRSM, and the degradation
36 of LP via UV-C/S₂O₈²⁻ also enhanced acute toxicity although electric energy
37 efficiency per order identified UV-C/S₂O₈²⁻ as the most efficient process for the
38 removal of this compound. Finally, different transformation products obtained
39 during the degradation of caffeine under the different UV-C AOPs suggested that
40 distinct degradation routes were involved in each treatment tested.

41

42 Keywords: advanced oxidation processes, persulfate, UV-C process, quantum
43 yield, contaminants of emerging concern

44

45 1. Introduction

46 After the scientific community raised awareness regarding the presence of
47 contaminants of emerging concern (CECs) in different water resources (i.e.
48 drinking water, groundwater, surface water, and wastewater) these compounds
49 have been intensively studied over the past two decades. Therefore, many
50 technologies have been developed for the removal of CECs from these matrices.

51 Advanced oxidation processes (AOPs) have proven to be effective methods for
52 the degradation of CECs [1]. AOPs incorporating UV-C irradiation (UV-C AOPs)
53 are attractive alternatives within this category [2, 3], because the UV-C reactors
54 already being used worldwide in water and wastewater treatment plants could be
55 easily adapted for these processes [4].

56 Photoperoxidation (UV-C/H₂O₂) is one of the most disseminated AOPs [5],
57 wherein H₂O₂ undergoes UV-C photolysis ($\lambda=254$ nm) and is cleaved into two
58 hydroxyl radicals (HO•) [6]. HO• presents a high redox potential ($E^0= 1.8-2.7$ V),
59 thus being highly reactive and non-selective [7]. In addition, the UV-C/H₂O₂
60 process does not require pH adjustment, simplifying operational requirements in
61 comparison to those involved in other AOPs such as Fenton and photo-Fenton
62 [8, 9].

63 Most of the studies using UV-C/H₂O₂ to remove CECs from water have used pure
64 solutions of target compounds in synthetic matrices [6, 10-12]. Meanwhile, in real
65 matrices containing natural organic matter (NOM), inorganic ions (HCO₃⁻, Cl⁻, NO₃⁻
66 , and SO₄²⁻), and dissolved oxygen (DO), UV-C/H₂O₂ reactions may be disturbed
67 due to quenching of HO• [13], thus reducing the process efficiency. There has,

68 thus, been increased interest in alternative systems that employ strongly reactive
69 yet selective radicals, such as the sulfate radical ($\text{SO}_4^{\cdot-}$) [14].

70 In irradiated systems, $\text{SO}_4^{\cdot-}$ ($E^0 = 2.55\text{--}3.1\text{ V}$) is formed when persulfate (PS,
71 $\text{S}_2\text{O}_8^{2-}$) or peroxymonosulfate (PMS, SO_5^{2-}) are cleaved under UV-C (254 nm)
72 irradiation [15]. $\text{SO}_4^{\cdot-}$ reacts primarily via an electron transfer mechanism, and is,
73 thus, more selective and resistant than HO^{\cdot} in the presence of matrix constituents
74 such as NOM and inorganic ions [16]. In addition, $\text{SO}_4^{\cdot-}$ is not as easily influenced
75 by carbonate ions (HCO_3^-) due to the lower rate constant of the reaction between
76 $\text{SO}_4^{\cdot-}$ and HCO_3^- ($2.6\text{ to }9.1 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$) compared to that of the reaction between
77 HO^{\cdot} and HCO_3^- ($10^7\text{ M}^{-1}\text{ s}^{-1}$) [6, 14, 17-20]. The removal of CECs via UV-C/ H_2O_2
78 and UV-C/ $\text{S}_2\text{O}_8^{2-}$ varies according to the chemical structure of the compound
79 involved and as a consequence of the different reaction mechanisms promoted
80 by each radical [2, 21, 22].

81 Toxic intermediates may be generated during UV-C AOPs [23], and appropriate
82 treatment conditions for the simple removal of target compounds may not
83 effectively eliminate their toxic effects [24]. Therefore, it is essential to follow the
84 evolution of the toxicity of compounds during their treatment by UV-C AOPs in
85 order to comprehensively understand treatment efficiency [25], especially with
86 regard to UV-C/ $\text{S}_2\text{O}_8^{2-}$, for which only a few studies have investigated toxicity
87 evolution [26, 27]. In addition, since in industrial applications these advanced
88 treatments would not be utilized to achieve complete mineralization of CECs, it is
89 necessary to investigate the evolution of toxicity resulting from the degradation of
90 various harmful CECs present in environmental samples, as well as to identify
91 any intermediates and/or byproducts of their degradation processes.

92 Considering the vast diversity of emerging contaminants present in surface water,
93 four CECs were chosen as representative compounds for different classes of
94 contaminants because of their environmental relevance as they have been
95 increasingly consumed and consequently detected in surface water worldwide.
96 Losartan potassium (LP) and furosemide (FRSM) represent pharmaceutical
97 drugs. These compounds are widely prescribed to hypertensive patients
98 worldwide and have been detected in environmental matrices in various locations
99 [28-33], especially in developing countries where sanitary conditions are
100 inadequate [34]. Caffeine (CAF) was chosen due to its regular occurrence in
101 surface water and drinking water resources, for which it was recently proposed
102 as an urban pollution tracer [35-37]. The fungicide carbendazim (CBZ), which has
103 been detected in surface water around the world and is known for its toxicity,
104 represents the diverse group of agrochemicals [36, 38, 39].

105 In this context, the goals of this study were to assess the susceptibility LP, FRSM,
106 CAF and CBZ to UV-C photolysis; to evaluate the performance of UV-C/S₂O₈²⁻
107 and UV-C/H₂O₂ in the degradation of each target compound individually in pure
108 water as well as that of the four compounds in conjunction in pure water and real
109 surface water; and to investigate the impact of each UV-C AOP on acute toxicity.

110 2. Material and Methods

111 2.1 Determination of quantum yields

112 LP, FRSM, CAF, and CBZ were purchased from Sigma-Aldrich. Table S1
113 (Supplementary Material) shows the chemical structures and some
114 physicochemical properties of each of the four CECs. Figure S1 shows the UV-
115 Vis absorption spectra of the CECs at the natural pH of each solution.

116 Experiments for the determination of quantum yields (Φ) were conducted in a UV-
117 C bench reactor (volume 0.0035 L, pathway length 1 cm²) equipped with a low-
118 pressure mercury-xenon lamp (LightningCure LC8, Hamamatsu City, Japan)
119 under constant agitation by using a magnetic stirrer. Lamp intensity (I_0) was
120 determined prior to experiments using H₂O₂ ($I_0 = 2.54 \text{ J m}^{-2} \text{ s}^{-1}$) and atrazine ($I_0 =$
121 $2.14 \text{ J m}^{-2} \text{ s}^{-1}$) as actinometers [40, 41]. A UV filter (254 nm; Semrock MaxLamp)
122 was placed at the light source. Initial concentrations of LP, FRSM, CAF, and CBZ
123 were 2.2, 3.0, 5.2, and 5.5 μM , respectively. Quantum yields were calculated by
124 quantifying the decay of each compound when exposed to light at pH = 3.0, the
125 natural pH of the solution (6.0 for LP, 5.5 for FRSM, 5.8 for CAF, and 7.1 for
126 CBZ), and at pH = 9. The pH was adjusted using 0.01 M HCl or 0.01 M NaOH
127 solutions.

