20 Signaling: Benchmarking Simulations by Measured Yields of Initial DNA Damage after Ion
21 Microbeam Irradiation. *Radiat. Res.*

22 Advances in accelerator technology enabling radiotherapy performing conformal irradiations
23 with charged hadronic species has brought benefits to patients but also, potentially, new risks. For
24 a better understanding of the effects of ionizing radiation on tumor and surrounding tissue
25 investigating and quantifying the relation between energy deposition at nanometric scale and the
26 initial biological events is a key issue. Monte Carlo track structure simulation codes provide a
27 powerful tool for investigating this relation; however, their success and reliability rely on their
28 improvement and development accordingly to the dedicated biological data to which they are
29 challenged. For this aim, microbeam facility that allows the controlling of the fluence down to
30 one ion per cell nucleus was used to evaluate relative frequencies of DNA damage following the
31 interaction between the incoming ion and DNA according to radiation quality. Primary human
32 cells were exposed to α particles of three different energies with respective LETs of about 36, 85
33 or $170 \text{ keV}\cdot\mu\text{m}^{-1}$ at the cells' center position, or to protons ($19 \text{ keV}\cdot\mu\text{m}^{-1}$). Statistical evaluation
34 of nuclear foci formation (53BP1/ γ -H2AX) observed by immunofluorescence and related to a
35 particle traversal was undertaken in a large population of cell nuclei. The biological results were
36 adjusted considering the factors that drive the experimental uncertainties and, then challenged
37 with results using Geant4-DNA code modeling the ionizing particle interactions on a virtual
38 phantom of the cell nucleus with the same mean geometry and DNA density as the cells used in
39 our experiments. Both results show an increase of relative frequencies of foci (or simulated DNA
40 damage) in cell nuclei as a function of increasing LET of the traversing particles, reaching a

41 quasi-plateau when the LET exceeds 80-90 keV· μm^{-1} . For the LET of an α particle ranging from
42 80-90 to 170 keV· μm^{-1} , 10-30% of the particle hits do not lead to DNA damage inducing 53BP1
43 or γ -H2AX foci formation.

55

56 **Introduction**

57 In radiation biology, the absorbed dose is used as a fundamental physical quantity on
58 which we rely to estimate biological effects caused by ionizing radiation. Indeed, the absorbed
59 dose is defined as the mean value of the specific energy, i.e. the ratio of the amount of energy
60 deposited by ionizing radiation within a volume to the mass contained in that volume (unit: $\text{J}\cdot\text{kg}^{-1}$)
61 ¹⁾ (1). At *macroscopic* scale, such as tissues or organs, this mean value is a good estimate of the
62 actual energy deposition in the volume. Nevertheless, even at the *macroscopic* scale equal
63 absorbed doses of different types of radiation do not produce equal biological effects (2, 3).
64 These differences are based on the distribution of imparted energy at the *microscopic* level (2, 4)
65 which is not considered by the mean value given by the absorbed dose (5, 6). For microscopic
66 volumes such as cells or subcellular structures, the distribution of the specific energy has a larger
67 spread around the value of the absorbed dose, and this variability causes the differences between
68 radiation qualities.

69 Charged particles lose their energy in a discontinuous manner, by inelastic collisions
70 (mainly ionizations or excitations) with the target molecules. This leads to a spatially non-
71 uniform distribution of the energy transfer points (the so-called track structure) which is
72 concentrated along and around the path of a charged particle and depends on the ion type and
73 energy. The linear energy transfer (LET) is the average energy deposited per traveled unit
74 distance ($\text{keV}\cdot\mu\text{m}^{-1}$) (7, 8) and is often used as a *macroscopic* measure for the *microscopic*
75 properties of radiation (9). It may be relevant at the cell or cell nucleus compartment levels
76 (typically micrometers in size) but it does not account for random fluctuation in individual
77 interactions of a given particle (10). Therefore, the *nanometric* resolution (scale of molecules

78 such as DNA molecules) of the individual energy depositions is required to better apprehend the
79 mechanisms of radiation effects at cellular or subcellular levels.

80 To overcome these limitations, Monte Carlo track structure simulation has become a powerful
81 tool to model energy deposition processes in biological structures such as cell nuclei. In some
82 cases, these codes can also handle the simulation of the physico-chemical and chemical processes
83 that follow in time the initial energy deposition and contribute to the final extent of DNA damage
84 for different radiation qualities (11-13). This simulation technique has a huge potential to better
85 explain the relation between energy deposition and the initial induced cellular damage. However,
86 the major difficulty is determining which descriptive parameters have the key role for a given
87 application (9). This simulation requires the estimation of some parameters (used either to
88 shortcut complex processes or as decision-criteria (14)) that are usually based on data coming
89 from biological experiments. Regarding the interaction, at the sub-micrometer level, between
90 charged hadronic species and living matter, the availability of relevant biological measurements
91 are rare or nonexistent. Designing and carrying out sets of suitable and dedicated biological
92 experiments, used as benchmarks so as to establish and adjust description parameters of the
93 phenomena at their origin, is essential for developing biophysical models as well as for
94 understanding the characteristics (physical or biological) of the initial radiation-induced damage
95 (15).

96 Recent advances in irradiation techniques and molecular biology have enabled the
97 observation and quantification of DNA damage of individual cells to single ionizing particles,
98 rather than averaging the effect over multiple cells and crossing ions. Indeed, microbeam
99 technology is offering the possibility to deliver a predetermined number of particles of a certain
100 radiation quality (type and energy) in a specific area of the cells, nucleus, or cytoplasm, with
101 micrometric spatial resolution (16-18). In parallel, the study of the initial induced cellular

102 damages related to a particle traversal performed on a large population of cells is achievable
103 combining *in situ* observations on platforms of high-throughput microscopy including a powerful
104 and robust infrastructure necessary for a massive image analysis.
105 Thus, the observation of nuclear foci formation by immunofluorescence, such as phosphorylation
106 on serine 139 of the histone variant H2AX (γ -H2AX) and p53 binding protein-1 (53BP1), and the
107 analysis of their characteristics (location, size, fluorescence intensity ...) make a foci-based assay
108 well suited to study markers of DNA damage produced by the ionizing particles. Phosphorylation
109 of H2AX and relocation of 53BP1 are among the best characterized biomarkers for DNA DSB
110 detection for which evidence suggests a close association between the two of them (19-22)
111 although this point is still debated (23-27).

112 In this work, we investigate the relative frequencies of interaction between protons or
113 α particles of different energies and DNA leading to at least one 53BP1 or γ -H2AX focus
114 formation when the primary ionizing particles traverse the cell nucleus. We perform statistical
115 evaluations of radiation-induced 53BP1 foci and γ -H2AX appearance in cell populations wherein
116 each cell nucleus was traversed by a given number of particles delivered by the microbeam
117 facility of Physikalisch-Technische Bundesanstalt (PTB) (18). The obtained foci number
118 distributions were converted into relative frequencies of radiation-induced foci detected per
119 particle track and corrected for the influence of the experiment's conditions. Indeed, all these
120 factors should be considered to properly evaluate the relative frequencies of at least one 53BP1 or
121 γ -H2AX focus formation as a function of the radiation LET. In parallel, simulation procedures
122 using the Geant4-DNA Monte Carlo code were developed, to which the biological results are
123 compared. This should allow the relation between the topology of energy deposition and early
124 signaling of DNA damage to be elaborated.

125 **Materials and methods**

126 **Cell culture**

127 Cultures of primary human umbilical vein endothelial cells (HUVEC) were obtained from Lonza
128 (Bâle; Suisse). All cells tested negative for mycoplasma, bacteria, yeast, and fungi. HIV-1,
129 hepatitis B and hepatitis C were not detected for all donors. Cells at passage 2 (4–5 doubling
130 population) were grown in endothelial cell growth media (EBM[®] and supplements) (Lonza)
131 containing 4.72% (vol/vol) fetal bovine serum (Lonza), hydrocortisone, hFGF-B, VEGF, R3-
132 IGF-1, ascorbic acid, hEGF, gentamicin and amphotericin-B (EGM-2BulletKit, Lonza). They
133 were maintained at a temperature of 37°C in humidified incubators in an atmosphere of 5% CO₂
134 (vol/vol) in air. For experiments, cells were seeded at numbers that allowed them to reach the
135 density-inhibited state within five days in 12.5 cm² polystyrene flasks. They were then fed twice
136 on alternate days. The karyotype and the genomic stability of cells were evaluated to ensure an
137 equivalent DNA content in all cells of a population (28).

138

139 **Microbeam irradiation**

140 The microbeam facility of Physikalisch-Technische Bundesanstalt (PTB) in Braunschweig,
141 Germany, and the irradiation procedure have been previously described in detail (18, 29, 30).
142 Briefly, protons and α particles were accelerated to the selected beam energies using an energy-
143 variable cyclotron (The Cyclotron Corporation (TCC), model CV-28). Single-particle irradiation
144 is facilitated with a signal from a detector system, consisting of thin scintillator and photo
145 multiplier tube, which is used as a trigger for a fast beam deflector (18). The detection efficiency
146 for ion passage and the spatial resolution have been estimated for each set of experiments. Owing

147 to energy losses of the particles in the microbeam exit window, a 10 or 40 μm -thick scintillator
148 and a 25 μm -thick bioFoil, the energy in the cell nuclei's center, obtained using SRIM code (31),
149 was 1.6 MeV for the protons and 17.8 MeV, 5.5 MeV, and 1.86 MeV for α particles. These
150 energy values correspond to average LET values of the ions of $19 \text{ keV}\cdot\mu\text{m}^{-1}$, $36 \text{ keV}\cdot\mu\text{m}^{-1}$,
151 $85 \text{ keV}\cdot\mu\text{m}^{-1}$ and $170 \text{ keV}\cdot\mu\text{m}^{-1}$. The physical characteristics of the beam for the different
152 projectiles and energies used for biological experiments are reported in Table 1.

