HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

Rare gas systematics on Lucky Strike basalts (37°N, North Atlantic): Evidence for efficient homogenization in a long-lived magma chamber system?

Manuel Moreira,¹ Javier Escartin,¹ Eric Gayer,¹ Cédric Hamelin,¹ Antoine Bezios,² Fabien Guillon,¹ and Mathilde Cannat¹

Received 15 January 2011; revised 3 March 2011; accepted 8 March 2011; published 20 April 2011.

[1] We present rare gas data in fresh glasses from the Lucky Strike segment located on the Mid Atlantic Ridge ($\sim 37.3^\circ\text{N}$), close to the Azores plateau. We analyzed the helium and neon isotopes in 28 samples by melting as well as He-Ne-Ar-Kr-Xe isotopes in 9 samples by crushing. Samples were collected during the Graviluck06, MOMAR08, and Bathyluck09 cruises over a ridge length of ~ 13 km (mean sample spacing of ~ 500 m), and at depths ranging from 1550 m to 2174 m. The helium isotopic ratio varies between 84,410 and 88,235 (R/Ra between 8.19 and 8.56). The samples having the “most” primitive helium isotopic ratio are the enriched samples (e.g. high $\text{K}_2\text{O}/\text{TiO}_2$) although the difference to the depleted samples is small. It appears that all of our samples derive from the same and well-homogenized magma chamber. Neon isotopes clearly show the influence of the Azores hotspot, which is not seen with helium because of lower ${}^3\text{He}/{}^{22}\text{Ne}$ in the plume source compared to the MORB source. **Citation:** Moreira, M., J. 1. Introduction

[2] Rare gases are excellent tracers of plume-ridge interaction due to the primitive signature seen in Oceanic island basalts (OIB). Indeed, Mid Oceanic Ridge Basalts (MORB) show a ${}^4\text{He}/{}^3\text{He}$ ratio of $90,000 \pm 10,000$ ($\text{R/Ra} = 8 \pm 1$ where R is the ${}^3\text{He}/{}^4\text{He}$ ratio and Ra is the atmospheric ratio of $1.384 \cdot 10^{-6}$) whereas OIB show lower ratios (higher R/Ra), down to 15,000 ($\text{R/Ra} = 50$) for the ancient Iceland plume [Stuart et al., 2003]. To explain the lower ${}^4\text{He}/{}^3\text{He}$ ratios in OIB than in MORB, it is generally proposed that mantle plumes sample a gas-rich reservoir [Kurz et al., 1982]. Neon isotopes show a similar behavior to that of helium isotopes. The ${}^{21}\text{Ne}/{}^{22}\text{Ne}$ ratio is lower in OIB than in MORB [Honda et al., 1991; Valbracht et al., 1997]. Because the ${}^{21}\text{Ne}$ is nucleogenic (e.g. ${}^{18}\text{O}(\alpha,\text{n}){}^{21}\text{Ne}$ or ${}^{24}\text{Mg}(\text{n},\alpha){}^{21}\text{Ne}$),

it is generally proposed that in order to preserve a lower ${}^{21}\text{Ne}/{}^{22}\text{Ne}$, the OIB source has to be enriched in ${}^{22}\text{Ne}$ compared to the MORB source. Therefore, both helium and neon are very sensitive to plume-derived magmas due to these expected high concentrations. Previous studies have demonstrated the interest of measuring the rare gases to constrain plume-ridge interactions [Graham et al., 1999; Hopp et al., 2004; Moreira et al., 1995; Poreda et al., 1986; Sarda et al., 2000; Stroncik et al., 2008].

[3] The objective of this study is to constrain the influence of the Azores hotspot along the Mid Atlantic Ridge, as well as to investigate the scale of mantle heterogeneities. We present helium and neon isotopes in 28 samples from the Lucky Strike segment, North Atlantic ($37^\circ 20'\text{N}$), as well as He-Ne-Ar-Kr-Xe elemental compositions and isotopic ratios in 9 samples from this segment.