128 The photolysis coefficient (C_p) was calculated for each of the target compounds.
129 C_p is defined as the product of the quantum yield ($\Phi_{254\text{nm}}$) and the molar
130 attenuation coefficient ($\xi_{254\text{nm}}$) of a substance, and can be calculated according
131 to Equations 1 and 2 [4]:

$$132 \quad k_d = (\Phi_{254\text{nm}} \times \xi_{254\text{nm}} \times 2302)/U = (C_p \times 2302/U) \quad (\text{Eq. 1})$$

$$133 \quad C_p = (k_d \times U)/2302 \quad (\text{Eq. 2})$$

134 where k_d is the fluence-based pseudo-first-order rate constant (units J⁻¹ cm²), U
135 is the energy per mole of photons at 254 nm ($4.72 \times 10^5 \text{ J Einstein}^{-1}$), and 2302
136 is a factor used for unit conversion purposes (base 10 to base e, and mJ to J).

137 2.2 High-Performance Liquid Chromatography analyses

138 A liquid chromatograph equipped with a UV detector (Agilent 1260 Infinity II

139 series, UV and diode array detector equipped with a 60 mm high-sensitivity cell)
140 was used for the quantification of CECs. The separation was performed on C₁₈
141 columns (Poroshell 120 EC-C18 (3 x 50 mm, internal diameter 2.7 μm) followed
142 by Poroshell HPH-C18 (4.6 x 150 mm, internal diameter 2.7 μm) at a flow rate of
143 0.5 mL min⁻¹. Ultra-pure water (40%) and MeOH (60%; MERCK HPLC grade,
144 98% purity), both containing 0.1% formic acid (SIGMA-ALDRICH HPLC grade,
145 98% purity), was used as the mobile phase for LP and FRSM, adapting previously
146 described procedures [42]. Both LP and FRSM were monitored at λ=240 nm.
147 Methods adapted from those described by the USA Environmental Protection
148 Agency (EPA) [43, 44] were used for the quantification of CAF (MeOH/H₂O 30/70
149 (v/v), 273 nm) and CBZ (MeOH/H₂O 50/50 (v/v); 285 nm).

150 2.3 Degradation of target compounds by UV-C AOP

151 UV-C, UV-C/H₂O₂, and UV-C/S₂O₈²⁻ treatments were performed in a 2 L
152 cylindrical bench photo-reactor equipped with a low-pressure mercury vapor lamp
153 emitting monochromatic radiation at 253.7 nm (Heraeus GPH212T5L/4, 10 W) in
154 the axial position. The optical pathway (1.7 cm) was calculated according to the
155 method developed by Beltran et al. (1995) [45]. Incident photonic flux (*I₀*) was
156 determined via actinometry experiments using H₂O₂ and atrazine as actinometers
157 [40, 41], the results of which indicated an *I₀* of 2.41 J m⁻² s⁻¹. The reactor was
158 coupled to a cooling system, and temperature was kept constant at 20 °C during
159 reactions.

160 The UV-C lamp was pre-heated for 20 minutes before each reaction. Once the
161 solution temperature was stabilized at 20 °C, H₂O₂ (commercial grade, 39%) or
162 sodium persulfate (Na₂SO₈, Aldrich) were added to the solution at a concentration

163 of 10^{-3} M (molar ratio of H_2O_2 or $\text{S}_2\text{O}_8^{2-}$: target substance 20:1 for CAF, LP, and
164 FRSM, and 32:1 for CBZ). Samples were withdrawn during the reactions for
165 quantification of the target compounds using HPLC, total organic carbon (TOC;
166 TOC-VCSH Total Carbon Analyzer, Shimadzu), and residual H_2O_2 or persulfate,
167 according to previously described procedures [46]. All conditions were tested in
168 duplicate, and the pH was monitored during reactions.

169 In order to assess the influence of natural scavengers, namely inorganic ions
170 (HCO_3^- , NO_3^- , PO_4^{3-}) and NOM, on the degradation of CECs via UV-C, UV-
171 C/ H_2O_2 , and UV-C/ $\text{S}_2\text{O}_8^{2-}$, reactions were performed in surface water and ultra-
172 pure water each containing all four target compounds. Both matrices were spiked
173 with a solution containing a mix of the four compounds such that the final
174 concentration of each compound was $10\ \mu\text{M}$ (total CEC_0 concentration = $40\ \mu\text{M}$).
175 The surface water (SW) used in these experiments was sampled from the Lys
176 River at Aire sur la Lys, France.

177 2.4 Acute toxicity assays

178 Acute toxicity analyses were performed using the Microtox® method (Model 500
179 Analyzer SDI) (ISO 11348-3:2007) on samples withdrawn during UV-C photolysis
180 and the UV-C AOP processes performed in the UV-C reactor, as described
181 previously [47]. *Allivibrio fischeri* was exposed to samples diluted to different
182 degrees, luminescence was measured after 5, 15, and 30 min of exposure, and
183 relative inhibition (EC_{50} , %) was obtained and converted to acute toxicity units
184 (a.T.u.; = $100/\text{EC}_{50}$). According to the method employed, samples were
185 considered toxic when the a.T.u. value was above 1.2 ($\text{EC}_{50} > 81.9\%$). Catalase
186 (Synth®, $460\ \text{mg L}^{-1}$ in $0.04\ \text{M}$ phosphate buffer) and ascorbic acid (Merck, 440

187 mg L⁻¹) solutions were used as quenching agents for the consumption of residual
188 hydrogen peroxide and persulfate present in the samples, respectively [48, 49].
189 Neither of these reagents are toxic to *Allivibrio fischeri*, as previously reported
190 [49] and as confirmed experimentally by blank tests. The pH was adjusted (to
191 6.5–7.5) prior to toxicity analysis.

192 2.5 Transformation products (TPs)

193 The samples withdrawn during UV-C and UV-C/AOP treatments were analyzed
194 via direct injection high-resolution electrospray ionization (ESI)-mass
195 spectrometry (Bruker micrOTOF-QII) in negative mode for LP and FRSM, and in
196 positive mode for CAF and CBZ. In order to increase the signal, formic acid was
197 added to the CAF and CBZ samples, and ammonium hydroxide was added to
198 the FRSM and LP samples (both at concentrations at 0.1%). A blank sample
199 containing water and formic acid or ammonium hydroxide was analyzed before
200 each measurement. The transformation products (TPs) obtained from the original
201 substances were proposed by considering two different strategies: a structure
202 showing the exact mass detected by the instrument; or simpler structures
203 considering oxidative radical attack and the energy required to break specific
204 chemical bonds in the original molecule.

205 3. Results and Discussion

206 3.1 Determination of quantum yields

207

208 Figure 1 shows the UV-C photolysis of each target compound at different pH
209 values, and Table 1 presents the quantum yields and C_p values obtained at acidic
210 (pH = 3.0), natural (pH of solution without adjustment), and basic (pH = 9.0) pH.