153 Spatial widths (full width at half maximum, FWHM) were achieved through focusing by the
154 electromagnetic elements of the microbeam. Before each setup of irradiation and using the same
155 type of dishes filled with medium, values in radial and axial ($d1 \times d2$) directions at the level of
156 cells were noted and are listed in Table 1. The actual coordinates for a particular particle hit
157 follow a Gaussian distribution in x- ($\mu = 0$, $\sigma1 = d1/2.355$) and y- ($\mu = 0$, $\sigma2 = d2/2.355$) axes.
158 The detection threshold and noise events in the particle counter were also quantified or estimated
159 for each set of irradiations (Table 1). Indeed, a certain percentage of particles may be considered
160 as delivered by the microbeam due to the detection of noise events while none was emitted.
161 Conversely, an ionizing particle may be emitted but not detected due to the detection threshold,
162 leading to delivery of a second particle, with two particles delivered instead of one. This may
163 occur at each position of the pattern.

164 About 20 h before irradiations, confluent cell cultures were trypsinized and approximately
165 4,000 cells were seeded as a drop of 25–30 μL onto the 25 μm -thick replaceable hydrophilic
166 biofoils (polytetrafluoroethylene foil) (In Vitro Systems & Services, Göttingen, Germany) at the
167 base of specially designed stainless-steels dishes (18). The cell monolayer covers a circular area
168 with a diameter of about 4 mm. Dishes were maintained in 37°C humidified incubators in an
169 atmosphere of 5% CO_2 (vol/vol) in air for 2 h. Then, they were filled with medium and put back

170 in the incubators overnight. Cell nuclei were stained with 150 nM solution of Hoechst 33342 dye
171 (17530, AAT Bioquest) for 30 min, rinsed with medium and then sealed with a cover glass. The
172 cell dishes were positioned perpendicularly to the beam on a computer-controlled *xy*-stage
173 (Märzhäuser, Wetzlar, Germany) mounted on an inverse microscope (Zeiss Axiovert 100). Then,
174 they were scanned using a magnification x20 lens and a sensitive CCD camera (18), an LED-
175 based light source Lumencor with 399 ± 9 nm wavelength for illumination and customized image
176 analysis software to detect the location of each nucleus. The narrow bandwidths of the filters and
177 light source allow a reduction of the possible interaction between UV light and Hoechst 33342
178 that leads to a background of γ H2AX foci formation. Special care was taken during all imaging
179 and adjustment procedures to minimize the exposure times and to otherwise limit this effect. The
180 dishes were maintained at 37°C during the scan and irradiation period, using a dish holder
181 connected to a thermostat. Cell cultures were exposed to the particles and energies listed in
182 Table 1. Each cell nucleus was targeted with the same pattern of five particles placed at the
183 corners of a 4 μ m side square with one target point in the middle, positioned at the barycenter of
184 each cell nucleus (Fig. 1A). A typical duration for the whole procedure of the scan and irradiation
185 of a cell dish containing 4,000 cells was about 30 minutes. After irradiation, the dishes with the
186 cells were put back into the incubator. Control cell cultures (noted C) and sham-irradiated cell
187 dishes (noted S) were handled in the same way as the test cultures, but were not irradiated.
188 However, sham-irradiated cell cultures were subject to cell nuclei recognition.

189

190 ***In situ* immune detection of 53BP1 and γ -H2AX**

191 53BP1 and γ -H2AX are sensitive markers of DNA damages (23, 32, 33). Briefly, at different
192 times after irradiation, cells were fixed with 4% paraformaldehyde and 2% sucrose in PBS for

193 15 min at room temperature, and rinsed with PBS. Subsequently, the cells were permeabilized
194 with a Triton-X buffer [(0.5% TritonX-100, 300 mM sucrose, 3 mM MgCl₂, 20 mM HEPES
195 Buffer (pH 7.4), 50 mM NaCl in water)] at 4°C for 3 min. The fixed and permeabilized cell
196 monolayers were reacted with rabbit polyclonal anti-53BP1 (A300-272A, Bethyl) and mouse
197 monoclonal anti-phospho-histone H2AX (Ser139) (05-636, Upstate) antibodies diluted
198 respectively to 1:1000 (vol/vol) and 1:800 (vol/vol) in a blocking buffer [2% (vol/vol) BSA in
199 PBS] for 1 h at room temperature which was followed by blocking buffer wash. After incubation
200 for 1 h with goat anti-rabbit IgG coupled to Texas Red®-X (T6391, Invitrogen) and goat anti-
201 mouse IgG₁ coupled to Alexa Fluor® 488 (A21121, Invitrogen) secondary antibodies, both
202 diluted to 1:1000 in blocking buffer, the cells were washed in PBS. Nuclei were stained with
203 570 nM 4',6'-diamidino-2-phenylindol dihydrochloride (DAPI) solution (1050-A, Euromedex)
204 for 5 min at room temperature. Prolong Gold antifade reagent (P36930, Invitrogen) was used in
205 mounting the samples. Distributions of 53BP1 and γ -H2AX foci formation were examined.

206

207 **Automated imaging acquisition**

208 All the images within the same data set were captured with a Scan[®] platform (Olympus). It
209 consists of an inverted microscope IX81 (Olympus) equipped with a motorized stage SCAN IM
210 IX2 (Märzhäuser) and a MT20 fluorescence illumination system with fast filter wheel. The
211 images were acquired using a UPLSAPO 100XO oil immersion objective lens (Olympus) (N.A.
212 1.4) associated with a high-resolution cooled digital CCD camera (ORCA-R2, Hamamatsu) and
213 standard filter sets for DAPI ($\lambda_{\text{ex}}/\lambda_{\text{em}} = 342/450$ nm), AlexaFluor488 ($\lambda_{\text{ex}}/\lambda_{\text{em}} = 488$ nm/519 nm),
214 and Texas Red-X ($\lambda_{\text{ex}}/\lambda_{\text{em}} = 595/615$ nm). The image pixels were squares and their side length
215 was measured to be 0.064 μm . The limit of resolution based on the N.A. of the objective lens in

216 the Alexa 488 channel is 0.2 μm (Rayleigh limit). Images were captured so that intensities for a
217 given experiment were within the 12-bit linear range. In order to capture all nuclei in full, the
218 images were acquired with an overlap of 15% between fields. For each channel, images were
219 acquired as five z-stack images with step size of 0.25 μm between planes (one at the focal plane
220 and four around). The images of the 3D stack were projected to 2D xy-images using maximum
221 intensity projection.

222

223 **Automated image analysis**

224 The collected images were analyzed using the Olympus Scan[®] analysis software with edge
225 segmentation algorithm that allows the simultaneous detection of nuclei (objects), 53BP1, and γ -
226 H2AX foci (sub-objects) stained with different fluorescent probes. Nuclei and foci were
227 identified using defining parameters such as intensity threshold for recognition, minimum and
228 maximum object dimensions on a few example images and keeping the parameters constant for
229 the entire set of images for a specific slide. Nuclei on the border were excluded from the analysis
230 and duplicate nuclei due to overlap of 15% between images were suppressed. Automated image
231 analysis enabled the efficient measurement of numerous topological parameters on foci and
232 nuclei such as area, shape (i.e. circularity factor, elongation factor, etc.), integrated and mean
233 intensity of DAPI, Alexa Fluor[®] 488 and Texas Red[®]-X, and relative positions in images and
234 slides on the whole population of nuclei (~4,000 cells) exposed to the same irradiation condition.
235 Data generated were plotted in two-dimensional dot plots and a first selection was made based on
236 nucleus area and circularities which permits objects corresponding to clusters of nuclei and
237 cellular debris to be removed from the analysis and for only isolated nuclei to be extracted (28).
238 To eliminate complications in the interpretation of the results that arise from changes in

239 responses to ionizing radiation at different phases of the cell cycle (34), non-divided cells were
240 selected. As the γ -H2AX foci background is higher in cell nuclei in divisions (S, G2, and
241 metaphase) associated with DNA replication (35), non-replicating cells were discriminated from
242 S-phase cells on the basis of integrated intensities of DAPI (DNA content) and Alexa Fluor® 488
243 (associated to γ -H2AX foci) of each object (28). Using this representation, a subpopulation of
244 nuclei with low levels of integrated intensity of DAPI and Alexa Fluor® 488 can be sequentially
245 separated not only in non-irradiated condition but also in irradiated condition (28). This allowed
246 the selection of a well-defined population of nuclei mainly in G₀/G₁ phase of the cell cycle that
247 correspond to approximately 1,500 to 3,000 cell nuclei per dish.

