16 **Abstract**

17 Nitrogen (N) emissions associated with urbanization exacerbate the atmospheric
18 nitrogen influx to remote ecosystems – like mountains –, leading to well-documented
19 detrimental effects on ecosystems (e.g., soil acidification, pollution of freshwaters).
20 Here, the aim was to evaluate the importance and fate of N deposition in a watershed
21 along a montane to urban gradient, using a multi-isotopic tracers approach ($\Delta^{17}\text{O}$,
22 $\delta^{15}\text{N}$, $\delta^{18}\text{O}$ of nitrate, $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of water). **In this setting, the montane streams**
23 **had** higher proportions of atmospheric nitrate compared to urban streams, and
24 exported more atmospheric nitrate on a yearly basis (0.35 vs 0.10 kg-N ha⁻¹ yr⁻¹). **In**
25 **urban areas, nitrate exports were driven by groundwater, whereas in the catchment**
26 **head nitrate exports were dominated by surface runoffs. The main sources of nitrate**
27 **to the montane streams were microbial nitrification and atmospheric deposition**
28 **whereas microbial nitrification and sewage leakages contributed most to urban**
29 **streams.** Based on the measurement of $\delta^{15}\text{N}$ and $\delta^{18}\text{O}\text{-NO}_3^-$, biological processes
30 such as denitrification or N assimilation **were not predominant** in any streams in this
31 study. The observed low $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ range of terrestrial nitrate (*i.e.*, **nitrate not**
32 **coming from atmospheric deposition) in surface water** compared to literature
33 suggests that atmospheric deposition may **be underestimated as a direct source of**
34 **N.**

37 **Keywords: Nitrogen, deposition, $\Delta^{17}\text{O}$, subalpine, isotope, Lautaret**

38

39 **Highlights**

40

41 How is nitrogen deposition reflected in streams NO_3^- exports in the French Alps?

42

43 NO_3^- exports in seven streams along an altitude gradient were monitored for two
44 years.

45

46 NO_3^- isotopic composition ($\Delta^{17}\text{O}$, $\delta^{15}\text{N}$, $\delta^{18}\text{O}$) was analyzed to apportion the sources.

47

48 Up to 21% of NO_3^- in montane streams and 5% in urban streams was unprocessed

49 $\text{NO}_3^-_{atm}$.

50

51 Nitrification of atmospheric and mineralized NH_4^+ was the ubiquitous main NO_3^-

52 source.

53 1. Introduction

54 Atmospheric nitrogen (N) deposition has increased 10-fold over the past
55 century, increasingly contributing to the global N **availability** (Galloway et al., 2004).
56 Anthropogenic activities such as fossil-fuel combustion, agriculture, and fertilizers
57 use are responsible for this increase (Fowler et al., 2015; Galloway et al., 2008;
58 Vitousek et al., 1997), with impacts **observed** in remote ecosystems (Hastings et al.,
59 2009; Holtgrieve et al., 2011; Preunkert, 2003). **High N loading to the environment**
60 **has been documented for many ecosystems** (Aber et al., 1989; Clark et al., 2017;
61 Elser et al., 2009; Matson et al., 2002). To address this issue, global efforts are
62 underway to alleviate N inputs into ecosystems, aiming at “minimizing the
63 consequent harm to humans and the environment” (International Nitrogen Initiative,
64 <http://www.initrogen.org>).

65 Nitrate concentrations, and fluxes in soils and streams have often been used
66 to assess the N saturation status in watersheds (Aber et al., 1989; Baron and
67 Campbell, 1997; Lovett and Goodale, 2011). However, N exports in stream depend
68 on multiple parameters such as basin topography (Balestrini et al., 2013; Clow and
69 Sueker, 2000), land-cover (Barnes et al., 2014; Williams et al., 2016) and land-
70 management (Barnes and Raymond, 2010; Burns et al., 2009; Lefebvre et al., 2007).
71 As streams integrate many processes at the watershed scale, **understanding the**
72 **specific sources of NO₃⁻** is important to (1) evaluate the respective contribution of
73 biological and anthropogenic sources, (2) clarify the fate of deposited N in the
74 environment, and (3) understand the origin and the development of N saturation.

75 Mountainous ecosystems are particularly sensitive to increased N inputs by
76 atmospheric deposition (Baron et al., 2000, 2005, 2011), as they are historically N-
77 limited (Kaye and Hart, 1997). Critical loads for these ecosystems are among the

78 lowest for pristine environments (Baron et al., 2011; Bowman et al., 2006; Nanus et
79 al., 2017), making them vulnerable to long-range transport of atmospheric N emitted
80 from distant sources (Mast et al., 2014; Wasiuta et al., 2015). Atmospheric deposition
81 of N has been shown to contribute significantly, either directly or indirectly, to year-
82 round NO_3^- exports from mountainous catchments (Hundey et al., 2016; Nanus et al.,
83 2008), typically showing a pulse at spring as soils subsurface NO_3^- reservoirs are
84 flushed by snowmelt water (Kendall et al., 1995; Williams et al., 2009; Williams and
85 Melack, 1991).

86 Atmospheric deposition is also a major source of N to urban areas, which
87 receive much higher loads than adjacent environments (Bettez and Groffman, 2013;
88 Fang et al., 2011; Hall et al., 2014; Rao et al., 2014; Templer et al., 2015). Local and
89 regional emissions and subsequent deposition of fuel-combustion derived NO_x and
90 ammonia (NH_3) are responsible for **this** pattern (Galloway et al., 2004; Kean et al.,
91 2000). **NO_x compounds** are oxidized into NO_3^- within hours (Beirle et al., 2011), then
92 scavenged from the atmosphere by wet and dry deposition (Hertel et al., 2012). In
93 the atmosphere, NH_3 is in equilibrium with ammonium (NH_4^+), the other primary
94 component of bulk N deposition. Because of the particular topography of urban
95 basins (extended impervious surface, rapid precipitation runoff), urbanization can
96 lead to high NO_3^- exports in freshwater bodies (Groffman et al., 2004; Riha et al.,
97 2014), with major ecological, economic and health consequences (Dodds et al.,
98 2009).

99 **This study aims at evaluating** how atmospheric deposition of N is reflected **in**
100 NO_3^- exports in several streams along a montane to urban gradient in the French
101 Alps. **Isotopic ($\Delta^{17}\text{O}$, $\delta^{15}\text{N}$, $\delta^{18}\text{O}$ of nitrate, $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of water) and hydro-**
102 **chemical techniques were combined** to evaluate the drivers of NO_3^- inputs and

103 removal in all streams. **The first hypothesis was that** due to a higher contribution from
104 other sources (e.g., sewage, fertilizers) in urban areas compared to the mountains,
105 coupled with higher local atmospheric N inputs, total NO_3^- and atmospheric nitrate
106 ($\text{NO}_3^-_{atm}$) exports should increase along the gradient. **The second hypothesis was**
107 that different $\text{NO}_3^-_{atm}$ export dynamics should be observed in urban streams compare
108 to montane streams, due to different hydrological drivers that need to be determined.
109 To test these hypotheses, (1) **NO_3^- concentration and isotopic composition were**
110 **determined** in six streams and one lake, ranging from 2000m **above sea level (a.s.l.)**
111 to 200m **(a.s.l.)** in the French Alps, (2) the annual export fluxes of $\text{NO}_3^-_{atm}$ and total
112 NO_3^- **were compared across sites** along the gradient, (3) the hydrological drivers of
113 the seasonal variability in $\text{NO}_3^-_{atm}$ proportion were identified and (4) the additional
114 sources of NO_3^- in each watershed were determined.
115

116 **2. Methods**

117 **2.1 Study site and selected streams**

118 The Romanche Valley, located in the central French Alps, spreads from the
119 Lautaret pass (2058m a.s.l.) down to Grenoble (250m a.s.l.) (Figure S1a and b). The
120 Grenoble conurbation counts around 500 000 inhabitants, and is the biggest alpine
121 metropolis in France.