211

212 Figure 1. Photolysis (UV-C_{254nm}) of LP (2.2 μ M), FRMS (3.0 μ M), CAF (5.2 μ M),
213 and CBZ (5.5 μ M) in ultrapure water at acidic, natural (non-adjusted), and basic
214 pH ($I_0 = 2.54 \text{ J m}^{-2} \text{ s}^{-1}$, volume 3.5 mL) as a function of incident energy per area
215 (mJ cm^{-2}).

216

217 Table 1 – Quantum yields and photolysis coefficients (C_p) obtained for each
218 compound at 254 nm at different pH values.

pH	$\Phi_{254 \text{ nm}} (\text{mol Einstein}^{-1})$			$C_{p \text{ 254 nm}} (\text{L Einstein}^{-1} \text{ cm}^{-1})$		
	3	n	9	3	n	9
LP	0.0115 \pm 0.0001	0.0153 \pm 0.0001	0.0144 \pm 0.0006	123.6	190.2	190.2
FRSM	0.0815 \pm 0.0001	0.0294 \pm 0.0006	0.0245 \pm 0.0006	380.4	95.1	95.1
CAF	0.0007 \pm 0.0001	0.0005 \pm 0.0002	0.0008 \pm 0.0001	4.1	1.9	3.8
CBZ	0.0027 \pm 0.0001	0.0016 \pm 0.0001	0.0021 \pm 0.0001	7.6	4.7	9.5

n = pH of solution without adjustment (6.0 for LP, 5.5 for FRSM, 5.8 for CAF, 7.1 for CBZ). Errors were calculated from duplicate measurements.

219

220 Considering the high $\epsilon_{254\text{nm}}$ of LP ($12 \text{ 355 M}^{-1} \text{ cm}^{-1}$) at pH 6, its degradation by
221 direct UV-C photolysis could have been supposed. The chemical structure of LP
222 (Table S1) consists of two aromatic rings and various unsaturated bonds and
223 functional groups containing nitrogen, all of which are known as absorbers [11],
224 thus explaining the high molar attenuation coefficient (Table S1) [10]. The
225 susceptibility of LP to photolysis at 254 nm in medical formulations based on a
226 drinkable cherry syrup has been reported previously [50, 51]. However, there are
227 no previous reports on the photolysis nor on the values of quantum-yield for LP
228 in water. The quantum yields obtained for LP (Table 1) varied from 0.011 to 0.015
229 mol Einstein^{-1} (Figure 1, Table 1), and was slightly lower at acidic pH compared
230 to the values obtained at pH 9 and 6 (Figure 1A). The slightly higher molar
231 absorptivity and photolysis coefficients obtained at pH 6 and 9 in comparison to

232 that at pH 3 could be explained by the pKa of this compound (4.15) (Table S1).
233 According to the pKa, LP would exist in its neutral form at pH 3 but in the
234 dissociated form at pH 6 and 9. As the chemical structures of the neutral and the
235 protonated form are distinct, the molar absorptivity may be affected [40].
236 Specifically, it was slightly higher for the dissociated form of LP than for the
237 neutral form, as confirmed by the $\epsilon_{254\text{nm}}$ values which increased from 10 700 M⁻¹
238 cm⁻¹ at pH 3 to 13 140 M⁻¹ cm⁻¹ at pH 9 (Table S2).

239 As molar attenuation coefficient is influenced by the dissociated/non-dissociated
240 structure and C_p describes a relation between the quantum yield and the molar
241 attenuation coefficient, the C_p values obtained for LP also varied according to pH
242 (Table 1), specifically being higher at pH 6 and 9 than at pH 3. The C_p obtained
243 for LP is higher than the value of 40 which indicates that a compound is
244 susceptible to direct photolysis [3]. The C_p is also similar to those obtained for
245 atrazine and pentachlorophenol [4]. Atrazine also presents functional groups that
246 contribute to light absorption and photolysis. Although atrazine exhibits a lower
247 ϵ_{254} (3860 M⁻¹ cm⁻¹ at pH 7) than LP, atrazine has a higher quantum yield (0.046
248 mol Einstein⁻¹). Therefore, these compounds show similar susceptibility to
249 photolysis (C_p atrazine = 160) [4]. In addition to direct UV-C photolysis, chain
250 reactions may be triggered after a compound undergoes photolysis due to the
251 formation of other radicals in the system, such as Cl• [4]. Considering that LP,
252 atrazine, and pentachlorophenol all contain chlorine atoms in their structures, Cl•
253 radicals may be generated, which would lead to further degradation of these
254 compounds under UV-C irradiation.

255 As shown in Figure S1, FRSM has a lower light absorption coefficient at 254 nm,
256 while it absorbs strongly at 230 nm and 270 nm. In addition, the molar attenuation

257 coefficients obtained for FRSM at 254 nm ranged from 3200 to 4700 M⁻¹ cm⁻¹,
258 corresponding to pH 5.5 and 3, respectively (Table S2). As the pKa of FRSM is
259 3.9 (Table S1) [52], this compound exists in its neutral form at pH 3, where it
260 exhibited a higher absorptivity and molar attenuation coefficient at 254 nm (Table
261 S2) than at other pH values. As a consequence, photolysis coefficient, and UV-
262 C photolysis of FRSM were higher at acidic pH (Table 1, Figure 1). The photo-
263 instability of FRSM in the neutral form has been previously reported, and the
264 photolysis product showed increased reactivity, solubility in water, and
265 genotoxicity in comparison to the parent compound [53, 54].

266 As the molar attenuation coefficient (4660 M⁻¹ cm⁻¹) of FRSM at 254 nm was
267 highest at pH 3, the photolysis coefficient C_p of this compound was more than 3
268 times higher at pH 3 than at pH 5.8 and 9 (Table 1). The photolysis coefficient of
269 FRSM at pH 3 is comparable to that of the antibiotic sulfamethazine, likely due to
270 the presence of similar functional groups present, such as sulfonamide and
271 chlorobenzene moieties. These functional groups are light absorbers, thus
272 contributing to UV-C photolysis and to the occurrence of secondary chain
273 reactions [4]. Meanwhile, when the solution pH was above the pKa, the
274 absorbance of the dissociated form of the compound was lower (Table S2).
275 Therefore, molar absorptivity and photolysis coefficients were also lower under
276 these conditions. The quantum yield obtained at pH 5.5 for FRSM was 0.0294
277 mol Einstein⁻¹, which is in agreement with previously reported values (0.02200 ±
278 0.0028 mol Einstein⁻¹) [55].