248

249 **Simulation using Matlab**

250 In this work, each cell nucleus of a population was targeted with the same pattern of irradiation.
251 However, the real size of each nucleus together with microbeam characteristics such as beam size
252 or detection thresholds and noise events in the particle counter could deviate from the square
253 shape of the pattern and reduce the real number of particles reaching the particular nucleus.
254 Following Hoechst staining, some cell nuclei were not detected and this ratio was estimated at
255 2% of the cell nuclei population by comparison of cell nuclei images as obtained during cell
256 nuclei detection before irradiation and after DAPI staining. To estimate how features can affect
257 the real number of hits and their localization in cell nuclei, calculations were undertaken using
258 Matlab R2010b.

259

260 **Morphology of cell nuclei**

261 As the pattern is fixed, the morphology (size and orientation) of cell nuclei vary from one to the
262 other and could have an impact on the number of particles hitting each cell nucleus in different
263 replicate experiments. To adapt our script closer to reality, for each dish, each nucleus of the cell
264 population was simulated as an ellipse considering their specific major and minor axes and their
265 orientation (Supplementary Figures 1A and 2A-B) determined during image analysis and after
266 fixation and staining with DAPI. Nuclear size varies with the equivalent major ellipse axis
267 ranging between 13.7 and 23.8 μm and equivalent minor ellipse axis ranging between 9.2 and
268 16.0 μm whereas the nuclei area ranges between 103.2 and 277.6 μm^2 (Supplementary Fig. 3).
269 The mean values \pm SD were, respectively, (18.3 \pm 1.4) μm , (12.2 \pm 0.9) μm , and
270 (175.9 \pm 21.5) μm^2 . The cell nuclei thickness was estimated using a confocal microscope on the
271 same dishes used for the experiments as (2.4 \pm 0.2) μm (SD).

272

273 **Validation of the chosen irradiation pattern size**

274 The beam parameters combined with the measured size and orientation of each cell nucleus and
275 the size of the irradiation pattern allow a corrected number of ionizing particles reaching each cell
276 nucleus to be assessed. Indeed, although the irradiation pattern is fixed, the coordinates of each
277 particle hit of the irradiation pattern with respect to the nominal position had a Gaussian
278 distribution along the x- ($\mu = 0$, $\sigma_1 = d_1/2.355$) and y- ($\mu = 0$, $\sigma_2 = d_2/2.355$) axes
279 (Supplementary Fig. 1).

280 We attempted to minimize both the risk of missing a cell nucleus and the probability that two
281 particles hit a given nucleus at less than 2 μm from each other. Indeed, two particle hits too close
282 may lead to one big focus instead of two distinct foci. Supplementary Fig. 4, obtained by

283 simulation based on all size of cell nuclei analyzed during experiments, illustrates the relation
284 between these phenomena for each dish studied (n=14). The likelihood of getting two particle
285 hits at a distance of less than 2 μm from one another within a given nucleus (red curves) and the
286 likelihood of cell nuclei being reached by less than five particle hits (blue curves) were calculated
287 as a percentage for different side lengths of the square irradiation pattern taking into account the
288 real size of each cell nuclei analyzed. The more the size of the pattern increases, the greater the
289 probability that the ion misses the cell nucleus, and the lower the probability that two particles hit
290 a nucleus with a distance of less than 2 μm from one another. Therefore, a value of 4 μm side of
291 the irradiation pattern, as used in our experiments, is an optimum compromise that allows a
292 maximum number of cells hit by exactly five particle trajectories to be obtained while limiting
293 the probability of getting two particle hits within 2 μm of one another to around 20%. Despite the
294 optimization of these two parameters, both have to be considered in order to calculate the
295 probabilities of 53BP1 or γ -H2AX foci formation as a function of the LET of radiation.

296

297 **Statistics**

298 Part of the data was represented as relative frequency distributions of the number of
299 53BP1 or γ -H2AX foci per nucleus (Fig. 2 and 4 and Supplementary Fig. 5). To take into account
300 the inter-dish variability and to increase the statistical power of the analysis, data were pooled.
301 The mean number of foci per nucleus (m) was calculated on pooled data and associated with the
302 standard deviation (SD) computed as the square root of the variance of the given pooled
303 distribution. A two-sample Kolmogorov-Smirnov test was performed to compare the distributions
304 of the number of foci (γ -H2AX and 53BP1) per nucleus between control and sham-treated
305 samples. It is a non-parametric test with no hypothesis on the form of the distribution (36).

306 The other part of the data was represented as relative frequencies of at least one focus
307 formation along a particle track traversal (Fig. 5). Considering raw data (Fig. 5A and B), the
308 means are the means of pooled data with the standard deviation associated. In Fig. 5C and D, the
309 means and bar errors represent the mean and the standard error obtained after a Monte Carlo
310 maximum likelihood optimization as proposed by Stram and Kopecky (37) in which the
311 parameter estimation and the corresponding inference is derived through Poisson likelihood
312 function integrated over the 525 corrected raw data simulations.

313

314 **Probabilities**

315 The relative frequencies of at least one radiation-induced focus formation per particle track
316 traversing the cell nucleus depend on the cell nucleus thickness. In the biological experiments,
317 the average cell nucleus thickness was 2.4 μm , whereas in the simulations a thickness of 2 μm
318 was considered. Therefore, it was necessary to derive a relation between the probabilities for the
319 formation of at least one observable focus along particle tracks of different lengths. Let's denote
320 by Δp the probability that a focus forms when the particle traverses a distance Δd and suppose
321 that Δp is independent of what happened before according to the Markov process referring to the
322 memoryless property of the process. Furthermore, the hypotheses were made that the DNA
323 density as well as the particle's LET are stationary along the particle track. Then, if n consecutive
324 path segments of length Δd forming a total path length of $n \times \Delta d$ are considered, for each of them
325 the probability of foci formation is equal to Δp and the number of segments in which foci
326 formation occurs would have a binomial probability distribution. The probability that in all of the
327 n path segments no foci is formed is then $(1-\Delta p)^n = (1-\Delta p)^{d/\Delta d}$. The expression $(1-\Delta p)^{d/\Delta d}$ can also
328 be used for the probability that there are no foci along a path length d if d is not an integer

329 multiple of Δd . The probability of detecting at least one focus when the particle travels a distance
330 d is then $p_d = 1 - (1 - \Delta p)^{d/\Delta d}$, which can be solved to give $\Delta p = 1 - (1 - p_d)^{\frac{\Delta d}{d}}$. Thus, if two
331 different path lengths d_1 and d_2 are considered, the conversion between the two probabilities is
332 given by $p_{d_2} = 1 - (1 - p_{d_1})^{\frac{d_2}{d_1}}$.

333

334 **Monte Carlo simulation**

335 A full simulation chain presented in detail in (38) was used in this work in order to simulate the
336 DNA damage generated either by direct or indirect effects. In this simulation, three important
337 aspects can be distinguished: the target description, the simulation of the physical interactions
338 leading to direct DNA damage, and the chemical interactions leading to indirect DNA damage.

339 **Target description**

340 The target in the simulation consisted of a unique cell nucleus phantom representing the mean
341 shape and dimensions of the endothelium cell nucleus irradiated in this work: a cylinder with an
342 elliptical base of major semi-axis $a = 9.5 \mu\text{m}$, minor semi-axis $b = 5.5 \mu\text{m}$, and $2 \mu\text{m}$ height.
343 These geometrical parameters were taken from a previous biological experimental measurement
344 with endothelium cells grown in a different foil than the one used in the microbeam experiments.
345 This phantom was then filled with the whole genome of a eukaryotic cell ($\sim 6 \text{ Gbp}$) that was built
346 using the DNAFabric tool (39). This geometrical DNA description takes into account the
347 complex organization of the chromatin at different scales as described in (38) and can be seen in
348 Supplementary Fig. 7. Briefly, the $\sim 6 \text{ Gbp}$ of the genome were distributed in spherical regions
349 representing chromatin domains containing $\sim 1 \text{ Mbp}$ that are placed homogeneously within the
350 cell nucleus phantom in order to simulate cells in the G_0/G_1 phase of the cell cycle. Each of these

351 chromatin domains was filled with voxels containing a geometrical representation of the
352 chromatin fiber of helicoidal shape. There are five different types of voxels that can be combined
353 in order to form chromatin loops within the domains. The chromatin fiber itself is formed by
354 nucleosomes placed helicoidally, each of them composed of a sphere representing the histone
355 proteins and surrounded by two turns of the DNA double helix. Eventually, the DNA double
356 helix is described at molecular scale, where each of the molecules of a nucleotide (sugar,
357 phosphate, or base) is represented by a sphere whose volume is equal to the real molecular
358 volume. In this target geometrical model, the nucleosomes in the chromatin fiber are linked
359 forming a continuous DNA double helix for a given chromosome territory (group of chromatin
360 domains).

361 **Simulation of the physical stage**

362 This target geometry built with DNAFabric software was then exported to the simulation chain,
363 which uses a slightly modified version of Geant4-DNA (Geant4 V10.01) (40, 41) for simulating
364 both the physical and chemical interactions after the passage of the protons or α particles through
365 the cell nuclei.

366 In the Monte Carlo simulation of the physical stage, the default processes and models were used
367 in this version of Geant4-DNA. These processes allow the transport of secondary electrons on
368 liquid water down to a few eV (~ 7 eV) on an event-by-event basis and thus the track structure at
369 nanometric scale of the ionizing radiation can be obtained. Nevertheless, they use physical
370 models based on liquid water cross sections in order to calculate the type of interaction (elastic,
371 ionization, and excitation) and the amount of energy that is deposited at each of the track
372 interaction points. Thus, in this simulation, all the volumes in the target geometries were

373 considered to be composed of liquid water, the interaction cross sections of which are generally
374 believed to be a good approximation for those of biological materials.