122 Six streams and one lake were sampled from the Lautaret pass to Grenoble,
123 draining watersheds of increasing size and with distinct geomorphic and
124 biogeographic characteristics (Table 1). Two alpine streams were sampled at
125 ~2000m a.s.l.. These drain the South exposed side of the Lautaret pass (S-upper
126 montane, n = 157) and the North exposed side (N-upper montane, n=93), where for
127 the latter the stream is mainly fed by glacier melt (Figure S1c). The mid montane
128 stream (n=67) was sampled at ~1600 m a.s.l., 6km down from the Lautaret pass
129 (Figure S1c). All three streams are tributaries of Romanche (lower montane stream,
130 n=127) that was sampled 15km down from the Lautaret pass at ~1000m a.s.l., before
131 ending in Chambon lake (Figure S1d). The lake (~ 900m a.s.l., n=29) is an artificial
132 reservoir managed by the French national electricity company (EDF), 21km down
133 from the Lautaret pass. The two urban streams (~210 m a.s.l.) were located, for one,
134 upstream from Grenoble main urbanized area (upper urban stream, n=48) and, for
135 the other, downstream (lower urban stream, n=45), and were separated by 8km
136 (Figure S1e). The lower urban stream waters are derived from the lower montane
137 stream (and the lake). The upper urban stream, Isère, has surface water from
138 another alpine valley. The upper urban stream flows through residential areas,
139 gardens, and some arable fields prior to the sampling location whereas the lower

140 urban site abuts industrial developments as well as residential neighborhoods
141 (Dutordoir, 2014).

142

143 **2.2 Deposition and streams sampling, discharge and conductivity**

144 **Atmospheric** wet and dry **deposition** samples were collected using a WADOS
145 Kroneis collector (GmbH Austria) at the S-upper montane site from April 2016 to April
146 2017. **A moving lid – connected to heated moisture sensor – ensured the separated**
147 **collection by covering alternatively the dry funnel (under rain or snow conditions) and**
148 **the wet funnel (the rest of the time).** The deposition collector was installed on the roof
149 of the **Lautaret pass Alpine Research Station (~210 m a.s.l.)**,
150 <https://www.jardinalpindulautaret.fr>) to reduce the impact of ground turbulence and
151 input of soil particles. Samples were collected **approximately** every three weeks.
152 Precipitation samples were kept at 4°C during the sampling period, then frozen until
153 further analysis. After exposure to the atmosphere, the dry deposition funnel was
154 rinsed with 500 mL of MilliQ water, and the sample was stored at -20°C.

155 Stream and lake water was sampled at all sites according to the Niwot Ridge
156 LTER protocol (Williams and Melack, 1991). In short, samples (total n = 566) were
157 collected manually in 1L Nalgene bottles, previously washed 3 times with MilliQ water
158 ($18.2 \text{ M}\Omega\cdot\text{cm}^{-1}$ at 25°C) and rinsed three times with stream water before collection.
159 All samples were then kept at -20°C until further treatment. Water samples were
160 collected on a weekly to monthly basis from January 2015 to December 2016, with
161 increased sampling frequency in two of the upper tributaries from April to May 2016.
162 During this intensive sampling period, water was collected using three automatic
163 water samplers (Teledyne ISCO® 3700) every two or three hours at the S-upper and
164 lower montane sites. Water conductivity, shown to be a good proxy of discharge

165 (Weijs et al., 2013), and water temperature were also intensively monitored (2
166 minutes stepwise) over that period using CTD-Diver[®] sensors. Spring sampling was
167 sporadic in the N-upper montane site because of persistent snow cover. Winter
168 sampling was not possible at the lake site as it was frozen.

169 Discharge data was obtained from the national discharge-monitoring network
170 (Banque Hydro) or measured every hour for both lower montane and urban site.
171 Stream stage at the upper urban site was monitored every 30 minutes using water
172 level gauge sensor (OTT[®]) at Grenoble Campus station (more details in Mano, 2008;
173 Némery et al., 2013). Discharge was estimated from stage measurements by using
174 rating curve (water level vs discharge) (Némery et al., 2013). Continuous discharge
175 could not be measured at the upper and mid montane sites **due to the torturous**
176 **nature of the streams**. Precipitation data were obtained from the Alpine Mountain
177 Meteorological Office Network (www.romma.fr) at the upper montane site and using
178 a rain gauge (Précis Mécaniques[®]) on a building roof of the Grenoble Campus, close
179 to the upper urban site.

180

181 **2.3 Chemical and isotopic analysis**

182 All stream and deposition samples were left to unfreeze at ambient
183 temperature prior to being filtered using 0.45µm Whatman GD/X syringe filters linked
184 to a peristaltic pump. They were subsequently analyzed for ion concentrations
185 ($[\text{NH}_4^+]$, $[\text{NO}_3^-]$, $[\text{SO}_4^{2-}]$, $[\text{Cl}^-]$, $[\text{Ca}^{2+}]$) using a colorimetric technique (Gallery Plus,
186 Thermo Fisher Scientific, Waltham, Massachusetts, USA). **An analytical error <0.01**
187 **mg L⁻¹ was determined for all ions based on the standard deviation of commercial**
188 **control solutions (ThermoFisher[®]) analyzed as unknowns**. Major ions such as sulfate
189 and calcium and chloride are often used as hydro-chemical tracers of water

190 flowpaths or water sources (Briand, 2014; Devito et al., 2000; Hall et al., 2016;
191 Stoewer et al., 2015), and were measured to identify the dominating hydrological
192 regimes in the studied sites.

193 All samples were concentrated on an anionic resin (0.6mL AG 1-X8 resin, Cl⁻-
194 form, Bio-Rad) with recovery efficiency over 98.5% (Erbland, 2011) and eluted with
195 10mL of a 1M NaCl solution for isotopic analysis (Templer and Weathers, 2011).
196 Isotopic analyses of NO₃⁻ ($\Delta^{17}\text{O}$, $\delta^{18}\text{O}$ and $\delta^{15}\text{N}$) were conducted on an MAT 253
197 IRMS using an adapted version of the denitrifier method (Kaiser et al., 2007; Morin et
198 al., 2008). More details about the experimental setup can be found elsewhere (SI
199 Text). **The analytical errors – calculated as the standard deviation of the residuals
200 from the linear regression between raw data of the reference standards (USGS 32,
201 USGS 34 and USGS 35) and their accepted values – were ± 0.4 , 1.5 and 0.3‰ for
202 $\Delta^{17}\text{O}$, $\delta^{18}\text{O}$ and $\delta^{15}\text{N}$ of NO₃⁻, respectively. Slopes and intercepts of the linear
203 regressions are then used to convert raw sample data into calibrated values
204 (VSMOW scale for O isotopes, and N₂-air scale for N isotopes).**