2. Lucky Strike Segment and Sampling

[4] The ~ 70 km-long Lucky strike segment is centered at $\sim 37^\circ 20'\text{N}$ on the Mid Atlantic Ridge, and ~ 350 km West of the Azores hotspot. It shows a 15–20 km wide axial valley with axial depths that vary from >4000 m at the segment ends to 1550 m at the center of the segment. The volcano located at the center of the segment is ~ 10 km wide and 15 km long along the ridge axis, and hosts an active hydrothermal field discovered in 1992 during the FAZAR cruise [Langmuir et al., 1997]. A depression at the summit of the volcano, surrounded by three highs, hosts the hydrothermal fields and a lava lake (Figure 1). An axial magma chamber (AMC) is present at a depth of 3.4 km below the seafloor under the volcano, and extends ~ 7 km along axis and ~ 3 km perpendicular to it [Singh et al., 2006]. This AMC probably supplies the heat necessary for the hydrothermal field and may be the source of the erupted lava flows. From a geochemical point of view, basalts from the Lucky Strike segment are enriched in incompatible elements [Langmuir et al., 1997]. Samples were collected during the Graviluck06, MOMAR08 and Bathyluck09 cruises over a distance of ~ 13 km (mean sample spacing of ~ 500 m). Sampling depths vary from 1550 m to 2174 m. Note that we have duplicated a previously analyzed sample from the FAZAR cruise, A127 D15-1 [Moreira and Allègre, 2002] and provided by C. Langmuir. All the analyses are from glass samples, except for two olivines picked from picritic basalts (GRA N16-8 and GRA N17-4) without glass. Two samples (GRARC07 and MOM08V02) are considered as very enriched in trace elements (e.g. high K/Ti

ratio) compared to the other samples (A. Bezos, unpublished data, 2011).

3. Analytical Procedure and Results

[5] Samples were cleaned with distilled water and ethanol in an ultrasonic bath. When Mn crust was present, peroxide was used. Two noble gas mass spectrometers were used for this study: ARESIBO II and our new Noblesse (Nu instruments ©). Crushing and melting under vacuum was used for the gas extraction. Only He and Neon were analyzed on the Noblesse whereas the abundances of the five rare gases were determined, as well as isotopic ratios of He-Ne and Ar, on the ARESIBO II mass spectrometer. The analytical procedure on ARESIBO II is given by *Moreira and Allegre [2002]*. The Noblesse mass spectrometer analytical procedure will be given elsewhere. During the course of the Lucky Strike segment analyses, the precision (1 standard deviation) of the standards was 0.3% for the helium isotopic ratios and 0.2% and 0.5% for $^{20}\text{Ne}/^{22}\text{Ne}$ and $^{21}\text{Ne}/^{22}\text{Ne}$, respectively.

[6] Blanks were $1.4 \cdot 10^{-10}$ ccSTP for ^{4}He and $7 \cdot 10^{-14}$ ccSTP for ^{22}Ne for the crushing experiments whereas they were $1.4 \cdot 10^{-10}$ ccSTP for ^{4}He and between $8 \cdot 10^{-13}$ and $3 \cdot 10^{-12}$ ccSTP for ^{22}Ne for the melting procedure. A single heating step at 1400°C was applied on the samples.

[7] Rare gas results are given in Tables 1 and 2. Bulk helium concentrations in glass samples vary from $3 \cdot 10^{-6}$ to $2.2 \cdot 10^{-5}$ ccSTP/g, typical of MORB, whereas crushing experiments give slightly lower helium concentration ($3 \cdot 10^{-6}$ to $8.5 \cdot 10^{-6}$ ccSTP/g). Olivine samples give concentration of $5.2 \cdot 10^{-9}$ and $1.1 \cdot 10^{-8}$ ccSTP/g, typical of concentrations in olivines. The $^{4}\text{He}/^{3}\text{He}$ ratio varies from 84,409 to 88,235 for the melted glass samples. Crushed glasses give lower helium isotopic ratios, from $78,540 \pm 1540$ to $87,790 \pm 18,30$. The two olivine samples gave $^{4}\text{He}/^{3}\text{He}$ ratios of $91,350 \pm 3350$ and $84,310 \pm 1280$. All the isotopic ratios are typical of

MORB. The two most incompatible element enriched samples (GRARC07 and MOM08V02) do not present helium isotopic ratios different from the depleted samples: 84,409 and 85,005, respectively (Figure 1b).