375 All the inelastic interactions leading to an energy deposition within the DNA volumes (sugar,
376 phosphate, base, and hydration shell) were recorded to be analyzed afterwards and to calculate
377 the number of direct damages as proposed in (38). Indeed, in this work, we considered that a
378 direct strand break (SB_{dir}) was created if the amount of energy deposited by the physical
379 interactions in the backbone region of one nucleotide (sugar + phosphate + hydration shell)
380 exceeds 17.5 eV.

381 **The simulation of the chemical stage**

382 Physical interactions between the ionizing irradiation and the water molecules surrounding the
383 DNA lead to water radiolysis and thus to the generation of water-derived radicals and solvated
384 electrons that diffuse and react chemically between themselves but also with the DNA
385 constituents. Some of these chemical reactions can then break the backbone and generate indirect
386 strand breaks (SB_{ind}). In this work, the processes and models implemented in the Geant4-DNA
387 V10.01 were used for simulating the water radiolysis and the radicals' diffusion and reactions. As
388 explained in (38), new chemical reactions were included in the simulations in order to take into
389 account the interactions between the radicals and the DNA constituents. Scavenging processes
390 were taken into account by two methods. Firstly a specific reaction between histones (represented
391 by a sphere of 2.4 nm radius) and all type of water radicals was included. In this reaction the
392 water radical is absorbed and the histone remains unchanged, thus simulating the histone
393 scavenging capacity. Nevertheless, in order to better simulate the whole contribution of
394 scavengers pertaining to other radicals, other parameters are used in the calculation chain:
395 chemical reactions are constrained in each voxel, i.e., chemical species cannot diffuse over the

396 voxel dimensions (50 nm length), and the chemical stage simulation is stopped 2.5 ns after the
397 end of the physical stage. Finally, for the determination of indirect damage, it was considered that
398 40% of the reactions between the OH° radical and the phosphate molecules led to an induced
399 strand break.

400 **Clustering algorithm and statistical uncertainties**

401 The locations in the DNA geometrical model of the direct and the indirect strand breaks were
402 registered during the simulation for each track. The DBSCAN algorithm (42) was used in order
403 to detect the damage clusters: a DSB damage cluster was defined when at least two SBs were
404 located at a distance lower than 10 bp in the geometry and on opposite strands. Finally, the initial
405 sets of clusters were also analyzed in order to determine whether they can be associated with each
406 other and merged into a larger cluster. As a result of this simulation, we obtained a number of
407 DSB clusters per track that can have different complexities, meaning a different number of SBs
408 involved in the DSB clusters with a minimum of two SBs.

409 The simulations were performed using only one cell nucleus phantom traversed by 1 000
410 particles per energy. The required calculation time for the 1,000 tracks depends on the ionizing
411 radiation LET, and for high LET values it could be as long as three weeks. The resulting
412 statistical uncertainty (SEM) on the mean number of DSBs per 2 μm track is always lower than
413 5%. Finally, in order to calculate the number of foci that the DSBs could produce in the x-y
414 plane, the hypothesis was done by considering that all individual DSBs along the track could lead
415 to a focus. Therefore, if at least one DSB was formed along the track, whatever its z-coordinate
416 is, the probability of observing a foci in the x-y plane was equal to 1. In figure 7, the three curves
417 corresponding to the simulated results use this hypothesis but they change the complexity of the

418 DSBs that are taken into account in order to be considered as a potential focus (DSBs with at
419 least two, three, or four SBs).

420

421 **Results**

422 **Raw distribution of the number of 53BP1 and γ -H2AX foci in HUVEC cultures wherein** 423 **each cell nucleus was targeted by 5 ions**

424 **Context**

425 To study the interaction between a charged hadronic particle and DNA, we examined γ -
426 H2AX and 53BP1 radiation-induced foci (RIF) formation *in situ* on a cell-by-cell basis and on a
427 large number of human umbilical vein endothelial cells (HUVEC). As described previously (28),
428 cells in G₀/G₁ were analyzed in order to eliminate potential interpretation issues due to the
429 amount of DNA and/or interference from cellular responses to ionizing radiation at other phases
430 of the cell cycle (34). Monolayers of primary HUVEC were irradiated perpendicularly with
431 single ionizing particles at an ion microbeam that deposits energy along their track (Fig. 1A).
432 Ionizing interactions in the cell nucleus lead to the formation of DNA double-strand breaks
433 (DSBs) and the ensuing formation of foci (Fig. 1B). The number of produced foci depends on the
434 radiation quality and the cell nuclei thickness which was estimated using confocal microscopy on
435 the same dishes as used for the experiments and gave a mean thickness of $2.4 \pm 0.2 \mu\text{m}$ (SD).

436 The radiation-induced 53BP1 or γ -H2AX foci in cells were detected *in situ* using a
437 combination of a high-speed microscopy platform and automated image analysis. Images from
438 multiple z-planes were acquired and then analyzed as collapsed maximum intensity projections

439 for improving the signal-to-noise ratio (43) when quantifying foci on the whole population of cell
440 nuclei exposed to the same irradiation condition (Fig. 1C). The aim was to obtain the relative
441 frequency of presence (or absence) of radiation-induced foci following one particle traversal
442 within a typical endothelial cell nucleus of 2.4 μm mean thickness as a function of particle LET.

443

444 **Characterization of 53BP1 and γ -H2AX foci background**

445 Prior to irradiation, cell nuclei were stained with Hoechst-33342 dye and then scanned in
446 order to be identified. This step may induce an increase in the 53BP1 and γ -H2AX signal that is
447 independent of the irradiation. Therefore, additional cell samples that received no radiation were
448 treated in parallel with irradiated dishes to evaluate 53BP1 and γ -H2AX foci background. Parts of
449 them were sham-treated as they were subjected to cell nuclei recognition (using Hoechst-33342
450 staining), whereas other cell cultures were considered as controls.

451 In control and sham-treated samples, a significant number of cells also harbored foci, the
452 frequencies of which slightly fluctuated between experiments. In Fig. 2, the data are represented
453 as distributions of the number of 53BP1 or γ -H2AX foci per nucleus for the five and seven
454 replicate experiments related, respectively, to control (Panel A) and sham-treated dishes (Panel
455 B). For each background estimation experiment, between 427 and 3,793 cell nuclei in G_0/G_1
456 phase of the cell cycle were evaluated. To take into account the inter-dish variability, graphically
457 viewable in Fig. 2A and 2B, and to increase the statistical power of the analysis, data were
458 pooled. It reached a total of 8,132 and 15,236 cell nuclei for control and sham-irradiated samples,
459 respectively. For both, 53BP1 or γ -H2AX, the distributions of the number of foci per nucleus are
460 significantly different between control and sham-treated samples ($p < 0.0001$). The mean number
461 of 53BP1 foci per nucleus \pm SD of control samples was 0.24 ± 0.67 while it reached 0.50 ± 0.86

462 for sham-treated samples (Fig. 2C). The percentage of cell nuclei without any 53BP1 focus
463 decreased from 83.5% for control to 65.4% for sham data while the percentage of cell nuclei with
464 at least one focus doubled going from 16.5% to 34.6%. Similarly, the mean number of γ -H2AX
465 foci per nucleus \pm SD doubled from 0.09 ± 0.48 to 0.21 ± 0.72 between control and sham-treated
466 samples and the percentage of cell nuclei with at least one γ -H2AX focus increased from 5.1%
467 for control samples to 13.2% for sham-treated samples. Thus, the protocol of cell nuclei
468 recognition induces an increase of the number of cell nuclei harboring 53BP1 and γ -H2AX foci
469 in sham samples compared with control samples (Fig. 2C). It may be explained by the interaction
470 between Hoechst-33342 stain and photons in the 385–405 nm wavelength range exposure during
471 cell nuclei recognition, which has been reported to induce DNA damage (44-46). Consequently,
472 to obtain a number of radiation-induced 53BP1 or γ -H2AX foci per cell nucleus significantly
473 higher than the sham background, we performed experiments based on five particle traversals per
474 cell nucleus where the different ions were targeted at different positions in the cell nucleus.

475
476 **Distribution of the number of 53BP1 and γ -H2AX foci in HUVEC cell cultures wherein**
477 **each cell nucleus was targeted by five projectiles as a function of particle type and LET**

478 We examined 53BP1 and γ -H2AX foci *in situ*, in HUVEC cell cultures, fixed at 10 or
479 30 min after exposure to 1.86, 5.5, or 17.8 MeV α particles with respective LET values in the
480 center of the cell nuclei of about $170 \text{ keV}\cdot\mu\text{m}^{-1}$, $85 \text{ keV}\cdot\mu\text{m}^{-1}$, and $36 \text{ keV}\cdot\mu\text{m}^{-1}$ and also to
481 1.6 MeV protons (LET $\sim 19 \text{ keV}\cdot\mu\text{m}^{-1}$). Each cell nucleus was targeted by five particles according
482 to a cross pattern with the four outer target points located on a square of $4 \mu\text{m}$ side length and the
483 middle one aimed at the barycenter of the cell nucleus (Fig. 3A). In Fig. 3B, 53BP1 (Panel B-2)
484 and γ -H2AX (Panel B-3) foci formation in a primary HUVEC cell nucleus (DAPI staining, Panel

485 B-1) after exposure to 17.8 MeV α particles reveals the irradiation pattern. The merged Fig. 3B
486 (Panel B-4) shows a good superimposition of 53BP1 and γ H2AX foci. However, despite the
487 theoretical five particle hits per nucleus, the number of foci observed per cell is not constant from
488 one nucleus to another.