205 A subset of stream, rain, and snow samples (collected in winter 2015-2016)
206 were sent for $\delta^2\text{H}$ and $\delta^{18}\text{O}$ analyses on a Picarro L2130-i at the Laboratoire des
207 Sciences et du Climat (LSCE) in Paris, France. **The analytical error – inferred from
208 the replicate analysis of internal standards calibrated against V-SMOW2 et V-SLAP2
209 standards – was ± 0.7 and 0.2 ‰ for $\delta^2\text{H}$ and $\delta^{18}\text{O}$ of H₂O, respectively.**

210

211 **2.4 NO₃⁻ sources apportionment**

212 A number of previous studies have used the dual isotope approach ($\delta^{18}\text{O}$ and
213 $\delta^{15}\text{N}$ of NO₃⁻) to track the spatio-temporal variability of sources contribution to NO₃⁻
214 pools in a large variety of environmental matrixes (Campbell et al., 2002; Durka et al.,

215 1994; Elliott et al., 2009; Yang and Toor, 2016). Biochemical processes such as
216 denitrification or assimilation have also been shown in laboratory experiments to
217 distinguishably enrich residual NO_3^- in heavier isotopes, here ^{15}N and ^{18}O (Granger et
218 al., 2004, 2010; Treibergs and Granger, 2017), although this enrichment can be
219 diluted by newly nitrified NO_3^- with low N and O isotopic values (Granger and
220 Wankel, 2016; Mayer et al., 2002). Environmental studies also reported characteristic
221 NO_3^- isotopic enrichment for denitrification (Clément et al., 2003; Fang et al., 2015;
222 Wexler et al., 2014), assimilation (Emmerton et al., 2001; Estrada et al., 2017; X.-Y.
223 Liu et al., 2013) or photolysis (Frey et al., 2009; Shi et al., 2015; Ye et al., 2016).
224 However, the isotopic fingerprint of biological processes can lead to inaccurate NO_3^-
225 source apportionment in some cases, especially in delineating the respective
226 contribution of the microbial and the atmospheric sources (Michalski et al., 2004;
227 Riha et al., 2014; Rose et al., 2015a).

228 In the past few years, a growing number of studies have used an isotopic
229 particularity of $\text{NO}_3^-_{atm}$ to quantify the contribution of atmospheric deposition to
230 terrestrial N pools (Costa et al., 2011; Hundey et al., 2016; Tsunogai et al., 2014).
231 $\text{NO}_3^-_{atm}$ is enriched in ^{17}O due to its production pathways (*i.e.*, oxidation of NO_x by
232 O_3), showing a deviation from the Terrestrial Fractionation Line (Thiemens, 2006).
233 $\Delta^{17}\text{O}$ is a quantification of this deviation, calculated as $\Delta^{17}\text{O} = \delta^{17}\text{O} - 0.52 * \delta^{18}\text{O}$ in
234 the present work. $\Delta^{17}\text{O}$ value of $\text{NO}_3^-_{atm}$ generally ranges between 20 and 35‰ in
235 temperate latitudes (Morin et al., 2009; Savarino et al., 2007), whereas $\Delta^{17}\text{O}$ value of
236 NO_3^- from all other sources (industrial fertilizers, nitrification) or of biologically
237 processed $\text{NO}_3^-_{atm}$, is 0‰ (Michalski et al., 2004, 2015). In this study, these two
238 distinct $\Delta^{17}\text{O}$ values were used as end-members in a simple mixing model to quantify
239 unprocessed $\text{NO}_3^-_{atm}$ proportion (f_{atm}) in streams, according to Michalski et al.

240 (2004):

241

242 (Eq. 1)
$$f_{atm} = (\Delta^{17}\text{O-NO}_3^- \text{ sample} / \Delta^{17}\text{O-NO}_3^- \text{ atm})$$

243

244 The atmospheric fraction (f_{atm}) and the terrestrial fraction of NO_3^- ($f_{ter} = 1 -$
245 f_{atm}) can be used to remove the isotopic influence of $\text{NO}_3^- \text{ atm}$ on samples, and allow
246 for a better interpretation of biological processes that affect $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ (Dejwakh
247 et al., 2012; Michalski et al., 2004; Riha et al., 2014; Tsunogai et al., 2010). $\delta^{18}\text{O}$ vs
248 $\delta^{15}\text{N}$ plots have been intensively used to evaluate sources of N and potential
249 processes (denitrification, assimilation) in the environment (Burns et al., 2009; Durka
250 et al., 1994; Griffiths et al., 2016; Kendall et al., 1995; X.-Y. Liu et al., 2013).
251 However, because of strongly distinct $\delta^{18}\text{O-NO}_3^- \text{ atm}$ values compared to $\delta^{18}\text{O-NO}_3^- \text{ ter}$,
252 even a low f_{atm} can lead to scatter in a dual-isotope plot. Removing the atmospheric
253 $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ components from environmental samples leads to an easier
254 assessment of biological processes, such as assimilation or denitrification. This
255 isotope correction was applied on the samples using the isotopic mass balances from
256 Riha et al. (2014):

257

258 (Eq.2)
$$\delta^{18}\text{O}_{ter} = (\delta^{18}\text{O}_{sample} - \delta^{18}\text{O}_{atm} * f_{atm}) / f_{ter}$$

259

260 (Eq.3)
$$\delta^{15}\text{N}_{ter} = (\delta^{15}\text{N}_{sample} - \delta^{15}\text{N}_{atm} * f_{atm}) / f_{ter}$$

261

262 $\delta^{15}\text{N}_{atm}$ and $\delta^{18}\text{O}_{atm}$ were inferred from NO_3^- in wet and dry **atmospheric** deposition
263 (see section 3.2). A formal propagation of uncertainty was performed to assess the
264 error associated with individual values of f_{atm} , $\delta^{18}\text{O-NO}_3^- \text{ ter}$ and $\delta^{15}\text{N-NO}_3^- \text{ ter}$. Although

265 the error associated with individual values can be large (Figure S2), averaging across
266 samples throughout the year results in a robust estimate of annual f_{atm} , $\delta^{18}\text{O-NO}_3^-$
267 and $\delta^{15}\text{N-NO}_3^-$ values (Dejwakh et al., 2012).

268

269 **2.5 Fluxes of NO_3^- and $\text{NO}_3^-_{atm}$**

270 **NO_3^- yields** (F_m in kg-N w^{-1}) were calculated at each site – when possible – on
271 a weekly basis using the mean weekly discharge (Q_m in $\text{m}^3 \text{s}^{-1}$) and instantaneous
272 concentrations ($[\text{NO}_3^-]_i$ in mg-N L^{-1}), as follows:

273

$$274 \text{ (Eq.4) } \quad \mathbf{F_m = Q_m * [NO_3^-]_i}$$

275

276 Total specific annual stream loads of NO_3^- (F_{tot} in $\text{kg-N ha}^{-1} \text{ yr}^{-1}$) were calculated as
277 the annual sum of weekly NO_3^- exports during the study period (2015 and 2016), as
278 follows:

279

$$280 \text{ (Eq.5) } \quad \mathbf{F_{tot} = (\sum_m F_m) / (\text{watershed area})}$$

281

282 Finally, total annual $\text{NO}_3^-_{atm}$ loads (F_{atm}) were calculated for each year by multiplying
283 the total annual stream yield of NO_3^- (F_{tot}) by the discharge-weighted annual mean
284 f_{atm} in the stream (see Eq. 1), according to Tsunogai et al. (2014, 2010):

285

$$286 \text{ (Eq. 6) } \quad \mathbf{F_{atm} = F_{tot} * f_{atm}}$$

287

288 When $[\text{NO}_3^-]$ or $\Delta^{17}\text{O}$ values were not available for a given date ($n=4$, 2 and 2 for the
289 **lower montane, upper urban and lower urban streams, respectively**), they were

290 replaced by the mean $[\text{NO}_3^-]$ or $\Delta^{17}\text{O}\text{-NO}_3^-$ values measured on the previous and the
291 following dates, to capture temporal variations due to hydrological events. Note that
292 the use of instantaneous $[\text{NO}_3^-]$ to calculate weekly streams NO_3^- loads might over or
293 under estimate the real NO_3^- yield in streams.