279 The absorption spectrum (Figure S1) of CAF reveals that absorbance of this
280 compound at 254 nm was reduced when compared to 205 nm and 273 nm, and
281 to the absorbance of LP and FRSM at this wavelength. According to the molar

282 attenuation coefficients obtained at 254 nm (Table S2), the molar absorptivity of
283 CAF did not change significantly with pH. This suggests that the structure of CAF
284 is not influenced by the pH, which is in agreement with previous reports that the
285 pKa of CAF is either above 10 [56] or “not observable within the pKa scale in
286 water (0-14)” [10] (Table S1). Therefore, photolysis coefficients obtained for CAF
287 in acidic and basic conditions were similar (Table 1). This testifies for the photo-
288 stability of CAF over the tested pH range (Figure 1). The quantum yield obtained
289 for CAF in this study was similar to the value reported in the literature (0.0003
290 mol Einstein⁻¹) [12]. Carlson et al. [10] also reported insignificant photolysis of
291 caffeine, thus confirming that this compound is not susceptible to UV-C
292 photolysis. As the molar absorptivity was similar at pH 3, 5.5 and 9, the photolysis
293 coefficients of CAF were low in all of the tested pH range, ranging from 1.9 to 4.1
294 mol Einstein⁻¹. Interestingly, the photolysis coefficients obtained for CAF were
295 similar to those reported for carbamazepine ($C_p = 7$), which is also resistant to
296 UV-C photolysis [4]. As caffeine and carbamazepine have been increasingly
297 detected in water resources, their low susceptibility to photolysis would call for
298 other alternative methods for their treatment in wastewater effluent or in drinking
299 water treatment processes.

300 The absorbance of CBZ at 254 nm was relatively low (Figure S1). Thus, UV-C
301 photolysis of this compound was expected to be relatively low in comparison to
302 compounds that absorb strongly at this wavelength, such as LP. The slightly
303 higher molar attenuation coefficients measured at pH 7 and 9 (Table S2), which
304 are above the pKa (4.2), in comparison to that measured at pH 3, indicate that
305 the substance more readily absorbs photons in its dissociated form. Quantum
306 yield values (Table 1) obtained for CBZ confirm the stability of this compound

307 under UV-C irradiation (Figure 1). In addition, the quantum yields shown in Table
308 1 agree with the values reported previously [57, 58]. The slightly higher decay of
309 CBZ observed at pH 9 in comparison to that at pH 3 or 7 is also in agreement
310 with the molar absorptivity values (Table S2). As a consequence of the lower
311 molar attenuation coefficient, the photolysis coefficients of CBZ at different pH
312 are also negligible and comparative to those obtained for CAF. Similarities in the
313 chemical structures (such as the imidazole moiety) of CBZ and CAF may explain
314 the correspondence between the quantum yield and C_p values obtained for both
315 compounds (Table 1, Figures 1C and D). In comparison to other pesticides such
316 as atrazine and alachlor, CBZ is much more resistant to photolysis [4]. The higher
317 photolysis of atrazine and alachlor in comparison to CBZ may be related to the
318 de-chlorination of these compounds [59, 60], which does not occur in CBZ since
319 it does not contain chlorine.

320 3.2 Degradation of target compounds via UV-C/H₂O₂ and UV-C/S₂O₈²⁻

321 Profiles of the degradation of target compounds, pH values, and consumption of
322 H₂O₂ and S₂O₈²⁻ over the courses of the UV-C AOP are shown in Figure 2.
323 Control experiments consisted of H₂O₂ or S₂O₈²⁻ in the same concentration
324 without UV-C irradiation, and showed neither removal nor mineralization of target
325 compounds (Figure S2). The use of these oxidants in combination with UV-C
326 irradiation increased the removal of all target compounds, especially for the
327 photo-stable compounds CAF and CBZ, resulting in degradation of over 90%
328 (Figure 2) with a dose of 300 to 600 mJ cm⁻² of UV irradiation, depending on the
329 target compound.

330

331 Figure 2. Left: Degradation of each target compound by UV-C AOPs: UV-C/H₂O₂
332 and UV-C/S₂O₈²⁻. Control experiments are also presented (UV-C photolysis,
333 H₂O₂, or S₂O₈²⁻ alone). Molar ratio of H₂O₂ or S₂O₈²⁻: compound = 20:1 for LP,
334 FRSM, and CAF, and 32:1 for CBZ; $I_0 = 2.41 \text{ J m}^{-2} \text{ s}^{-1}$. Right: consumption (%) of
335 H₂O₂ ($C_0 = 10^{-3} \text{ M}$), S₂O₈²⁻ ($C_0 = 10^{-3} \text{ M}$), and pH values monitored during UV-C
336 AOPs for each of the target compounds, as functions of incident energy per unit
337 area (mJ cm^{-2}).
338

339 Experiments conducted with LP showed that UV-C photolysis alone achieved up
340 to 85% removal in one hour (corresponding to 870 mJ cm^{-2}), while UV-C/S₂O₈²⁻
341 and UV-C/H₂O₂ reached the same removal rate (Figure 2) after 290 and 620 mJ cm^{-2}
342 incident energy, respectively, both achieving 98% removal by 870 mJ cm^{-2} .
343 UV photolysis of FRSM reached 87% removal after 870 mJ cm^{-2} incident energy,
344 while in the presence of H₂O₂ or S₂O₈²⁻, the same efficiency was achieved with
345 435 and 650 mJ cm^{-2} , reaching 98% and 93% removal, respectively, after one
346 hour (Figure 2). Degradation rates of FRSM via UV-C only and UV-C/H₂O₂
347 determined in this study are in agreement with values reported in the literature
348 [61]. After one hour of reaction (total incident energy 870 mJ cm^{-2}), both UV-C
349 AOPs achieved efficient degradation of LP and FRSM, despite the maximum
350 TOC removals being limited to 10% and 6%, respectively (Fig. S2). These results
351 indicate the accumulation of organic transformation products in the system.

352 The limited consumption of H₂O₂ in the presence of LP and FRSM (10%) (Figure
353 2) probably occurred as a result of the molar attenuation coefficients of these
354 compounds ($\epsilon_{254\text{nm, LP, pH 7}} = 11772 \text{ M}^{-1} \text{ cm}^{-1}$, $\epsilon_{254\text{nm, FRSM, pH 6}} = 3700 \text{ M}^{-1} \text{ cm}^{-1}$)
355 (Table S2) being higher than that of H₂O₂ ($\epsilon_{254\text{nm, H}_2\text{O}_2} = 19.6 \text{ M}^{-1} \text{ cm}^{-1}$) [4, 62]. The
356 pharmaceuticals diclofenac and mecoprop, which are strong light absorbers, also
357 impaired the absorption of light by H₂O₂ during UV-C/H₂O₂ treatment [12], thus
358 reducing the process efficiency; this effect is a problem known to occur in the

359 presence of strong photon absorbers [63]. One other reason for the low
360 consumption of H₂O₂ in these systems, when compared to the consumption of
361 S₂O₈²⁻ (25%), may be related to the lower rate constants for the self-scavenging
362 effects of SO₄^{•-} with S₂O₈²⁻ ($k_{\text{SO}_4\cdot^-/\text{S}_2\text{O}_8^{2-}} = 6:6 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$ and $k_{\text{SO}_4\cdot^-/\text{SO}_4\cdot^-} = 3:1$
363 $\times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) in comparison to those of HO[•] toward H₂O₂ ($k_{\text{HO}\cdot/\text{H}_2\text{O}_2} = 2:7 \times 10^7 \text{ M}^{-1}$
364 s^{-1} and $k_{\text{HO}\cdot/\text{OH}\cdot} = 5:5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$) [17, 64, 65].