489 Distributions of the number of 53BP1 and γ -H2AX foci per nucleus were evaluated at 10
490 or 30 minutes after exposure to 1.6 MeV protons or 17.8 MeV, 5.5 MeV, or 1.86 MeV α particles
491 (Fig. 4). 53BP1 foci distributions are similar for the two fixation times studied, either after
492 irradiation to 1.6 MeV protons (LET $\sim 19 \text{ keV}\cdot\mu\text{m}^{-1}$) or 5.5 MeV α particles (LET $\sim 85 \text{ keV}\cdot\mu\text{m}^{-1}$)
493 (Supplementary Fig. 5). Likewise, the results for DNA damage marker γ -H2AX follow the same
494 propensity. As the two post-irradiation times tested (10 or 30 min) do not have any influence on
495 the foci number distribution, only one time point for each condition of irradiation was considered
496 in the further analysis. While theoretically five ionizing particles have reached each cell nucleus,
497 the observed number of 53BP1 or γ -H2AX foci per nucleus can spread from 0 up to 10 and
498 depends on the respective radiation quality used (Fig. 4).

499 Nonetheless, as previously indicated, our results showed a 53BP1 and γ -H2AX foci
500 background (Fig. 2) that is not negligible and interferes, inevitably, with the observed results after
501 exposure to ionizing particles. Moreover, the original irradiation pattern may have been distorted
502 due to physical characteristics of the microbeam, such as detection system and beam size at the
503 level of the cell culture, which, related to the size and orientation of cell nuclei, may lead to
504 variation in the number of particle traversals per cell nucleus. It also has to be considered that two
505 particle hits too close to each other may lead to one big focus instead of two distinct observable
506 foci due to the limit of resolution based on the numerical aperture (N.A.) of the objective lens
507 used in the microscope.

508 The measured distributions of number of detected foci were converted to relative
509 frequencies of radiation-induced 53BP1 or γ -H2AX foci per particle track as a function of the
510 radiation's LET taking into account all these factors biasing the experimental results.

511
512 **Evaluation of relative frequencies of at least one 53BP1 or γ -H2AX focus formation**
513 **following a particle traversal as a function of radiation's LET**

514 In order to evaluate relative frequencies of at least one interaction between an ionizing
515 particle and DNA along its track in nucleus thickness leading to 53BP1 or γ -H2AX foci
516 appearance, it is necessary to calculate, for each cell monolayer, the ratio by dividing the number
517 of appearing foci by the total number of particles emitted. However, corrections, applied on the
518 numerator and denominator of the ratio, allow us to apprehend the impact of different factors
519 mentioned above.

520 First of all, the relative frequencies of at least one focus formation per primary particle
521 track traversing 2.4 μm thickness of endothelial cell nucleus were determined based on raw data:

522
$$\frac{\text{raw nb of foci}}{5 \text{ ionizing particles} \times \text{nb of cell nuclei}} \quad (\text{eq. 1})$$

523 The relative frequencies of at least one focus formation per particle track based on raw
524 data are plotted in Fig. 5A and 5B as a function of the LET of protons (circles) and α particles
525 (diamonds) for each replicate experiment (open symbols) as well as the mean of all replications
526 for each irradiation condition (closed symbols) for, respectively, 53BP1 (Panel A) and γ -H2AX
527 (Panel B).

528 Secondly, as indicated above, for sham-treated samples subjected to cell nuclei
529 recognition, around a third of cell nuclei present at least one 53BP1 focus whereas ~10% present
530 at least one γ -H2AX focus (Fig. 2C). Thus, to remove foci background and consider only
531 *radiation-induced foci*, we applied (eq. 2)

$$532 \quad \frac{\text{raw nb of foci} - \text{background nb of foci}}{5 \text{ ionizing particles} \times \text{nb of cell nuclei}} \quad (\text{eq. 2})$$

533 where the background number of foci was generated by random sampling based on the
534 distribution of pooled sham data.

535 Third, the interplay of physical characteristics of the microbeam, the cell's morphology,
536 and the choice of the irradiation pattern, together with the detection threshold and noise events in
537 the particle counter (as described in the materials and methods section), may affect the hit
538 distribution per cell nucleus. To account for these factors, we simulated, for each nucleus of each
539 replicate experiment, the microbeam irradiation sampling the ion-hit coordinates from the
540 mentioned Gaussian distributions. Examples of graphic outputs of the sampling of hit patterns in
541 different cell nuclei are shown in Supplementary Fig. 2. Although each cell nucleus theoretically
542 should have received five particles according to the cross pattern, the number of traversing
543 particles may vary slightly from one nucleus to another depending on the irradiation
544 characteristics and cell nuclei geometry.

545 Table 2 reports in the fourth column the theoretical number of particles emitted from the
546 microbeam (number of cell nuclei times five ionizing particles per nucleus) and in the fifth
547 column the mean assessed number of particle hits in cell nuclei for each sample of each
548 irradiation condition. On average, around 98% of the emitted particles hit their target (cell
549 nuclei), and ~90% of the cell nuclei received five hits while the remaining cell nuclei (~10%)

550 were reached by mainly four or six particles. Therefore, the denominator of (eq. 2) was adjusted
551 by an *estimated number of particle hits in the cell nuclei* such as in (eq. 3):

$$552 \quad \frac{\text{raw nb of foci} - \text{background nb of foci}}{\text{estimated nb of particle hits in the cell nuclei}} \quad (\text{eq. 3})$$

553 The relative frequency estimators of at least one 53BP1 or γ -H2AX focus formation per
554 particle track (\pm SE) based on raw data (purple symbols), taking into account sham background
555 (green symbols) and combined with the accurate number of particles (orange symbols), were
556 plotted in Fig. 5C and 5D. Although the general evolution of adjusted results versus LET is
557 similar to estimators of the relative frequencies of at least one focus formation per particle track
558 based on raw data (purple symbols), they follow a downward trend (green and orange markers).
559 However, the corrections linked to real numbers of particles do not affect the results significantly
560 (orange markers compared to green markers). The slight uncertainty in the number of ionizing
561 particles reaching cell nuclei (Table 2) induces a slight increase in the estimation of relative
562 frequencies (Fig. 5C and 5D).

563 Fourth, another correction factor taken into account in the analysis of the microbeam
564 experiment results is the fact that two particle hits reaching a given cell nucleus at a distance less
565 than 2 μm from each other may form *two* foci not distinguishable and analyzed as *one* focus
566 formation. For a given size of the irradiation pattern, the occurrence of this phenomenon depends
567 on the size of the particle beam, the number of particles that reach the cell nucleus, *and the*
568 *relative frequencies of at least one focus formation per particle traversal itself* (that needs to be
569 corrected). Therefore, using the simulated coordinates of each particle traversal calculated during
570 the previous process of irradiation pattern reconstruction (as described in Supplementary Fig.1
571 and 2C), we simulated an artificial focus formation. This was performed by a Bernoulli schema

572 with success (conversion of a particle track into an artificial focus) probability increasing
573 iteratively from 0 to 1 by steps of 0.05. For a given probability of conversion, a set of artificial
574 foci was generated and pairs of foci located less than 2 μm apart from each other were combined
575 into one observable focus. Thus, we obtained a relation between relative frequencies of
576 supposedly observable foci and the underlying particles interacting at least once with DNA along
577 the particle track in the nucleus' thickness (Fig. 6). As this relation depends on the initial
578 irradiation characteristics (beam size and cell morphology), the relation was established for each
579 replicate experiment of each irradiation condition. Using those relations, we converted the
580 observed relative frequencies of at least one focus formation per particle traversal obtained by
581 (eq. 3) (orange curve in Fig. 5C and D) in the final estimate of relative frequencies of at least one
582 focus formation per particle traversal (red curve in Fig. 5C and D). Hence, the red curves of
583 Fig. 5C and D represent the most accurate estimates of relative frequencies of at least one
584 radiation-induced 53BP1 and γ -H2AX focus formation as a function of the particle LET when
585 traversing 2.4 μm thickness of an endothelial cell nucleus.

586 As the LET increases from about 19 $\text{keV}\cdot\mu\text{m}^{-1}$ for 1.6 MeV protons up to 36 $\text{keV}\cdot\mu\text{m}^{-1}$
587 and to 85 $\text{keV}\cdot\mu\text{m}^{-1}$ for, respectively, 17.8 and 5.5 MeV α particles, the estimated relative
588 frequency of at least one radiation-induced 53BP1 focus formation per particle track (\pm SE)
589 (Fig. 5C, red curve) increase progressively and significantly from 0.23 ± 0.03 up to 0.40 ± 0.01
590 and to 0.70 ± 0.02 53BP1 foci per particle hit. Beyond this value for the LET (85 $\text{keV}\cdot\mu\text{m}^{-1}$), the
591 relative frequency seems to reach a plateau with 0.66 ± 0.09 53BP1 foci per particle hit traversing
592 2.4 μm thickness of endothelial nucleus after exposure to 1.86 MeV α particles (170 $\text{keV}\cdot\mu\text{m}^{-1}$)
593 (Fig. 5C, red curve). Concerning γ -H2AX foci formation (Fig. 5D, red curve), although the
594 estimate of relative frequencies of at least one γ -H2AX focus formation per particle track (\pm SE)

595 follows the same increasing trend from 0.22 ± 0.04 for 1.6 MeV protons ($19 \text{ keV} \cdot \mu\text{m}^{-1}$) reaching
596 0.69 ± 0.04 for 1.86 MeV α particles ($170 \text{ keV} \cdot \mu\text{m}^{-1}$), the slope is less pronounced. Besides,
597 concerning γ -H2AX foci formation, the values are not significantly different between 1.6 MeV
598 protons ($19 \text{ keV} \cdot \mu\text{m}^{-1}$) and 17.8 MeV α particles ($36 \text{ keV} \cdot \mu\text{m}^{-1}$).