[8] ^{22}Ne concentrations vary from $2.3 \cdot 10^{-12}$ to $4.8 \cdot 10^{-10}$ ccSTP/g for melted samples and from $1.54 \cdot 10^{-12}$ to $1.42 \cdot 10^{-11}$ ccSTP/g for crushing. $^{20}\text{Ne}/^{22}\text{Ne}$ ratios vary from 9.97 to 12.09 for melting experiments and from 10.42 to 12.29 for the crushing ones. The $^{21}\text{Ne}/^{22}\text{Ne}$ is correlated with $^{20}\text{Ne}/^{22}\text{Ne}$ and varies from 0.0300 to 0.0499 (melting) and from 0.0335 to 0.0481 (crushing). Results are plotted on Figure 2. Samples from Lucky Strike fall on a different line than the classical MORB line defined by [Sarda et al., 1988]. Note that both mass spectrometers give the same neon systematics.

[9] ^{36}Ar concentrations vary from $1.1 \cdot 10^{-11}$ to $3.2 \cdot 10^{-10}$ ccSTP/g (only crushing) and is correlated to ^{22}Ne abundances (not shown). $^{38}\text{Ar}/^{36}\text{Ar}$ ratios are between 0.1878 and 0.1911 (air = 0.1880). $^{40}\text{Ar}/^{36}\text{Ar}$ ratios are between 482 and 3439. The highest ratio (3439) is far from the mantle value estimated at $\sim 30,000$ [Staudacher et al., 1989]. ^{84}Kr and ^{130}Xe abundances are correlated with neon and argon abundances. ^{84}Kr is comprised between $3.2 \cdot 10^{-13}$ and $9.6 \cdot 10^{-12}$ ccSTP/g. ^{130}Xe varies from $2.1 \cdot 10^{-15}$ and $5.7 \cdot 10^{-14}$ ccSTP/g. Heavy rare gases will not be discussed in this paper. Indeed, $^{40}\text{Ar}/^{36}\text{Ar}$ ratios correlate with the $^{20}\text{Ne}/^{22}\text{Ne}$ (not shown). This correlation can be interpreted as the result of a mixture between a magmatic component and an atmospheric component. The $[\text{magmatic}/\text{air}]_{^{22}\text{Ne}/^{36}\text{Ar}}$ that is necessary to explain the Ne-Ar correlation is ~ 50 , far above the ratio observed for undegassed samples such as the popping rock 2πD43, which presents a ratio of 1.6 [Moreira et al., 1998]. Such a strong hyperbolic mixture doesn't allow the determination of the uncontaminated $^{40}\text{Ar}/^{36}\text{Ar}$ ratio of the Lucky Strike magma. This high $[\text{magmatic}/\text{air}]_{^{22}\text{Ne}/^{36}\text{Ar}}$ ratio clearly reflects the

4. Discussion

4.1. Homogeneity of the Helium Isotopic Ratios and the Evidence for a Well-Mixed Magma Chamber

[10] Figure 1b shows the helium isotopic ratio obtained by melting reported versus the latitude. Ratios show very homogeneous results, with a mean ratio of $86,649 \pm 1010$ ($\text{R/Ra} = 8.34 \pm 0.09$). Olivine samples from two picrites give the same helium isotopic ratio as the glass samples within uncertainties. The isotopic variation (~1%) is small compared to that reported for a complete ridge (few percents) [Allègre *et al.*, 1995] or a ridge section (~3% for SWIR [Georgen *et al.*, 2003]).