365 As shown in Figure 2 (left column), after 200 mJ cm⁻² of incident energy, the
366 concentrations of LP and FRSM were reduced by a factor of 2. Therefore,
367 competition for light decreased and H₂O₂ and S₂O₈²⁻ consumption subsequently
368 increased (Figure 2, right). However, concentrations of both reagents were still
369 high at this moment since consumption was lower than 5% of initial concentration
370 ($9.5 \times 10^{-4} \text{ M}$ of remaining H₂O₂ and S₂O₈²⁻) (Figure 2, right column). As
371 regeneration of hydrogen peroxide from hydroxyl radicals via self-scavenging
372 occurs more readily than the regeneration of S₂O₈²⁻ from sulfate radicals, the final
373 consumption of H₂O₂ at the end of treatment was limited to a maximum of 10%
374 of initial concentration after 850 mJ cm⁻² of incident energy, when compared to
375 nearly 30% consumption of S₂O₈²⁻ in the presence of LP and FRSM (Figure 2,
376 right column).

377 During LP degradation, 30% of initial S₂O₈²⁻ were consumed after 430 mJ cm⁻² of
378 incident energy (Figure 2, right column), while H₂O₂ consumption was limited to
379 10%. Assuming stoichiometric conversion of reagents to oxidative radicals $6 \times$
380 10^{-4} M of sulfate radicals were generated when compared to $2 \times 10^{-4} \text{ M}$ of hydroxyl
381 radicals, thus explaining the faster LP degradation via UV-C/S₂O₈²⁻ (98% within
382 430 mJ cm⁻²) when compared to the degradation via UV-C/H₂O₂ (70% within 430
383 mJ cm⁻²) (Figure 2, left). On the other hand, both UV-C AOPs and the UV-C

384 photolysis exhibited similar patterns in terms of FRSM removal and reagent
385 consumption until 220 mJ cm^{-2} of incident energy (Figure 2, left column),
386 suggesting that photolysis was the predominant mechanism in the system, which
387 is supported by the fact that FRSM is a strong light absorber (Section 3.1, Figure
388 1, Table 1). However, after reaching 430 mJ cm^{-2} of incident energy, $\text{S}_2\text{O}_8^{2-}$
389 consumption reached 21% while only 5% of the initial H_2O_2 had been consumed.
390 Assuming stoichiometric conversions of $\text{S}_2\text{O}_8^{2-}$ and H_2O_2 to oxidative radicals,
391 nearly 4.2×10^{-4} M of sulfate radicals were formed in the system, compared to 10^{-4}
392 M of hydroxyl radicals. However, FRSM degradation via UV-C/ H_2O_2 at this
393 moment was 99%, while it was only 80% via UV-C/ $\text{S}_2\text{O}_8^{2-}$ (Figure 2, left column).
394 In contrast with LP, for which the degradation was higher in the UV-C/ $\text{S}_2\text{O}_8^{2-}$
395 system, this result suggests that FRSM is more reactive with hydroxyl radicals
396 than with sulfate radicals, which may be related to differences in the chemical
397 structures [3, 15].

398 CAF and CBZ did not undergo photolysis, which was expected due to their low
399 quantum yields and molar absorption coefficients. In contrast, both UV-C AOPs
400 achieved over 99% removal of CAF and CBZ (Figure 2, left column). CBZ
401 degradation was faster via UV-C/ H_2O_2 , reaching 99% removal after 290 mJ cm^{-2}
402 of incident energy, in comparison to the 650 mJ cm^{-2} required to achieve similar
403 removal by UV-C/ $\text{S}_2\text{O}_8^{2-}$. Mineralization of CAF and CBZ in the UV-C/ $\text{S}_2\text{O}_8^{2-}$
404 process was more extensive (reaching 60% and 70%, respectively) than it was
405 in the presence of hydroxyl radicals (reaching 25% and 35%, respectively)
406 (Figure S2). The drop in pH from 9 to 8 during UV-C/ $\text{S}_2\text{O}_8^{2-}$ (which was not
407 observed in UV-C/ H_2O_2) was due to the formation of SO_4^{2-} and H^+ [16]. Higher
408 mineralization rates through UV-C/ $\text{S}_2\text{O}_8^{2-}$ can likely be explained by the greater

409 selectivity and lifespan of sulfate radicals in comparison to hydroxyl radicals as it
410 is less reactive with inorganic species that may be formed during the degradation
411 of target compounds (O , Cl^- , NO_3^- and CO_3^{2-} , HCO_3^{2-}), and also towards $S_2O_8^{2-}$ and
412 sulfate radical itself (self-scavenging), thus increasing its persistence in the
413 system. This was also reported with other compounds such as 2,4-D,
414 carbamazepine, and azathioprine [14, 66-68]. In addition, the ability UV-C/ $S_2O_8^{2-}$
415 to degrade carboxylic acids and intermediate products usually formed during
416 oxidation processes has been previously confirmed [16].

417 As CAF and CBZ do not absorb UV-C light as extensively as LP and FRSM,
418 irradiation is promptly absorbed by reagents in the UV-C AOPs, leading to higher
419 and faster degradation when compared to UV-C photolysis (Figure 2, Table 2)
420 and higher consumption of H_2O_2 in the UV-C AOPs, reaching 23% for CAF and
421 30% for CBZ (Figure 2). An increase in pH at the beginning of the reactions was
422 observed during UV-C/ H_2O_2 treatments of CAF and CBZ (Figure 2 – right
423 column), which likely contributed to higher consumption of H_2O_2 as cleavage is
424 favored in alkaline conditions [69]. $S_2O_8^{2-}$ consumption exhibited similar behavior
425 to that of H_2O_2 during the degradation of CAF and CBZ.

426 Degradation data obtained during UV-C AOPs were fitted to a pseudo-first-order
427 kinetics model ($R^2 > 0.95$), and apparent rate constants were calculated for each
428 process for the different target compounds (Table 2). Electrical energy per order
429 of removal (EE/O; $kWh\ m^{-3}$) was also calculated in order to compare the
430 efficiencies of the different processes (Table 2). EE/O values represent the
431 amount of energy required to decrease the concentration of the compound by
432 one order of magnitude [66]. Therefore, higher k'_{app} values result in lower EE/O
433 values, revealing the most efficient process in terms of lowest energy

434 consumption [70]. However, EE/O should not be considered alone when aiming
435 to identify the most affordable process; reagent costs must also be considered,
436 as, for example, persulfate is more expensive than H₂O₂ [71]. When compared to
437 UV-C photolysis alone, k'_{app} values increased in the presence of hydroxyl and
438 sulfate radicals. Regarding UV-C photolysis, the EE/O values (Table 2) were
439 calculated using experimental data for FRSM, as this process reduced the
440 concentration of this compound by one order of magnitude within 650 mJ cm⁻² of
441 incident energy. In contrast, for LP, EE/O values were predicted using the k'_{UV-C}
442 obtained for this compound. As UV-C photolysis of CAF and CBZ did not fit the
443 pseudo-first-order model ($R^2 < 0.95$), it was not possible to estimate EE/O values
444 for the photolysis of these compounds. Apparent rate constants values for the
445 degradation of CAF via UV-C/H₂O₂ agree with the values obtained by Shu et al.
446 [12], who reported higher values of these constants for compounds with reduced
447 quantum yields (caffeine and carbamazepine). Therefore, data on the photolysis
448 coefficients and quantum yields of emerging contaminants present in water may
449 be a valuable tool to predict their degradability via UV-C photolysis, or whether
450 UV-C AOPs would need to be applied [3].