599 Considering α particle exposure, convergence of relative frequencies of at least one
600 53BP1 focus formation per particle track after exposure to 5.5 and 1.86 MeV α particles with
601 respective LETs in the nucleus of 85 and $170 \text{ keV} \cdot \mu\text{m}^{-1}$ is noticeable. This suggests that, for the
602 same type of particle with high LETs (85 and $170 \text{ keV} \cdot \mu\text{m}^{-1}$), the probability that an interaction
603 occurs between particle and DNA leading to detectable DNA damage (53BP1 or γ -H2AX focus
604 formation) is similar and is evaluated as ~ 0.65 . As a result, in 35% of cases, high LET α particles
605 do not induce DNA damage leading to 53BP1 foci formation.

606 As explained in the introduction, these biological data were compared with results
607 obtained by Monte Carlo simulations, modeling the ionizing particle interactions on a virtual
608 phantom of the $2 \mu\text{m}$ -thick cell nucleus filled with a DNA geometrical model in the G_0/G_1 phase.
609 However, subsequently, the cell nuclei thickness was estimated using a confocal microscope on
610 the same dishes used for the experiments as $(2.4 \pm 0.2) \mu\text{m}$ (SD). Accordingly, for the sake of
611 comparison to the simulations, the biological relative frequencies of at least one focus formation
612 following a particle traversal were, beforehand, converted to the probability per $2 \mu\text{m}$ path length
613 using a relation based on Markov property with the quantity of DNA traversed and LETs of the
614 particle constant as explained in the materials and methods section. As Fig. 7 shows (light and
615 dark grey for, respectively, 53BP1 and γ -H2AX foci formation), in doing so, all the frequency
616 values were reduced. However, the trend of the curves of converted data as a function of the LET
617 of the primary particle is similar to those of the experimental results.

618

619 ***In silico* estimate of probability of at least one radiation-induced focus formation per**
620 **particle track traversing the endothelial cell nucleus and comparison with biological results**

621 Simulation of particle interactions with DNA

622 The individual energy depositions originated from the projectile (proton or α particle) or
623 the secondary electrons were simulated using the Monte Carlo code Geant4-DNA. This
624 simulation allows the calculation of the physical and chemical interactions that can damage the
625 DNA target (direct and indirect effects, respectively). In particular, we simulated DNA DSB
626 clusters that are related to foci appearance. These are generated by the interaction between initial
627 energy depositions caused by ionizing radiation and the cell target as explained in the materials
628 and methods section and in (38). From the estimated values of DSB clusters produced along
629 particle tracks traversing the cell nucleus, a 2D projection allowed simulated foci to be obtained
630 that can be related to what is observable with microscopy methodology used in biological
631 experiments (Fig. 1). It is worth noting that, in this work, the hypothesis was made that each
632 simulated DSB cluster along the track is converted into a detectable focus. Nevertheless, and as
633 explained in the materials and methods section, the definition of the cluster damage that could
634 lead to a focus was studied and changed from all DSB clusters (at least two strand breaks with
635 one in an opposite strand to the others) to more complex DSB clusters (at least three or four
636 strands breaks contained in the clustered damage).

637 From this consideration, relative frequencies based on Monte Carlo simulation of at least one
638 focus formation were estimated for 0.5, 1, 10, or 20 MeV protons or 1.66, 5.27, or 17.39 MeV
639 α particles and plotted (blue, green and red lines) as a function of the LET of the primary protons

640 (circles) or α particles (diamonds) (Fig. 7). The choice of the α particle's energy in the simulation
641 was chosen to approach the estimated LET of the α particles at the cell center position in the
642 microbeam experiment. The additional protons' energies were also interesting to appreciate the
643 evolution of the simulation at lower LET.

644 Comparable to corrected biological data (light and dark grey for 53BP1 and γ -H2AX foci
645 formation, respectively), the simulated relative frequencies of at least one radiation-induced focus
646 formation per particle track (Fig. 7, blue, green and red lines) increase gradually. Considering
647 DSB clusters induced by at least two breaks in opposite strands (Fig. 7, blue line), the values rise
648 from 0.058 (corresponding to LET $\sim 2.7 \text{ keV}\cdot\mu\text{m}^{-1}$ for 20 MeV protons) up to 0.9 foci per particle
649 track (corresponding to LET $\sim 83 \text{ keV}\cdot\mu\text{m}^{-1}$ for 5.27 MeV α particles). At about a LET value of
650 $\sim 80 \text{ keV}\cdot\mu\text{m}^{-1}$, the curve seems to reach a plateau with simulated relative frequencies of ~ 0.9 foci
651 per particle hit traversing. Although the simulated relative frequencies follow the same tendency
652 of the corrected biological data (grey curves), this simulation (blue line) overestimates the
653 relative frequencies of experimental foci, whereas the simulation taking into consideration at least
654 four strand breaks to induce a DSB cluster underestimates the relative frequency except for the
655 last point (5.27 MeV α particles, LET $\sim 83 \text{ keV}\cdot\mu\text{m}^{-1}$). Moreover, the quasi-plateau found in the
656 simulated data (blue line) corresponds to a probability of at least one focus formation within a
657 track hitting the cell nucleus of ~ 1 within the statistical uncertainty and not to a saturation of the
658 DNA damage value. Indeed, the mean number of simulated DSB clusters along the track
659 increases with the LET of the incident particle going from 6.6 to 18.3 for, respectively, 5.27 MeV
660 (LET $\sim 83 \text{ keV}\cdot\mu\text{m}^{-1}$) and 1.66 MeV (LET $\sim 193 \text{ keV}\cdot\mu\text{m}^{-1}$) α particles. Therefore, we can
661 conclude that the probability of having at least one focus along a $2 \mu\text{m}$ track traversing the cell

662 nucleus is already ~ 1 for α particles of 5.27 MeV (LET $\sim 83 \text{ keV}\cdot\mu\text{m}^{-1}$) and thus, still 1 for
663 1.66 MeV α particles (LET $\sim 193 \text{ keV}\cdot\mu\text{m}^{-1}$).

664 **Discussion**

665 Computational modeling allows the simulation and the study of the behavior of complex
666 systems containing numerous variables that characterize the system being studied. As with all
667 computational models, multi-scale approaches of energy deposition of ionizing particles must be
668 rigorously tested against relevant biological data for proper validation prior to use as
669 experimental constructs (47). Indeed, the multi-scale code developed and applied here should
670 give information on how energy is deposited along the track of an ionizing particle and allow the
671 biological effects to be predicted. The relation between the topology of energy deposition and the
672 initial biological events (mainly DNA damage) is the first step in this process. Here, we provide
673 sets of dedicated biological experiments that are compared to results of track structure Monte
674 Carlo simulations using the Geant4-DNA multiparticle transport code.

675 When DNA is exposed to DNA-damaging agents, a **plethora** of damage-sensing and
676 repair proteins localize at the site of DNA damage. Here, we used the formation of 53BP1 and γ -
677 H2AX foci as a biomarker of DNA double-strands breaks (24, 48) to investigate radiation-
678 induced damage per particle track in primary human endothelial cell (HUVEC) cultures after
679 exposure to 1.6 MeV protons or to 1.86, 5.5, or 17.8 MeV α particles using the microbeam
680 facility at the PTB. Due to the orthogonal configuration of the irradiation, 53BP1 and γ -H2AX
681 foci observed in irradiated cell culture were expected to represent one ionizing particle traversal.

682 To estimate accurately the relative frequencies of at least one focus formation related to a
683 particle traversal, large numbers of cell nuclei were analyzed, and results were represented as a
684 function of the particle LET.

685 Beforehand, it is interesting to highlight the variabilities in control and in sham-treated
686 samples, namely in the number of cells that harbored 53BP1 or γ -H2AX foci which slightly
687 fluctuated between experiments (Fig. 2). First of all, the number of 53BP1 foci per nucleus is
688 higher than the number of γ -H2AX foci per nucleus, both in control and in sham-treated samples.
689 Indeed, it appeared that 53BP1 foci recognition in both control and sham-treated samples was
690 impeded due to basal pan nuclear distribution with some large nuclear “dots”, whereas post-
691 irradiation analysis is more reliable due to protein relocation to the site of DNA damage (49).
692 Conversely, as the selection of cell nuclei in G₀/G₁ phase of cell cycle was based on integrated
693 intensities of DAPI and Alexa Fluor® 488 (28), it may have induced a more stringent
694 discrimination based on γ -H2AX, hence a more robust measure of γ -H2AX foci in control and
695 sham samples compared to the 53BP1 foci measure. However, although the γ -H2AX foci
696 background is lower, the speckled nuclear patterns do not disappear post-irradiation; thus
697 radiation-induced γ -H2AX foci detection is less accurate. Moreover, the increased number of cell
698 nuclei with 53BP1 and γ -H2AX foci in sham samples compared to control samples (Fig. 2C)
699 confirms that pretreatment with Hoechst-33342 enhanced mainly the UV-induced (385–405 nm)
700 γ -H2AX foci formation (44-46). Consequently, in both cases, it is required to take into
701 consideration respective sham-induced foci in the post-irradiation analysis. However, for the
702 analysis of radiation-induced 53BP1 foci, the “cleaning” based on 53BP1 expression in sham-
703 treated samples may have induced the removal of non-specific 53BP1 foci. There is no perfect
704 biomarker, but it is necessary to know the pros and cons of each of them. Therefore, the intrinsic
705 difference between the two biomarker curves should not be interpreted as any difference between

706 53BP1 or γ -H2AX foci formation following ionizing exposure in our experiment (Fig. 5). In this
707 study, we focus on the trend of the relative frequencies of DNA DSBs, induced by ionizing
708 particles with different LET values traversing 2.4 μm thickness of endothelial cell nucleus.