294

295 **2.6 Statistical analysis**

296 A Mann-Whitney test was applied to surface water data to determine whether
297 mean concentrations and isotopic values were significantly different between
298 streams. A Spearman test was applied to evaluate the correlation between stream
299 water parameters (typically $\Delta^{17}\text{O}$, $\delta^{18}\text{O}$, $\delta^{15}\text{N}$ and ion concentrations). Differences
300 and correlations were considered significant when the p value was ≤ 0.05 . All
301 statistical analyses were conducted using R software (v3.2.3). Unless specified
302 otherwise, the uncertainty accompanying the mean values is the standard deviation.

303

304 **3. Results**

305 **3.1 Precipitation and discharge**

306 Cumulated precipitation was 537 and 609mm in 2015 and 804 and 740mm in
307 2016 at the upper montane and the urban sites, respectively. Discharge at the lower
308 montane site reflects a snowmelt influenced hydrological regime. It peaked up to 30
309 $\text{m}^3 \text{s}^{-1}$ in spring, and was significantly higher from April to October compared to the
310 rest of the year. Discharge at both urban sites was consistent with a hydrological
311 regime driven by snowmelt in spring-summer (main maximum), and rainfall in autumn
312 (secondary maximum), a dual contribution similar to what was obtained in the
313 Colorado Front Range (Cowie et al., 2017). At the upper urban site, discharge
314 peaked at $900 \text{ m}^3 \text{ s}^{-1}$, whereas maximum discharge was $300 \text{ m}^3 \text{ s}^{-1}$ at the lower

315 urban site, a difference due to the streams draining two distinct watersheds (Figure
316 S3).

317

318 **3.2 Comparison of dissolved solutes across sites**

319 Solute concentration varied by up to 3 orders of magnitude among
320 precipitation and streams samples (Table S2 and Figure 1). $[\text{NH}_4^+]$ was low in both
321 dry and wet deposition at the S-upper montane site, and mostly (>90%) under the
322 detection limit ($<0.02 \text{ mg L}^{-1}$) in all streams. $[\text{NO}_3^-]$ was significantly higher in rain
323 samples compared to stream samples. The highest annual mean $[\text{NO}_3^-]$ was
324 measured in the lower urban stream ($1.4 \pm 0.5 \text{ mg L}^{-1}$) and the lowest in the S-upper
325 montane stream ($0.2 \pm 0.2 \text{ mg L}^{-1}$). $[\text{NO}_3^-]$ at the N-upper montane, mid montane,
326 lower montane and upper urban sites were not statistically different (1.4 ± 1.3 , $1.1 \pm$
327 0.6 , 1.0 ± 0.6 and $1.1 \pm 0.4 \text{ mg L}^{-1}$, respectively). $[\text{SO}_4^{2-}]$ and $[\text{Ca}^{2+}]$ were both very
328 low in precipitation relative to streams. The S-upper montane stream exhibited the
329 highest annual mean $[\text{SO}_4^{2-}]$ and $[\text{Ca}^{2+}]$ (98.5 ± 39.5 and $44.5 \pm 18.2 \text{ mg L}^{-1}$,
330 respectively), followed by the upper urban stream (74.1 ± 26.9 and $35.2 \pm 13.1 \text{ mg L}^{-1}$,
331 respectively), and the lowest concentrations were measured at the N-upper
332 montane site (22.1 ± 35.9 and $16.5 \pm 16.0 \text{ mg L}^{-1}$, respectively). $[\text{Cl}^-]$ was very low in
333 precipitation samples and in most montane streams (mean values all $< 3 \text{ mg L}^{-1}$),
334 respectively. Higher annual mean $[\text{Cl}^-]$ were measured in the urban streams ($4.7 \pm$
335 1.8 and $16.6 \pm 12.3 \text{ mg L}^{-1}$ for the upper and lower urban stream, respectively).

336

337 **3.3 Isotopic composition of NO_3^- in precipitation and streams**

338 Mean annual $\text{NO}_3^-_{atm}$ isotopic values (Table S1) were non-significantly higher
339 in dry deposition than in wet deposition (significant only for $\delta^{15}\text{N-NO}_3^-$), a pattern

340 widely monitored at temperate latitudes (Beyn et al., 2014; Freyer, 1991; Mara et al.,
341 2009). Mean and associated standard deviation of $\Delta^{17}\text{O-NO}_3^-$ in precipitation and dry
342 deposition were 26.4 ± 3.2 and 24.7 ± 3.5 ‰, respectively. These values are in the
343 same range as previously reported data for $\Delta^{17}\text{O-NO}_3^-_{atm}$ (Costa et al., 2011;
344 Michalski et al., 2004; Tsunogai et al., 2010, 2016). The mean $\Delta^{17}\text{O}$ value for total
345 deposition was 25.6 ± 3.3 ‰, and was used to quantify the atmospheric component
346 of NO_3^- pools in streams (see section 2.4, Eq. 1). Mean annual total $\delta^{18}\text{O-NO}_3^-_{atm}$
347 (70.8 ± 7.2 ‰) and $\delta^{15}\text{N-NO}_3^-_{atm}$ (-4.8 ± 5.9 ‰) are also consistent with a reservoir of
348 exclusively $\text{NO}_3^-_{atm}$ (Kendall et al., 2007), and these values were used to correct
349 samples from their atmospheric $\delta^{18}\text{O}$ and $\delta^{15}\text{N}$ components (see section 2.4, Eq.2
350 and 3).

351 Significantly higher annual mean $\Delta^{17}\text{O-NO}_3^-$ was measured in montane
352 streams compared to urban streams, with the exception of the mid montane site (1.0
353 ± 0.7 ‰), which exhibited the lowest values (Figure 2a). Both upper and lower urban,
354 along with the mid montane streams were also characterized by the highest annual
355 mean $\delta^{15}\text{N-NO}_3^-$ (3.7 ± 1.0 ‰, 4.9 ± 5.6 ‰ and 4.0 ± 2.0 ‰, respectively) (Figure 2c).
356 The lake, fueled by the lower montane stream, presented the highest annual mean
357 $\Delta^{17}\text{O-NO}_3^-$ (5.1 ± 1.8 ‰) and $\delta^{18}\text{O-NO}_3^-$ (8.6 ± 6.2 ‰), and the lowest $\delta^{15}\text{N-NO}_3^-$ (-0.2
358 ± 2.4 ‰) (Figure 2a, b and c). It must be stressed out again that the lake was only
359 sampled when unfrozen (*i.e.*, late spring, summer and autumn), potentially biasing
360 NO_3^- mean isotopic values at this site.