451 Apparent rate constants obtained for the UV-C/H₂O₂ process were higher than
452 those of the UV-C/S₂O₈²⁻ process for all target compounds except LP. This is
453 likely due to the higher reaction rate of this compound with sulfate radical than
454 with the hydroxyl radical. A decrease in the concentration of LP by one order of
455 magnitude occurred after 20 minutes (290 mJ cm⁻² of incident energy) for UV-
456 C/S₂O₈²⁻ (Figure 2), yet 45 minutes (650 mJ cm⁻²) were required to achieve the
457 same removal (Table 2) by UV-C/H₂O₂, as reflected in the k'_{app} and EE/O values.
458 The lower k'_{app} values obtained for UV-C/S₂O₈²⁻ compared to that of UV-C/H₂O₂

459 during the degradation of FRSM, CAF, and CBZ may be related to the higher
 460 selectivity of $\text{SO}_4\cdot^-$ when compared to that of $\text{HO}\cdot$, since it acts preferentially via
 461 electron transfer whereas $\text{HO}\cdot$ also reacts via addition and H-abstraction [72].
 462 UV-C/ H_2O_2 required 20 minutes (290 mJ cm^{-2}) to reduce the FRSM concentration
 463 by one order of magnitude, while 45 minutes (650 mJ cm^{-2}) were required by UV-
 464 C/ $\text{S}_2\text{O}_8^{2-}$, thus explaining the higher EE/O of the former process (Table 2).

465 Table 2 – Pseudo-first-order rate constants (min^{-1}) obtained for each process for
 466 the different target compounds, and EE/O values obtained for UV-C/ H_2O_2 and
 467 UV-C/ $\text{S}_2\text{O}_8^{2-}$ for the different target compounds

Pseudo-first-order rate constant (k' ; min^{-1})	LP	FRSM	CAF	CBZ
k'_{UV-C}	0.011 ± 0.005	0.056 ± 0.004	*	*
k'_{UV-C/H_2O_2}	0.048 ± 0.0003	0.11 ± 0.01	0.100 ± 0.001	0.22 ± 0.01
$k'_{UV-C/S_2O_8^{2-}}$	0.0864 ± 0.0005	0.072 ± 0.002	0.085 ± 0.007	0.17 ± 0.04
EE/O (kWh m^{-3})				
UV-C	2.3 P**	1.5 P		
UV-C/ H_2O_2	1.5 P	0.67 P	0.5 P	0.25 P
UV-C/ $\text{S}_2\text{O}_8^{2-}$	0.6 P	1.5 P	0.5 P	0.33 P

*Did not fit the model due to low degradation ($R^2 < 0.95$). P is the lamp power (10 W)

468 **Estimated using the k'_{UV-C} value.

469 The EE/O values obtained for CAF degradation were the same for both UV-C
 470 AOPs (0.5 P), indicating that the energy required to remove this compound in
 471 water using either H_2O_2 or $\text{S}_2\text{O}_8^{2-}$ under UV-C irradiation was the same. This
 472 result agrees with the similarity between the kinetic rates obtained for each
 473 process (Table 2). For CBZ, both UV-C AOPs showed comparable k'_{app} and EE/O
 474 values (Table 2). The degradation of carbamazepine, another photo-resistant
 475 compound, via UV-C/ H_2O_2 and UV-C/ $\text{S}_2\text{O}_8^{2-}$ also led to similar EE/O values in a
 476 previous study [22]. Indeed, the quantum yield, photolysis coefficient, molar
 477 mass, and chemical composition of CAF and CBZ are all very similar, which might
 478 explain their comparable behavior when submitted to UV-C AOPs.

479 3.4 Evolution of acute toxicity

480 As shown in Figure 3, acute toxicity varied between treatments for all compounds,
481 indicating the formation of toxic intermediates during UV-C AOPS, as has been
482 reported in the literature for various emerging contaminants [23]. The LP solution
483 was not toxic to *Allivibrio fischeri* ($a.T.u. = 0.26$), and no acute toxicity was
484 observed during UV-C/H₂O₂ treatment. However, acute toxicity developed during
485 the UV-C-only and UV-C/S₂O₈²⁻ processes, despite the high degradation
486 efficiencies achieved during these processes (65% for UV-C and 98% for UV-
487 C/S₂O₈²⁻). According to Adachi et al. [73], the cyanide ion is formed when LP is
488 oxidized by sodium hypochlorite. Therefore, this ion could have been formed by
489 oxidation during the UV-C AOPs, which may have contributed to the increase in
490 acute toxicity. This difference between the degradation by sulfate and by hydroxyl
491 radicals have been described in previous studies [24]. However, there is no report
492 in the literature regarding the formation of toxic transformation products during
493 UV-C photolysis and UV-C/S₂O₈²⁻ oxidation of LP, nor of other sartans with similar
494 structures. In contrast, the EE/O values suggest that UV-C/S₂O₈²⁻ is more efficient
495 than UV-C/H₂O₂ in the removal of LP. This result indicates that it is not adequate
496 to consider the EE/O values alone for identifying the optimal treatment method.

497

498 Figure 3. Acute toxicity of samples withdrawn during the degradation of target
499 compounds via UV-C, UV-C/H₂O₂, and UV-C/S₂O₈²⁻ processes, shown as
500 functions of the total incident energy received (mJ cm⁻²). The horizontal lines
501 represent the threshold of 1.21 a.T.u.; bars crossing the line thus indicate toxic
502 samples.

503

504 FRSM was reported to be non-toxic to *Allivibrio fischeri* [54], yet its products of

505 photolysis and electro-Fenton degradation are considered toxic [74, 75]. In the
506 present study, before treatment, the FRSM solution exhibited a beneficial
507 stimulatory effect, known as hormesis, upon the photobacteria (Figure 3). This
508 effect occurs with luminescent bacteria as a consequence of exposure to small
509 concentrations of toxic chemicals [76]. As shown in Figure 3, acute toxicity was
510 generated during the UV-C photolysis of FRSM, but was eliminated within 600
511 mJ cm^{-2} of incident energy, when this process reached FRSM removal of 80%
512 (Figure 2). Meanwhile, there was no generation of toxicity during the UV-C/ H_2O_2
513 process. In contrast, UV-C/ $\text{S}_2\text{O}_8^{2-}$ exhibited similar behavior to the UV-C-only
514 process, as toxicity was generated at the beginning of the reaction but was
515 eliminated within 300 mJ cm^{-2} of incident energy, much less than that required
516 with the UV-C-only process (Figure 3).