709 Even though the impact of background foci corrections based on sham data is important
710 (Fig. 5, purple to green curve), the uncertainties associated with corrections are small compared
711 to variabilities between replicate experiments on the raw data. The same applies to the
712 uncertainties of adjustments related to physical microbeam characteristics as well as to the
713 correction based on the size and distance between foci.

714 Once all corrections are considered (Fig. 5C and D, red curves), for none of the radiation
715 qualities tested do the relative frequencies of at least one 53BP1 or γ -H2AX focus formation per
716 particle track traversal reach 1. In both cases, the relative frequencies increase with the LET up to
717 $85 \text{ keV} \cdot \mu\text{m}^{-1}$ (5.5 MeV α particles) where a quasi-plateau is observed. At this LET value, ~30–
718 40% of particle hits do not induce DNA damage detected by a 53BP1 or a γ -H2AX focus. In this
719 case, either the primary ionizing particle does not hit any DNA on the 2.4 μm -thick nucleus
720 traversed, or the induced DNA damages does not lead to a 53BP1 or γ -H2AX signal observable
721 10 or 30 minutes post-irradiation or, possibly, with a different kinetic. Considering the first
722 assumption, if the DNA was occupying the cell nucleus evenly (about 2.2% in volume for the
723 endothelial cell nucleus used in our experiments), the generation of DNA damage following
724 ionizing particle traversal would be a certain event. The relative frequencies of at least one
725 53BP1 and γ -H2AX focus per particle track would then be 1. The probability of DNA damage is
726 linked primarily to track structure (i.e. ionization density and core size) in relation to target
727 density (i.e. chromatin structure) (50-53).

728 The trend of relative frequencies of at least one focus formation per particle track
729 traversing a certain thickness of endothelial nucleus is confirmed by the simulation (Fig. 7). From
730 the estimated values of DNA DSBs produced along the particle tracks, a 2D projection allowed a
731 number of simulated foci to be obtained that can be related to what is observable with
732 microscopy.

733 The quasi-plateau observable *in vitro* is also observable *in silico* above a LET of
734 $\sim 80 \text{ keV}\cdot\mu\text{m}^{-1}$. However, as indicated in the results section, this quasi-plateau represents a
735 probability of ~ 1 within the statistical uncertainty as demonstrated by the mean number of
736 simulated DSBs per track that continue to increase between LETs of ~ 83 and $\sim 193 \text{ keV}\cdot\mu\text{m}^{-1}$
737 (6.576 and 18.342 respectively) (Supplementary Table 1). This result is intimately linked to the
738 hypothesis used in the simulation that every calculated DNA DSB leads to a visible focus
739 independent of its complexity or location in the DNA structure. Therefore, we decided to take
740 into consideration this complexity and test if this could be an indicator of foci formation. To do
741 so, we evaluated the probability of foci formation depending on the number of DNA strand
742 breaks (SBs) contained in the clustered damage and we increased from the minimum of two DNA
743 SBs used in the results to clustered DNA damage with a minimum of three or four DNA SBs
744 required to induce DNA DSB (Supplementary Table 1). As it can be seen in Fig. 7, the absolute
745 values on the calculated probability of foci formation are quite close to the experimental data for
746 clusters with a minimum of three SBs. Nevertheless, no saturation is observed for probabilities
747 between LET values of ~ 83 and $\sim 193 \text{ keV}\cdot\mu\text{m}^{-1}$, which indicates that, despite a decrease in the
748 absolute values compared to the initially simulated results, the increase in the number of
749 simulated foci with LET does not follow the biological observations and thus DSB complexity
750 itself cannot be the explanation of this observed quasi-plateau at probabilities around 0.7.

751 In the current state of this simulation, as in other models (54), a homogeneous distribution
752 of DNA inside the nucleus is assumed and a unique chromatin structure (close to
753 heterochromatin) is considered. In reality, local DNA concentration and compaction may vary in
754 the nucleus. Differences in DNA density between euchromatin and heterochromatin likely
755 influence the probability of inducing DNA damage but also the accessibility of DNA lesions and
756 the speed of their processing (55). In addition, the chromatin remodeling process must not be
757 forgotten, as it may play an essential role in orchestrating the recruitment of repair proteins and
758 their access to the damaged regions of the DNA (56-58). Taking into account DNA density and
759 compaction is in development and is expected to influence the simulation results. The possibility
760 that 53BP1 and γ -H2AX foci formation may give a signal only for a subsection of DNA DSB
761 damage or that it does it with a different kinetic and leads to underestimation from the present
762 biological data cannot be excluded either.

763 The data reported here highlight that biological data such as the frequency of DNA DSB
764 damage induced along an ionizing particle track may not only be a function of the macroscopic
765 parameter LET. The results show an initial increase of at least one focus formation along the
766 track as the LET increases until saturation occurs at a LET around $85 \text{ keV} \cdot \mu\text{m}^{-1}$. Additional
767 experiments are necessary to complete the current curve with ions with intermediate LETs or
768 with LETs higher than those analyzed and by using biomarkers known to be more specific to
769 other types of DNA damage (DNA single strand break, base damage, sugar damage etc.). Other
770 configurations of irradiation which provide access to the number of foci formed along the track
771 (50, 51, 59-61) and not only in 2D projection associated to binary response (presence or absence)
772 would be of interest to nourish the simulation.

773 Based on the same analysis, studying the early biological effects of two types of ions with
774 the same LET would be of great interest to study the effects of their specific track diameter and

775 ionization density. In this context, the improvement of DNA density description *in silico* that
776 varies as a function of cell types and phase of cell cycle needs to be developed in order to be
777 implemented in the simulation. The combination of biological experiments and simulation
778 developments allow the nature of biological effects induced by radiation to be deciphered along
779 with all reactions around the primary ionizing events. It is highly informative towards
780 understanding the spectrum of biological effects induced after exposure to single high-LET
781 particles. Together, these studies may greatly contribute to our understanding of the link between
782 energy deposition along the track and the initial DNA damage induced.

783

784 **Acknoledgments**

785 We thank O. Döhr, H. Eggestein, T. Heldt and M. Hoffmann for the operation of the PTB ion
786 accelerators, and A. Heiske, T. Klages and J. Rahm for their support with the irradiation of cells.

787 This work was carried out within the European Metrology Research Programme (EMRP) Joint
788 Research Project SIB06 “Biologically Weighted Quantities in RadioTherapy” (BioQuaRT). The
789 EMRP was jointly funded by the EMRP participating countries within EURAMET and the
790 European Union.

960

961

962 **Supporting information**

963 **Fig. 1: Representation of the microbeam irradiation (14).** [A] and [B] An endothelial cell
964 monolayer is positioned perpendicularly to the beam (red arrows) so that each charged particle
965 traversing the cell nucleus (average thickness 2.4 μm) deposits its energy along the particle track.
966 The yellow dots symbolize clusters of energy deposition in the cell nucleus. [C] In the
967 observation with microscopy methodology for *in situ* 53BP1 or γ -H2AX foci detection, foci
968 within a track overlap. For comparison of the simulations with the observations, multiple z-planes
969 were collapsed as 2D projection to obtain a number of simulated foci.

970

971 **Fig. 2: Characterization of 53BP1 and γ -H2AX foci background.** Distribution of the number
972 of 53BP1 or γ -H2AX foci per nucleus in G_0/G_1 phase of the cell cycle for the five and seven
973 replicate experiments related, respectively, to control (Panel A) and sham-treated dishes (Panel
974 B). For each replicate experiment (noted C1, C2 ...and S1, S2 ...), the number of cell nuclei is
975 indicated between parentheses. To take into account the inter-dish variability and to increase the
976 statistical power of the analysis, control and sham data were individually pooled with the total
977 number of cell nuclei indicated between parentheses (Panel C). The mean number of foci per
978 nucleus (m_{pool}) represents the mean of the distribution of given pooled data and is associated with
979 the standard deviation (SD) computed as the square root of the variance of the given pooled
980 distribution.

981

982 **Fig. 3: Definition of square pattern of irradiation and revelation of irradiation pattern by**
983 **53BP1 and γ -H2AX foci formation.** [A] Each cell nucleus was targeted by five particles

984 according to a cross pattern with the middle one positioned at the barycenter of the cell nucleus.
985 The sides of the square measure 4 μm . [B] The cultures were fixed for analysis at 10 min after
986 exposure to 20 MeV α particles. [B-1]: stained with DAPI, [B-2]: 53BP1 immunodetection (red),
987 [B-3]: γ -H2AX immunodetection (green), [B-4]: images in panels A-C are superimposed. (scale
988 bar = 6 μm).