361

362

363 **3.4 Trends in isotope composition of NO_3^- across sites**

364 Seasonal variations of stream NO_3^- isotopes and corresponding f_{atm} are
365 shown in Figure 3. The three montane streams followed a similar pattern of seasonal
366 variations in 2015 and 2016. At the S-upper montane site, $\Delta^{17}\text{O-NO}_3^-$ and $\delta^{15}\text{N-NO}_3^-$
367 were significantly negatively correlated, with brief but high $\Delta^{17}\text{O-NO}_3^-$ peaks in spring,
368 followed by a slow but continuous increase peaking late summer/beginning of
369 autumn. At the N-upper site, a saw tooth pattern in summer and autumn occurred
370 right after a small but temporally wider increase at snowmelt, in early summer. $\Delta^{17}\text{O-}$
371 NO_3^- and $\delta^{15}\text{N-NO}_3^-$ in the mid montane stream presented little variations throughout
372 the seasons, apart from a raise in $\delta^{15}\text{N-NO}_3^-$ in spring/summer 2016. $\Delta^{17}\text{O-NO}_3^-$ and
373 $\delta^{15}\text{N-NO}_3^-$ were significantly negatively correlated in the lower montane stream and in
374 the lake, with significantly higher $\Delta^{17}\text{O-NO}_3^-$ from April to October – relative to the
375 rest of the year – in a very similar way to discharge (Figure S3). Finally, $\Delta^{17}\text{O-NO}_3^-$
376 and $\delta^{15}\text{N-NO}_3^-$ were not correlated and did not vary much in urban streams, except for
377 some occasional high $\delta^{15}\text{N}$ peaks in spring and winter 2015 at the lower urban site.

378

379 **4. Discussion**

380 **4.1 NO_3^- exports in streams**

381 **4.1.1 $[\text{NO}_3^-]$ across the altitude gradient**

382 There were little differences in streams $[\text{NO}_3^-]$ along the elevation gradient
383 despite an expected higher contribution from anthropogenic activities to streams N
384 pool closer to urbanized areas (Groffman et al., 2004; Tsunogai et al., 2016). The
385 0.2-1.4 mg L^{-1} mean $[\text{NO}_3^-]$ range at the montane sites is consistent with the 0.6-1.6
386 mg L^{-1} range in other Alpine valleys (reviewed in Balestrini et al., 2013), and the 0.9-
387 1.5 mg L^{-1} range in elevated sites of the Colorado Front Range (Baron and Campbell,
388 1997; Campbell et al., 1995). The N-upper montane site had a much wider $[\text{NO}_3^-]$

389 range than the S-upper montane site, which is attributed to glacier melt influence
390 (Barnes et al., 2014; Williams et al., 2007). $[\text{NO}_3^-]$ in urban streams was low when
391 compared to other concentrations measured in urban settings, such as the Tucson
392 basin where values up to 62 mg L^{-1} were determined (Dejwakh et al., 2012) or up to
393 26 mg L^{-1} in the Gwynns Falls watershed (Groffman et al., 2004).

394

395 4.1.2 $\text{NO}_3^-_{atm}$ contribution to total NO_3^-

396 Atmospheric deposition contributed significantly more to NO_3^- pool in streams
397 at the montane sites relative to the urban sites – exception being the mid montane
398 site (Figure 2). The Chambon lake showed the highest f_{atm} , although it is possible
399 that sampling of this reservoir exclusively in summer resulted in a biased estimate of
400 mean annual $\text{NO}_3^-_{atm}$. High $\text{NO}_3^-_{atm}$ inputs in montane streams (up to 47%) clearly
401 outline the influence of the melting snowpack releasing its load of atmospheric nitrate
402 (see section 4.2.1), as widely reported elsewhere (Kendall et al., 1995; Ohte et al.,
403 2004; Pellerin et al., 2012; Tsunogai et al., 2014, 2016). The mid montane stream
404 exported the lowest proportion of $\text{NO}_3^-_{atm}$. Smoother topography gradient on this
405 watershed (slopes are 17%, Table 1) can account for this by impeding direct runoff to
406 stream during hydrological extremes (e.g., snowmelt), thus exerting a strong control
407 over NO_3^- isotopic values in the stream (Balestrini et al., 2013; Clow and Sueker,
408 2000). In addition, a smoother topography gradient also drives a higher $\text{NO}_3^-_{atm}$
409 residence time in soils that would overwrite its $\Delta^{17}\text{O}$ signature when recycled by
410 microorganisms. The low f_{atm} in urban streams is dissimilar to others results that
411 have shown an increasing f_{atm} in streams along an urbanization gradient (Riha et al.,
412 2014), or high $\text{NO}_3^-_{atm}$ inputs in urban runoff (Yang and Toor, 2016). In urban areas,
413 the combination of more impervious surface area coupled to higher atmospheric

414 deposition inputs is a strong driver that was expected to promote a higher proportion
415 of $\text{NO}_3^-_{atm}$ in urban streams, relative to montane sites. Indeed, NO_3^- atmospheric
416 concentrations in Grenoble's urban area are 10 to 100 times higher than atmospheric
417 concentrations observed at the Lautaret pass (Bourgeois, 2017; Tomaz et al., 2017),
418 which should have promoted higher $\text{NO}_3^-_{atm}$ loads in urban streams. However, higher
419 total $\text{NO}_3^-_{atm}$ loads are calculated at the lower montane site where $\text{NO}_3^-_{atm}$
420 represented 21% of the total annual NO_3^- exports (Table 2).

421 Elevated N deposition in the Alps – also illustrated by higher $[\text{NO}_3^-]$ in wet and
422 dry deposition compared to streams (Table S2) – is a well-documented phenomenon
423 (Kirchner et al., 2014; Rogora et al., 2006). Sustained nitrogen deposition in addition
424 to the steep slopes of the lower montane watershed (Table 1) can account for the
425 higher total $\text{NO}_3^-_{atm}$ flux at the montane site. Grenoble conurbation land cover is
426 mainly constituted of forest and lower vegetation (64%) followed by agricultural fields
427 (24%), and impervious surfaces (10%) are only a minor surface occupation (UE-
428 SOeS, CORINE Land Cover, 2006). $\text{NO}_3^-_{atm}$ inputs are thus likely to move to multiple
429 sinks, be biologically recycled or lost *via* different processes (e.g., denitrification,
430 photolysis (Clément et al., 2003; Ye et al., 2016)) before being collected by the urban
431 streams (Rao et al., 2014). Furthermore, a strong decoupling between atmospheric N
432 deposition and urban soils N cycling has recently been proposed, pointing at a
433 distinct urban biogeochemical N cycle – that entails that land-management practice,
434 not N deposition, is the ultimate driver of N cycling – and that would need further
435 investigation (Decina et al., 2017). Additionally, in France urban rainwater and
436 domestic wastewater are traditionally collected in the same pipe system before being
437 purified in a sewage treatment plant downstream of the cities. This would also limit
438 direct rainwater runoff to the streams, as illustrated by the statistically similar $[\text{NO}_3^-]$ in

439 urban streams compared to montane streams (Figure 1). One, or a combination of
440 several of these factors would lower $\text{NO}_3^-_{atm}$ exports in urban streams, even lower
441 than montane streams $\text{NO}_3^-_{atm}$ exports in this case. Therefore, the low f_{atm} in urban
442 streams certainly reflects the recycling and replacement of $\text{NO}_3^-_{atm}$ by terrestrial NO_3^-
443 sources along the smoother topography gradient, in a similar way to the mid-
444 montane stream.