517 Before treatment, the CAF solution exhibited an inhibitory effect ($\text{EC}_{50} = 76\%$;
518 $\text{a.T.u.} = 1.3$) on *Allivibrio fischeri*, as has been reported for similar tests using a
519 marine photobacterium as a bioindicator ($\text{EC}_{50} = 62.8\%$) [77]. Although a few
520 authors reported that there was no increase in CAF toxicity after AOP treatments
521 [78, 79], no reports on the effect of UV-C/ H_2O_2 or UV-C/ $\text{S}_2\text{O}_8^{2-}$ on CAF toxicity
522 have been published. This is alarming since caffeine is detected in surface waters
523 in a wide variety of locations in concentrations up to $\mu\text{g L}^{-1}$ [34], and was even
524 considered for use as an indicator of illegal sewage disposal [37]. Both UV-
525 C/ H_2O_2 and UV-C/ $\text{S}_2\text{O}_8^{2-}$ increased CAF toxicity at the beginning of the treatment,
526 although the toxic effects were entirely eliminated toward the end of the
527 treatments when the concentration of CAF was below 10% of its initial
528 concentration (Figure 3). This suggests the formation and degradation of toxic
529 transformation products within both processes. With regards to UV-C photolysis,

530 for which only the final sample was analyzed due to the negligible effect of this
531 process on the removal of CAF, an increase in toxicity during treatment was also
532 observed.

533 As confirmed by the results shown in Figure 3, CBZ is known to be toxic to
534 *Allivibrio fischeri* [80]. Similarly to what was observed for CAF, UV-C photolysis
535 alone was not able to remove CBZ due to its low molar absorptivity and quantum
536 yield. Consequently, UV-C photolysis had a negligible effect on the acute toxicity
537 of CBZ. Meanwhile, both UV-C/H₂O₂ and UV-C/S₂O₈²⁻ eliminated the toxic effect
538 of CBZ; as it was also observed by other irradiated AOPs under artificial and solar
539 irradiation in another study [80]. During UV-C/H₂O₂, CBZ degradation occurred
540 alongside the reduction in acute toxicity (Figure 3). In contrast, acute toxicity
541 increased during the initial stages of the UV-C/S₂O₈²⁻ process and decreased
542 toward the end, probably due to the formation of toxic transformation products.
543 This result agrees with the EE/O values (Table 2), as less energy was required
544 to reduce the toxicity of CBZ via UV-C/H₂O₂ compared to UV-C/S₂O₈²⁻.

545 3.5 Degradation of target compounds by UV-C/H₂O₂ and UV-C/S₂O₈²⁻ in surface
546 water

547 In order to assess the impact of the water matrix on the degradation of target
548 compounds, UV-C, UV-C/H₂O₂, and UV-C/ S₂O₈²⁻ treatments were applied to
549 surface water and ultrapure water each spiked with 10 µM of each compound.
550 Although degradation of all compounds occurred simultaneously, since all
551 compounds were present in the same matrix, the degradation of each pollutant
552 was quantified individually (Figure 3). Reduction in TOC and consumption of
553 H₂O₂ and S₂O₈²⁻ were also monitored (Figure 4).

554

555 Figure 4. Degradation of LP, FRSM, CAF, and CBZ (10 μM each) in ultra-pure
556 water and surface water by UV-C, UV-C/ H_2O_2 , and UV-C/ $\text{S}_2\text{O}_8^{2-}$ processes
557 ($\text{C}_{\text{OH}_2\text{O}_2}$ or $\text{S}_2\text{O}_8^{2-} = 10^{-3}$ M), shown as functions of total incident energy per area (mJ
558 cm^{-2}).
559

560 The presence of scavenger compounds that are naturally present in real surface
561 water, including HCO_3^- , natural organic matter (NOM), and Cl^- , among others,
562 may lead to a lower degradation of target compounds in practical applications
563 [70]. NOM is mainly comprised of humic acids which present various functional
564 groups that compete with the target compounds for hydroxyl and sulfate radicals
565 [81, 82]. As shown in Figure 4, UV-C photolysis of CBZ in the surface water and
566 in the presence of the other target compounds was similar to that observed in
567 pure water, still exhibiting an insignificant decrease in concentration due to its
568 lower quantum yield and molar absorptivity at 254 nm (Table 1). On the other
569 hand, the UV-C photolysis of each of LP, FRSM, and CAF was slightly higher in
570 surface water than in pure water. This likely happened due the formation of
571 oxidative radicals from the natural constituents of the Lys River surface water,
572 which presented a DOC of 1.2 mg L^{-1} ; O_2 concentration 8 mg L^{-1} ; NO_3^-
573 concentration 22 mg L^{-1} ; PO_4^{3-} concentration 0.1 mg L^{-1} ; Cl^- concentration 20 mg
574 L^{-1} ; and high alkalinity of $330 \text{ mg L}^{-1} \text{ HCO}_3^-$. A greater extent of photolysis of
575 FRSM in natural waters than in pure water was also observed previously [61].
576 When NOM, dissolved oxygen, and phosphate are submitted to UV-C $_{254\text{nm}}$
577 irradiation, oxidative species such as NOM^\bullet , singlet oxygen ($^1\text{O}_2$), and $\text{PO}_4^{2-\bullet}$ may
578 be formed [83, 84]. Although these radicals present lower redox potentials than
579 HO^\bullet and $\text{SO}_4^{\bullet-}$, they may have contributed to the enhanced photolysis of LP,
580 FRSM, and CAF [85]. Further, HO^\bullet may also be formed from the irradiation of

581 NO_3^- present in surface waters [86, 87].

582 Lower degradations of LP and FRSM were observed during UV-C AOPs in
583 surface water than in pure water. The high level of carbonate ions in surface water
584 may have contributed to the quenching of hydroxyl and sulfate radicals involved
585 in the degradation reactions. In contrast, for CAF and CBZ, the effect of matrix
586 constituents on the oxidative radicals formed during the UV-C AOPs could not be
587 observed, probably because their reaction rates with radicals are extremely high,
588 as shown in Table 2. The relatively high content of chloride ions, which react
589 strongly with sulfate radicals [88], may have influenced the effectiveness of the
590 UV-C/ $\text{S}_2\text{O}_8^{2-}$ process, thus leading to the lower removal of target compounds in
591 surface water than in pure water.

592 The consumption rates of H_2O_2 and $\text{S}_2\text{O}_8^{2-}$ were below 25% in all of the tested
593 conditions (Figure 5). H_2O_2 consumption in pure water was 13%, but 20% in
594 surface water, thus confirming that a higher consumption of this reagent occurred
595 in the presence of other matrix components. On the other hand, $\text{S}_2\text{O}_8^{2-}$
596 consumption was very similar in pure water (20%) and in the presence of matrix
597 components (24%). In addition, previous studies have confirmed that the
598 performance of the UV-C/ $\text{S}_2\text{O}_8^{2-}$ process is not disturbed by carbonate ions
599 (HCO_3^-) to such an extent as is the performance of the UV-C/ H_2O_2 process,
600 probably due to the lower reaction constants for the reaction of $\text{SO}_4^{\bullet-}$ with HCO_3^-
601 ($k_{\text{SO}_4^{\bullet-}, \text{HCO}_3^-} = 2.8 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) than that of OH^{\bullet} with HCO_3^- ($k_{\text{HO}^{\bullet}, \text{HCO}_3^-} = 8.5 \times 10^6$
602 $\text{M}^{-1} \text{ s}^{-1}$) [6, 14, 17-19]. Furthermore, the TOC removal (Figure 5) achieved by UV-
603 C/ $\text{S}_2\text{O}_8^{2-}$ (9% and 21% in pure water and surface water, respectively) was higher
604 than that achieved by UV-C/ H_2O_2 (5.7 and 14.9%, respectively) in both water
605 matrices, thus corroborating the results reported earlier in this study (Section 3.3).