[11] At that point, it is clear that we are not able to distinguish with helium any peculiar chemical heterogeneity in the mantle source of Lucky Strike segment. If the mantle has a marble cake structure [Allègre and Turcotte, 1986], the enriched component (e.g. pyroxenite) is easily homogenized with the depleted one for helium at the scale of our sampling interval (13 km along-axis). Homogenization could occur

before melting by diffusion of helium in the mantle [Hart *et al.*, 2008], homogenization by small-scale convection in the uppermost upper mantle [Graham *et al.*, 2001] or, more probably, after melting in a magma chamber considering the scale of our study. In this last case, we could conclude that all the MORBs from the Lucky Strike segment sample the same magma chamber, which was seismically imaged [Singh *et al.*, 2006].

4.2. Evidence for the Azores Influence on the Lucky Strike Volcano Source

[12] Azores island basalts are characterized by both relatively low ${}^4\text{He}/{}^3\text{He}$ ratios (high R/Ra) for the islands from the central group and by radiogenic helium for São Miguel island [Moreira *et al.*, 1999]. The interpretation for these helium isotopic ratios is the presence of a mantle plume deriving from a primitive mantle and centered under the central group, in agreement with melt fluxes [Bourdon *et al.*, 2005] and seismology [Yang *et al.*, 2006], and with the presence of a chemical heterogeneity with crustal affinity under São Miguel island [Beier *et al.*, 2008]. Neon systematics also suggest a primitive signature for the Azores hotspot [Madureira *et al.*, 2005].

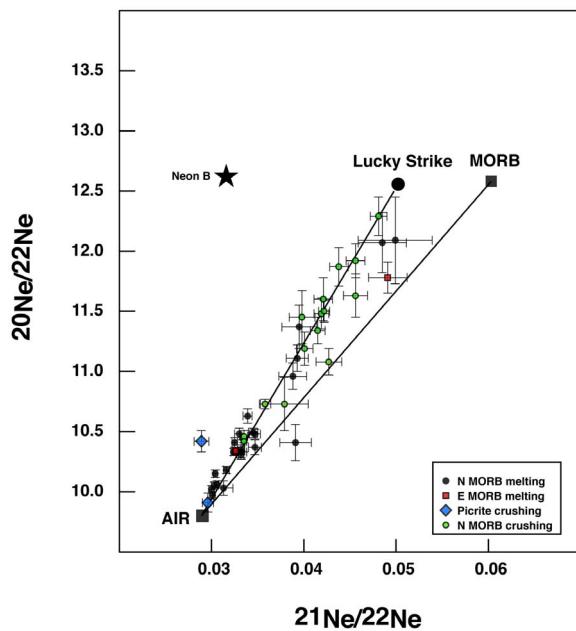

Figure 2. Three-isotope neon diagram. The MORB composition is derived from Sarda *et al.* [1988]. MORB from the Lucky strike segment show a different slope in this diagram, which can be attributed to mixing with a component having primitive neon. Uncertainties are 1σ .

[13] The helium isotopic ratios of samples from Lucky Strike are not different from the normal MORB value. Indeed, the mean north Atlantic MORB ratio is $89,380 \pm 9300$ [Allegre *et al.*, 1995] whereas the mean helium ratio of Lucky Strike samples is $86,480 \pm 1180$. Therefore, based

only on the helium isotopes, the Azores hotspot influence cannot be seen in the Lucky Strike segment.