445

446 **4.2 Links between hydrology, topography and $\text{NO}_3^-_{atm}$ exports**

447 4.2.1 Seasonal variations of $\text{NO}_3^-_{atm}$ proportion in streams

448 Seasonal variations of $\text{NO}_3^-_{atm}$ exports at the montane sites reflected the
449 influence of hydrologic and topographic features of the basins, and are thoroughly
450 discussed elsewhere (Bourgeois, 2017). The S-upper montane site exports are
451 governed by quick runoff to streams in the early stages of spring, followed by a
452 diffuse resurgence of infiltrated snowmelt water in summer and autumn. The period
453 between these two event lasts about 5 months both in 2015 and in 2016, an indicator
454 of either the water transit time in the calcareous substrate of the watershed or of the
455 aquifer refill time before flushing to the stream. The N-upper montane stream is
456 fueled by glacier melt, leading to higher $[\text{NO}_3^-]$ than its southern counterpart by 1
457 order of magnitude (Figure 1). This is a consequence of the permafrost thawing at
458 that site (Bodin et al., 2009), thus increasing nitrification and/or mobilization of stored
459 N from disturbed soils (Barnes et al., 2014; Hood and Scott, 2008; Louiseize et al.,
460 2014). Occasional higher f_{atm} at the N-upper site are triggered by rainstorm events
461 (Figure S3). The lower montane stream and the lake had very similar seasonal
462 variations of $\Delta^{17}\text{O}-\text{NO}_3^-$, featuring the gradual melting of upstream snowpack
463 throughout the growing season (May to October). The mid montane and the urban

464 streams showed no marked seasonal variation, **because of** the buffering effect of
465 soils and the higher N cycling rates inherent to more intensive land management
466 treatments **that prevented** $\text{NO}_3^-_{atm}$ inputs to streams (Table 1).

467

468 4.2.2 Groundwater and surface runoff respective influence $\text{NO}_3^-_{atm}$ proportion in 469 streams

470 Significant correlations between rock-derived solutes (SO_4^{2-} and Ca^{2+}) in all
471 streams (Figure S4) indicate groundwater contribution to streams as a unifying
472 feature along the montane to urban gradient. Varying concentrations of rock-derived
473 solutes are in good agreement with the geologic characteristics of each watershed
474 (*i.e.*, highest concentrations in the S-upper montane and the upper urban streams
475 draining calcareous basins, lowest concentrations in the N-upper montane stream
476 draining a less erodible bedrock, see Table 1 and Figure 1). In this study, year-round
477 detectable $\Delta^{17}\text{O}-\text{NO}_3^-$ translate the continuous $\text{NO}_3^-_{atm}$ exports in all streams (Figure
478 3), even during baseflow when streams are mostly fueled by groundwater. Most
479 studies focusing on NO_3^- dynamics in runoff reported $\text{NO}_3^-_{atm}$ only during stormflow or
480 snowmelt periods (Burns et al., 2009; Campbell et al., 2002; Pellerin et al., 2012).
481 However, these studies used the dual isotope approach (*i.e.*, $\delta^{18}\text{O}$ and $\delta^{15}\text{N}$ of NO_3^-),
482 which **does not** account accurately for $\text{NO}_3^-_{atm}$ in streams compared to the $\Delta^{17}\text{O}$
483 tracer (Michalski et al., 2004; Rose et al., 2015a). In a growing body of work using
484 $\Delta^{17}\text{O}-\text{NO}_3^-$ in streams, $\text{NO}_3^-_{atm}$ presence during baseflow is a unifying feature (Rose
485 et al., 2015a; Sabo et al., 2016; Tsunogai et al., 2016). In all these studies, f_{atm}
486 ranged from 1-12% in baseflow, except for a coniferous watershed in West Virginia,
487 which led to f_{atm} of 54% in stream, due to low sampling resolution (n=4). Here, f_{atm}
488 ranged from 1-20% (with a median associated error of 3%, Figure S2) in all streams

489 during the dormant season (in grey, Figure 3), somewhat higher than the literature
490 data range – because of the extended influence of snowmelt in mountainous sites
491 during the growing season. The high $\Delta^{17}\text{O-NO}_3^-$ peaks at the S-upper montane site in
492 March 2015 are due to a shorter winter this year.

493 However, even if groundwater contributed at all sites to streams water, its
494 influence on streams ionic exports **had most impact** in the urban reaches. No or near
495 static correlations between either NO_3^- isotopes or conservative ions and discharge
496 (Figure 4) imply that a geochemically equilibrated groundwater reservoir dominates
497 stream exports at the urban sites, instead of surface runoff (Hall et al., 2016).

498 Oppositely, $\Delta^{17}\text{O-NO}_3^-$ increased significantly with discharge at the lower montane
499 site, highlighting the influence of snowmelt on $\text{NO}_3^-_{atm}$ exports (Figure 4a).

500 Decreasing weathering products concentrations with high flow also evidence the
501 **decreasing contribution of groundwater towards more surficial water at snowmelt**
502 (Figure 4d and f). No significant correlation of $[\text{NO}_3^-]$ with discharge in any stream
503 implies a homogenized NO_3^- pool in groundwater reservoirs by infiltrated snowmelt
504 inputs. In line with this hypothesis, a dual isotope plot of water **illustrates** that
505 snowmelt more than rain fueled the streams, even down to the outskirts of Grenoble
506 (Figure S5). Other studies also reported similar findings of underground reservoirs
507 fed by snowmelt in mountains vicinity (Brooks et al., 1999; Hall et al., 2016; Williams
508 et al., 2009).

509

510 4.2.3 A focus on snowmelt period in montane streams

511 The intensive sampling campaign in spring 2016 at the S-upper montane and
512 the lower montane sites provided no evidence of diurnal pattern for any solutes in the
513 streams (data not shown). However, $\Delta^{17}\text{O-NO}_3^-$ **did follow** a diurnal pattern at the S-

514 upper montane site, a pattern not seen in the lower montane stream (Figure S6a).
515 Conductivity (at both sites) and discharge (lower montane site only) showed very
516 pronounced diurnal variations, highlighting the hydrological influence of snowmelt
517 during the day (Figure S6b and c), also consistent with previous studies in the same
518 location (Mano et al., 2009). At the lower montane site, discharge and conductivity
519 were negatively correlated (Figure 5d), as their diurnal variations were driven by
520 distinct hydrological regime (*i.e.*, baseflow for conductivity, snowmelt for discharge).
521 That conductivity is controlled by baseflow is also supported by significant positive
522 correlations between weathering solutes and conductivity at the S-upper montane
523 site (Figure 5c). Therefore, assuming a similar relationship between conductivity and
524 discharge **is true** at the S-upper montane stream, and considering that conductivity
525 and $\Delta^{17}\text{O-NO}_3^-$ were also negatively correlated (Figure 5a), snowmelt-induced
526 discharge **in daytime** is certainly **the driver** of the diurnal variations of $\text{NO}_3^-_{atm}$ exports.
527 Oppositely to another study showing in stream diurnal $[\text{NO}_3^-]$ variations at snowmelt
528 in northern Vermont (Pellerin et al., 2012), **no significant temporal trend in any of the**
529 **two streams was observed here. Yet, the lower montane stream was only on the**
530 **rising limb of discharge when sampled**, at the very beginning of the snowmelt period.
531 **Therefore**, the absence of observed diurnal cycle at this site at this time may not be
532 representative of day-night variations later in the season.