606 The higher mineralization efficiency in surface water than in pure water
607 corresponds to the degradation of NOM via sulfate radicals, as reported
608 previously [65].

609

610 Figure 5. Reagent consumption and TOC removal during UV-C AOPs in surface
611 water (filled symbols) and pure water (empty symbols), as functions of total
612 incident energy per area (mJ cm^{-2}) (Initial TOC in pure water 5.4 mg L^{-1} and in
613 surface water 6.6 mg L^{-1}).

614

615 3.3 Identification of transformation products

616 The mass spectra of CAF before UV-C radiation (zero min) shows two peaks:
617 protonated caffeine I ([caffeine+H⁺], $m/z = 195.08$) and another signal
618 ([caffeine+Na⁺], $m/z = 217.07$) which refers to the sodium adduct (Figure 6A). The
619 peak intensities corresponding to the transformation products detected during
620 CAF oxidation, along with the mass spectra after 315 mJ cm^{-2} of incident energy
621 in the UV-C/H₂O₂ (Figures 6B and C) and UV-C/S₂O₈²⁻ (Figures 6D and E)
622 processes show that a higher number of transformation products were formed
623 during UV-C/H₂O₂ than during UV-C/S₂O₈²⁻, likely due to the higher selectivity of
624 the sulfate radical than the hydroxyl radical. The oxidation of the six-membered
625 ring in UV-C/H₂O₂ first generated 2 main species which presented masses $m/z =$
626 125.98 and 142.06 (Figures 6B and C, at 50 mJ cm^{-2} , and Figure 7), with smaller
627 peaks corresponding to $m/z 128.02$ and 168.04 (Figures 6B and C and Figure 7).
628 However, after 300 mJ cm^{-2} of incident energy, species with $m/z = 110.01$,
629 128.02 , and 146.03 were identified in the UV-C/H₂O₂ system (Figures 6B and C
630 and Figure 7).

631 Figure 6. Mass spectra of (A) Caffeine solution in pure water, (B and D) signals
632 corresponding to masses detected during UV-C/H₂O₂ and UV-C/S₂O₈²⁻
633 treatments, and (C and E) mass spectra obtained after UV-C/H₂O₂ and UV-
634 C/S₂O₈²⁻ treatments with 300 mJ cm⁻² of total incident energy.
635

636 Meanwhile, the transformation products accumulated during UV-C/ S₂O₈²⁻ were
637 different ($m/z = 164.92$ and 142.94 ; Figures 6D and E), thus suggesting a different
638 transformation pathway which has not yet been reported for caffeine in the
639 literature. These results are very relevant considering that the use of caffeine as
640 an indicator of so-called 'fresh' contamination of surface waters has been
641 suggested by some authors [35-37].

642 Considering the spectra obtained during the degradation of CAF via UV-C/H₂O₂,
643 a possible degradation route was proposed, as shown in Figure 7. The signal at
644 $m/z = 195.09$ (structure I) corresponds to the protonated adduct of caffeine. The
645 oxidation process led to a decrease in intensity of the $m/z = 195$ signal and
646 increases in the intensities of other signals associated to products of oxidation.
647 ChemCalc [89] was used to assign a formula to the exact mass and then propose
648 a structure based on these formulae. The two first products (II: $m/z = 142.06$ and
649 III: $m/z = 125.98$) would be formed from a break of the pyrimidine moiety and the
650 opening of the imidazole ring (Figure 7). A signal of $m/z 142$ was also detected
651 by Dalmazio et al., (2005) [90] during the degradation of caffeine via UV-C/H₂O₂.
652 However, considering the exact mass obtained here, the product proposed in the
653 referred paper was not realistic in our case. Species of $m/z 128.02$ (III) and
654 146.03 (IV) would be formed from the further oxidation of II, leading to an
655 isocyanate structure [80] and the formation of carboxylic acid moieties. Then,
656 compound VI would later accumulate in the system as a product of oxidation of
657 the intermediate compounds. However, no structure could be proposed for the

658 detected signals. No structures were proposed for the oxidation products of the
659 UV/S₂O₈²⁻ process, as the formulae proposed for the mass obtained were not
660 relevant for the process [89].

661 Figure 7. Degradation pathway proposed for the formation of transformation
662 products generated during the oxidation of caffeine via UV-C/H₂O₂

663

664 These analyses were also performed with samples withdrawn during the
665 oxidation of LP, FRSM, and CBZ via UV-C/H₂O₂ and UV-C/S₂O₈²⁻. However, as
666 shown in Figures S3, S4, and S5, decreases in the signal intensities of the target
667 compounds were observed, yet no other signals of significant intensity were
668 detected. TPs could not be observed using this methodology as they would not
669 have been ionized by the ESI used here.

670 4. Conclusion

671 In this study, the quantum yields and photolysis coefficients were calculated for
672 target compounds, indicating that LP and FRSM are susceptible to photolysis in
673 the UV-C range (80% removal of each LP and FRSM under UV-C photolysis
674 alone at total levels of 800 and 600 mJ cm⁻² incident energy). In contrast, the UV-
675 C photolysis of both CAF and CBZ by this process was negligible. UV-C/H₂O₂
676 and UV-C/S₂O₈²⁻ were extremely effective in the removal of all target compounds,
677 achieving over 90% degradation in a pure water matrix under the same
678 conditions. *k'*_{app} rates were obtained for UV-C/H₂O₂ on the degradation of FRSM,
679 CAF, and CBZ, when compared to UV-C/ S₂O₈²⁻ due to the reactivity of hydroxyl
680 radicals toward these compounds and their intermediates. On the other hand,
681 mineralization rates and reagent consumption were higher in the UV-C/S₂O₈²⁻
682 system, probably due to the greater light absorption and lower self-scavenging

683 exhibited by sulfate radicals as compared to hydroxyl radicals. During acute
684 toxicity analysis using *Allivibrio fischeri*, samples withdrawn during the UV-C-only
685 and UV-C/S₂O₈²⁻ processes exhibited higher toxicity than those withdrawn during
686 the UV-C/H₂O₂ process. Simultaneous degradation of target compounds in real
687 surface water indicated higher stability of the UV-C/S₂O₈²⁻ system in the presence
688 of natural scavengers in comparison to that of the UV-C/H₂O₂ system. A lower
689 number of transformation products were detected during CAF degradation via
690 UV-C/S₂O₈²⁻ as compared to UV-C/H₂O₂, confirming the higher selectivity of the
691 sulfate radical than the hydroxyl radical, and suggesting distinct reaction
692 mechanisms for each radical.