[14] Neon isotopes give a different view of the Azores influence from that of helium. Indeed, as illustrated by Figure 2, the slope of the Lucky Strike samples in the three-isotope neon diagram is higher than the MORB line defined by [Sarda *et al.*, 1988]. This line is interpreted as reflecting a mixing between a mantle-derived component and an atmosphere-derived component (e.g. crust assimilation, seawater interaction, air introduction in the samples). That different slope than MORB means that the mantle beneath Lucky strike has a lower $^{21}\text{Ne}/^{22}\text{Ne}$ than the normal Atlantic mantle and this can be attributed to the Azores hotspot influence. Figure 3 shows the $^4\text{He}/^3\text{He}$ versus the $^{21}\text{Ne}/^{22}\text{Ne}$ isotopic ratio extrapolated to $^{20}\text{Ne}/^{22}\text{Ne} = 12.6$ (e.g. corrected for air contamination), which corresponds to the value of the “Neon B”, representative of the mantle value [Raquin and Moreira, 2009; Trieloff *et al.*, 2000]. Mantle plume magmas have lower $^3\text{He}/^{22}\text{Ne}$ ratio than the MORB magmas (by a factor 5 to 10) [Moreira *et al.*, 2001; Yokochi and Marty, 2004] due either to different $^3\text{He}/^{22}\text{Ne}$ ratios in the two sources, or to mixing of degassed magmas [e.g., Moreira *et al.*, 2001]. Therefore, in Figure 3, mixing is not linear but hyperbolic, which means that neon is more sensitive to the Azores mantle source influence than helium. The isotopic ratios for Terceira Island (Azores) and Lucky strike segment are reported on Figure 3. One can clearly see that the Lucky Strike magma are a mixture between magma from the normal MORB mantle and magma from a primitive component, being the Azores mantle plume.

5. Conclusions

[15] Rare gases in MORB from the central part of the Lucky Strike segment show that the mantle beneath this

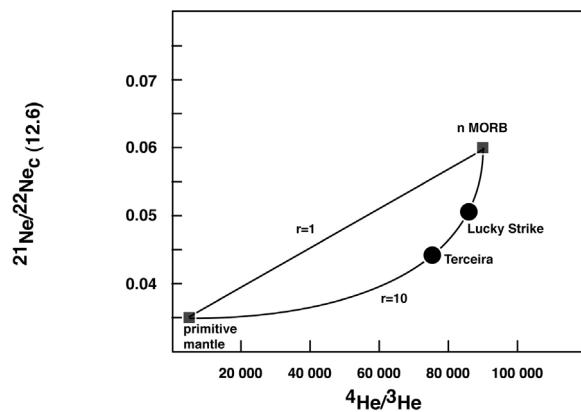

Figure 3. Extrapolated ${}^{21}\text{Ne}/{}^{22}\text{Ne}$ ratios of the regression line of all Lucky Strike samples (at a ${}^{20}\text{Ne}/{}^{22}\text{Ne}$ of 12.6) plotted versus the mean ${}^4\text{He}/{}^3\text{He}$ ratio. The hyperbola is derived from [Kurz et al., 2009]. The Terceira Island (Azores) isotopic ratios are given by Madureira et al. [2005]. The r parameter is ${}^3\text{He}/{}^{22}\text{Ne}_{\text{MORB}}/{}^3\text{He}/{}^{22}\text{Ne}_{\text{Primitive mantle}}$. For most OIB and on-ridge hotspots, r is close to 10 [Kurz et al., 2009; Moreira and Allègre, 1998].

segment is extremely homogeneous. Neon isotopes clearly suggest the influence of the Azores hotspot, although this is not seen with helium isotopes. We conclude that all the analyzed samples derive from the same central magma chamber, and that it is very well homogenized. This is easily achieved for helium, and may be neon, due to their high diffusivity in melt.

[16] **Acknowledgments.** We acknowledge the effort and support of the officers, crew, and science parties of the Graviluck'06, MoMAR'08, and Bathyluck'09 cruises and the team operating the Nautilus submersible and the VICTOR remotely operated vehicle. Ship time was financed by CNRS/INSU and IFREMER, with additional support from ANR (MOTHSEIM Project NT05-3_42213) to J. Escartin. Philippe Sarda and Pete Burnard are thanked for their very constructive reviews. The editor thanks Pete Burnard and Philippe Sarda for their review.