533

534 **4.3 Isotopic composition of $\text{NO}_3^-_{ter}$**

535 **4.3.1 NH_4^+ nitrification is the main source of $\text{NO}_3^-_{ter}$ in all streams**

536 Isotopic values of $\text{NO}_3^-_{ter}$ (*i.e.*, NO_3^- corrected from the atmospheric component
537 accordingly to Eq. 2 and 3) are reported in a dual isotope ($\delta^{18}\text{O}$ and $\delta^{15}\text{N}$) plot in
538 Figure 6. This allows the evaluation of the respective contribution of terrestrial

539 sources of NO_3^- to streams. Here, most $\delta^{15}\text{N}-\text{NO}_3^-$ in streams span a 0 to 7‰
540 range, delineating nitrification of NH_4^+ as the main source of stream NO_3^- contents
541 (Figure 6). This is in line with watersheds land cover consisting principally in natural
542 or semi-natural vegetation (Table 1), where NO_3^- fertilizers are rarely used. Only very
543 few samples ($n = 4$) had both $\delta^{15}\text{N}-\text{NO}_3^-$ and $\delta^{18}\text{O}-\text{NO}_3^-$ characteristic of NO_3^-
544 fertilizers. It is complicated to segregate the substrate of nitrification (*i.e.*, deposited
545 atmospheric NH_4^+ ($\text{NH}_4^+_{atm}$) or mineralized soil NH_4^+ ($\text{NH}_4^+_{org}$)) that led to the
546 production of NO_3^- in streams. Indeed, nitrification of $\text{NH}_4^+_{atm}$ and $\text{NH}_4^+_{org}$ produces
547 NO_3^- with overlapping $\delta^{15}\text{N}$ ranges (Kendall et al., 2007). However, a fraction of
548 samples, mostly from montane streams, had $\delta^{15}\text{N}-\text{NO}_3^-$ lower than 0‰, consistent
549 with nitrification of $\text{NH}_4^+_{atm}$ (Kendall et al., 2007; T. Liu et al., 2013).

550

551 4.3.2 Biological removal of NO_3^- was not predominant in any stream

552 Weak negative correlations between $\delta^{18}\text{O}-\text{NO}_3^-$ and $\delta^{15}\text{N}-\text{NO}_3^-$ at all sites,
553 exception made of the lower urban site, indicate that biological processes such as
554 denitrification or assimilation do not control NO_3^- cycling in streams. Indeed, such
555 processes, if dominant, should enrich residual $\delta^{18}\text{O}-\text{NO}_3^-$ and $\delta^{15}\text{N}-\text{NO}_3^-$ along a
556 positively correlated line (Granger et al., 2008, 2010; Kendall et al., 2007), in a similar
557 fashion to what is observed at the lower urban site. Yet, that $\delta^{15}\text{N}-\text{NO}_3^-$ was
558 significantly correlated to $[\text{Cl}^-]$ in this stream (data not shown) rather proves that the
559 high $\delta^{15}\text{N}-\text{NO}_3^-$ values are due to interception of sewage-originated wastewater (Hall
560 et al., 2016). Decreasing $\delta^{15}\text{N}-\text{NO}_3^-$ and $[\text{Cl}^-]$ with discharge (Figure 4b and e) at this
561 specific site also supports a groundwater origin of these nitrate pollution episodes.

562

563 4.3.3 Low $\delta^{18}\text{O}-\text{NO}_3^-$ calls for a more systematic use of the $\Delta^{17}\text{O}$ tracer

564 $\delta^{18}\text{O}\text{-NO}_3^-$ values as low as -20‰ were obtained after removing the
565 atmospheric imprint (Figure 6 and Figure S7). The mean $\delta^{18}\text{O}\text{-NO}_3^-$ ranged
566 between -6.3 and -8.0‰ in the mountainous streams, significantly lower than
567 previously reported values of terrestrial $\delta^{18}\text{O}\text{-NO}_3^-$ in freshwater systems (from -2.9 to
568 -4.2‰ in Tsunogai et al. (2016, 2014, 2010)) or produced through in vitro incubation
569 experiments (> 0‰ in Burns and Kendall (2002), Mayer et al. (2001) and Spoelstra et
570 al. (2007)). The mean $\delta^{18}\text{O}\text{-NO}_3^-$ range between -2.6 and -2.8‰ in the urban
571 streams, far lower than values > 9‰ inferred in other urban areas (Riha et al., 2014)
572 or mostly positive values in a semiarid urban setting (Dejwakh et al., 2012).

573 The theoretical range for $\delta^{18}\text{O}\text{-NO}_3^-$ (*i.e.*, theoretical $\delta^{18}\text{O}\text{-NO}_3^-$ after
574 nitrification) is -15 to 15‰, assuming soil-water and O_2 respectively contribute to NO_3^-
575 -O accordingly to $\delta^{18}\text{O}\text{-NO}_3^- = 1/3 (\delta^{18}\text{O}\text{-O}_2) + 2/3 (\delta^{18}\text{O}\text{-H}_2\text{O})$ (Kendall et al., 2007).
576 Here, a subset of 5 snow-water samples and 2 rain samples were analyzed for $\delta^{18}\text{O}$,
577 with respective mean values of -16.6 and -8.2‰. Soil-water isotopes were not directly
578 measured, but assimilated to precipitation water isotopes. Assuming $\delta^{18}\text{O}$ values of
579 air- O_2 of 23.88‰ (Barkan and Luz, 2005), we ended up with $\delta^{18}\text{O}\text{-NO}_3^- = -3.3‰$ (if
580 the end-member is snow water) and +2.3‰ (if the end-member is rain water) for NO_3^-
581 *nit*. Even though this approach comes with a number of assumptions and caveats
582 (Rose et al., 2015b; Snider et al., 2010), the calculated values are significantly higher
583 – by ca 4‰ – than the mean annual $\delta^{18}\text{O}\text{-NO}_3^-$ (Table 3). In a study focusing on an
584 estuarine system in San Francisco Bay, it was postulated that rapid recycling of NO_3^-
585 under low [NO_3^-] conditions (<0.9 mg L⁻¹) could result in an increased incorporation of
586 $\text{H}_2\text{O}\text{-O}$ atoms into the NO_3^- molecule (Wankel et al., 2006). Another work focusing on
587 nitrification in forests soils of central Japan attributed low $\delta^{18}\text{O}\text{-NO}_3^-$ to a combination
588 of O atoms exchange between H_2O and NO_2^- and kinetic isotope fractionation

589 associated with oxygen incorporation throughout the nitrification process in acidic
590 soils (Fang et al., 2012). The latter hypothesis could explain the generally acidic
591 subalpine soils characterized by slow N cycling (Robson et al., 2007), but further
592 investigation is warranted to understand the cause of ^{18}O depleted NO_3^- .

593 When calculating f_{atm} using the approach described by Barnes et al. (2008):

594

595 (Eq.7)
$$f_{atm} = (\delta^{18}\text{O}_{sample} - \delta^{18}\text{O}_{nit}) / (\delta^{18}\text{O}_{atm} - \delta^{18}\text{O}_{nit})$$

596

597 and by using either $\delta^{18}\text{O}\text{-NO}_3^-_{ter}$ or $\delta^{18}\text{O}\text{-NO}_3^-_{nit}$ as nitrification end-member,
598 significant differences between the estimated f_{atm} are obtained (Table 3). These
599 findings suggest that atmospheric NO_3^- inputs to an ecosystem are underestimated
600 (e.g., up to 6% in this study, Table 3) when calculated using Eq.7 with $\delta^{18}\text{O}\text{-NO}_3^-_{nit}$ as
601 nitrification end-member.