989
990 **Fig. 4: Distribution of number of 53BP1 and γ -H2AX foci per nucleus following exposure of**
991 **each cell nucleus of each replicate experiment by five distinct particles placed at different**
992 **positions.** For each irradiation condition (type and quality of ionizing radiation listed in Table 1),
993 and for each replicate experiment (noted I1, I2 ...), the number of cell nuclei is indicated between
994 parentheses. The mean number of 53BP1 and γ -H2AX foci per nucleus, $m_r \pm \text{SE}$, expressed as
995 the mean of the means and as the SE between the means obtained between replicate experiments
996 are indicated on each graph as well as the standard error of the mean (SEM), computed as the SE
997 divided by the square root of the number of replicates. While five ionizing particles have
998 theoretically reached each cell nucleus, the distribution can spread from zero up to ten 53BP1 or
999 γ -H2AX foci per nucleus and differs as a function of the respective radiation quality used.

1000
1001 **Fig. 5: Estimated relative frequencies of at least one 53BP1 or γ -H2AX focus formation**
1002 **following a particle traversal as a function of the LET of the radiation and impact of**
1003 **different corrections due to experimental conditions.** Relative frequencies of observed foci
1004 formation per particle track traversing 2.4 μm thickness of endothelial cell nucleus based on raw
1005 data (purple symbols) as a function of the LET of protons (circles) and α particles (diamonds) for
1006 each replicate experiment (open symbols) as well as the mean of all replications for each
1007 irradiation condition (closed symbols) are plotted for, respectively, 53BP1 [A] and γ -H2AX [B].

1008 [C] and [D] represent, respectively for 53BP1 and γ -H2AX, the previous curve (purple symbols),
1009 sham background subtracted curve (green symbols), combined with the corrections for the
1010 number of particles hitting cell nuclei (orange symbols) and for foci related to different particle
1011 tracks that are too close to be distinguished (red symbols). The LET of primary ionizing particles
1012 was $\sim 19 \text{ keV}\cdot\mu\text{m}^{-1}$ (1.6 MeV protons), $\sim 36 \text{ keV}\cdot\mu\text{m}^{-1}$ (17.8 MeV α particles), $\sim 85 \text{ keV}\cdot\mu\text{m}^{-1}$
1013 (5.5 MeV α particles) (LET), 1.86 MeV α particles (LET $\sim 170 \text{ keV}\cdot\mu\text{m}^{-1}$). The red curve
1014 represents the best estimates of relative frequencies of at least one radiation-induced 53BP1 and
1015 γ -H2AX focus formation as a function of the LET of the ionizing particle traversing $2.4 \mu\text{m}$
1016 thickness of endothelial cell nucleus. (* $P < 0.05$; ** $P < 0.01$, *** $P < 0.001$)

1017

1018 **Fig. 6: Example of the relation between the relative frequencies of foci per particle traversal**
1019 **“observable in microscopy” and the assumed probabilities of conversion from a particle**
1020 **track into an artificial focus.** From simulated coordinates of each particle traversal in a given
1021 nucleus, a Bernoulli schema with success probability of conversion of particle tracks into foci
1022 from 0 to 1 by steps of 0.05 was applied. For a given probability of conversion, a set of artificial
1023 foci is generated, and only the pairs of them located less than $2 \mu\text{m}$ away are combined
1024 (reflecting the observable foci, as they are not distinguishable in microscopy). Thus, we obtain a
1025 relation between relative frequencies of supposedly observable foci (after association of foci in
1026 too close proximity) and the underlying theoretical probabilities of particles interacting at least
1027 once with DNA along the particle track in nucleus thickness. As this relation depends on the
1028 initial irradiation characteristics (beam size and cell morphology), the relation was established for
1029 each replicate experiment of each irradiation condition.

1030

1031 **Fig. 7: Comparison of relative frequencies of at least one focus formation per particle track**
1032 **converted from 2.4 to 2 μm -thick endothelial cell nucleus and results based on Monte Carlo**
1033 **simulation with cell nucleus thickness of 2 μm as a function of LET of incident projectile.**

1034 For the sake of comparison to the simulations, the biological relative frequencies of at least one
1035 focus formation following a particle traversal were, beforehand, converted to the probability per
1036 2 μm path length based on Markov property (memoryless property) with quantity of DNA
1037 traversed and constant LET of the particle. In simulated results, we considered that each
1038 simulated DNA DSB was induced by a minimum number of clustered DNA SBs varying here
1039 from two to four and that every simulated DNA DSB along the track is converted into a
1040 detectable focus (blue curves).

1041
1042 **Supplementary Fig. 1: Visualization of variation in cells' morphology and fixed irradiation**
1043 **pattern.** [A] Simulation of each cell nucleus of the cell population, as an ellipse considering their
1044 specific major and minor axes and their orientation; [B] Each cell nucleus was exposed to the
1045 same theoretical pattern of five particles placed at the extremity of a 4 μm side square with one in
1046 the middle, positioned at the barycenter of each cell nucleus; [C] The coordinates of each particle
1047 hit of the irradiation pattern with respect to the nominal position were sampled from a Gaussian
1048 distribution along the x- ($\mu = 0, \sigma_1 = d_1/2.355$) and y- ($\mu = 0, \sigma_2 = d_2/2.355$) axes.

1049 **Supplementary Fig. 2: Examples of graphic outputs concerning the reconstruction of hit**
1050 **patterns in different cell nuclei.** [A] Real nuclei of cell population from irradiated dish; [B]
1051 Simulation mimicking the respective cell nucleus as an elliptic shape; [C] Simulated positions of
1052 particle hits indicated by red stars and estimated number of particle hits in the cell nuclei that may
1053 vary slightly from one nucleus to another depending on irradiation characteristics and cell nuclei
1054 geometry. Although each cell nucleus theoretically should have received 5 particles according to

1055 the cross pattern, the number of traversing particles may vary slightly from one nucleus to
1056 another depending on the irradiation characteristics and cell nuclei geometry.

1057 **Supplementary Fig. 3: Relative frequency distribution of the equivalent ellipse [A] major**
1058 **and [B] minor axis, and [C] area of the totality of cell nuclei analyzed in this study.** \bar{m} and
1059 SD represent, respectively, the mean of the distribution and the standard deviation (SD)
1060 computed as the square root of the variance of the distribution for each parameter analyzed.

1061 **Supplementary Fig. 4: Optimization of the irradiation pattern size.** Probability of getting two
1062 particle hits at a distance of less than 2 μm from one another in a given nucleus (red curves) and
1063 percentage of cell nuclei receiving less than five particle hits (blue curves) were calculated from
1064 simulation and plotted as a function of irradiation pattern size taking into account the real size of
1065 every cell nuclei analyzed for each of the 14 dishes used in this study.

1066 **Supplementary Fig. 5: Influence of time post-irradiation (10 or 30 minutes) on distribution**
1067 **of number of 53BP1 and γ -H2AX foci per nucleus following exposure to 1.6 MeV protons**
1068 **(LET in the nucleus $\sim 19 \text{ keV}\cdot\mu\text{m}^{-1}$) or 5.5 MeV α particles (LET in the nucleus**
1069 **$\sim 85 \text{ keV}\cdot\mu\text{m}^{-1}$).** Panel A: Distribution of number of 53BP1 and γ -H2AX foci per nucleus
1070 evaluated for each of the five and six replicate experiments (noted I1, I2, ...) 10 min and 30 min,
1071 respectively, after exposure to 1.6 MeV protons and on three replicate experiments both 10 min
1072 and 30 min after exposure to 5.5 MeV α particles. For each replicate experiment, the number of
1073 cell nuclei is indicated between parentheses. Panel B: Distribution of number of 53BP1 and γ -
1074 H2AX foci per nucleus evaluated as pooled data according to time point. Total number of cells
1075 counted is indicated between parentheses.

1076 **Supplementary Fig. 6: 3D representation of cell nucleus in the simulations through three**
1077 **levels of zoom (38).** The cell nucleus phantom is represented by a cylinder with elliptical base of
1078 major semi-axis $a = 9.5 \mu\text{m}$, minor semi-axis $b = 5.5 \mu\text{m}$, and 2 μm height. The whole genome of

1079 a eukaryotic cell (~6 Gbp) is distributed in spherical regions representing chromatin domains
1080 containing ~1 Mbp. These are placed homogeneously within the cell nucleus phantom in order to
1081 simulate cells in the G0/G1 phase of the cell cycle. Each of these chromatin domains was filled
1082 with voxels containing a geometrical representation of the chromatin fiber of helicoidal shape.

Table 1: Physical characteristics of the beam for the different projectiles and energies used for biological experiments

Selected Beam Energy	Scintillator Thickness (μm)	Biofoil Thickness (μm)	Estimated energy in the center of cell nucleus (MeV)	Estimated average LET values in the center of cell nucleus ($\text{keV} \cdot \mu\text{m}^{-1}$)	Beam size FWHM ^a $d_1 \times d_2$ ($\mu\text{m} \times \mu\text{m}$)	Detection thresholds and noise events in the particle counter (n_0/n_2) ^b
Protons 3 MeV	40	25	1.6 ± 0.2	19 ± 2	4.8×4.8	$1\% / 1\%$ ^c