602

603 5. Conclusions

604 **The** results showing higher $\text{NO}_3^-_{atm}$ exports in a montane stream relative to
605 urban streams have several key implications. First, **it sheds** light on the contribution
606 of snowmelt-derived groundwater to year-round $\text{NO}_3^-_{atm}$ exports in all streams at
607 baseflow. Contamination of groundwater by $\text{NO}_3^-_{atm}$ may be a widespread
608 phenomenon, regardless of emitting sources proximity: other studies also reported
609 ubiquitous presence of $\text{NO}_3^-_{atm}$ in groundwater (Dejwakh et al., 2012; Dietzel et al.,
610 2014; Nakagawa et al., 2013; Stoewer et al., 2015). **Second, hydrological events**
611 (e.g., snowmelt) are the main controls of upland $\text{NO}_3^-_{atm}$ exports, whereas a
612 chemically equilibrated groundwater reservoir dominates discharge in urban streams.
613 In a context of climate change, with temporally shorter and shallower snow coverage

614 of altitude catchments, decreasing exports of $\text{NO}_3^-_{atm}$ by snowmelt water could result
615 in proportional $\text{NO}_3^-_{atm}$ enrichment of alpine soils. However, how this would correlate
616 with elsewhere reported snow cover removal effects on microbial communities, N
617 retention, plants biomass and soil respiration is a complex question yet to be
618 addressed (Brooks et al., 2011; Gavazov et al., 2017; Sorensen et al., 2016;
619 Vankoughnett and Henry, 2013). **Third, the association** of $\Delta^{17}\text{O}$, $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ is a
620 potent tool to unravel the respective atmospheric and terrestrial sources contribution
621 to NO_3^- pools. **To correct** the $\delta^{18}\text{O}-\text{NO}_3^-$ from its atmospheric composition enables the
622 determination of the $\delta^{18}\text{O}-\text{NO}_3^-_{ter}$, which came significantly lower at all sites than the
623 theoretically calculated $\delta^{18}\text{O}-\text{NO}_3^-_{nit}$. This resulted in significantly higher estimated
624 f_{atm} when using a more robust $\delta^{18}\text{O}-\text{NO}_3^-_{ter}$ (compared to $\delta^{18}\text{O}-\text{NO}_3^-_{nit}$) as nitrification
625 end-member in Eq.7. Studies that did not use $\delta^{18}\text{O}-\text{NO}_3^-_{ter}$ in Eq.7 to determine f_{atm}
626 may have underestimated atmospheric nitrate inputs to the environment (e.g.,
627 Barnes et al. (2008), Durka et al. (1994), Griffiths et al. (2016), Pellerin et al. (2012),
628 Sebestyen et al. (2014)). **It is recommended** that more work be conducted using the
629 triple isotope technique to revise **the assessment of $\text{NO}_3^-_{atm}$ ubiquity** in the
630 environment.

631

632 **Acknowledgments**

633 This study was supported by grants from the Labex OSUG@2020 (“Investissements
634 d’avenir” - ANR10 LABX56), the ARC – Environnement Région Rhone-Alpes, the
635 Grenoble-Chambéry DIPEE CNRS. This work also benefited from the National
636 Research Agency supports (“Investissements d’avenir” - ANR11 INBS-0001AnaEE -
637 Services and “FloodScale project” - ANR 2011 BS56 027) and from the SAJF
638 research station (UMR 3370, UGA-CNRS) infrastructures and competences. The

639 study took place on a Long Term Ecological Research site of the ZAA (Zone Atelier
640 Alpes) and the Isère Campus monitoring site is a CNRS-labeled site of the ZABR
641 (Rhône Basin Long Term Ecological Research site). We would like to thank G. Nord,
642 J.-L. Jaffrezo, F. Masson, V. Lucaire, E. Vince and C. Arnoldi for help with either
643 laboratory or field work. We also want to acknowledge J. Renaud for help with SIG.

Table 1 Characteristics of the Romanche Valley and Isere watersheds along the montane to urban gradient

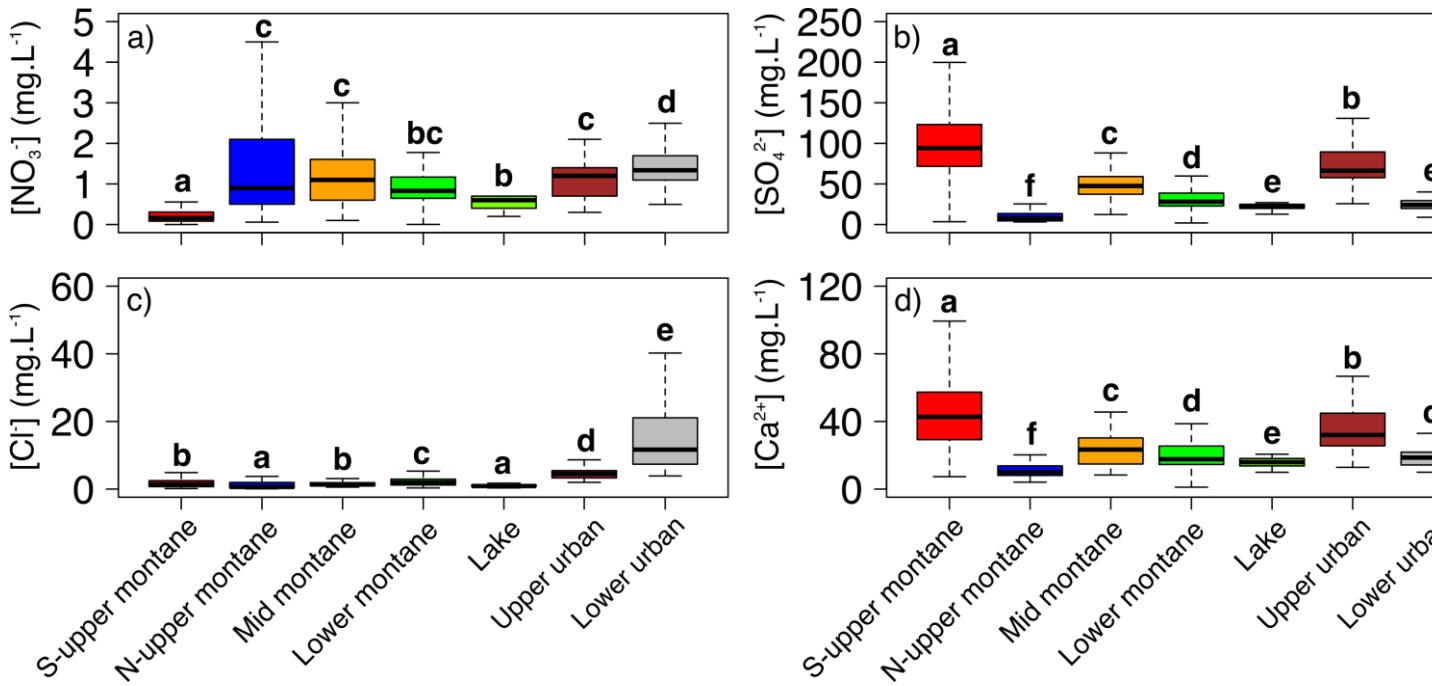

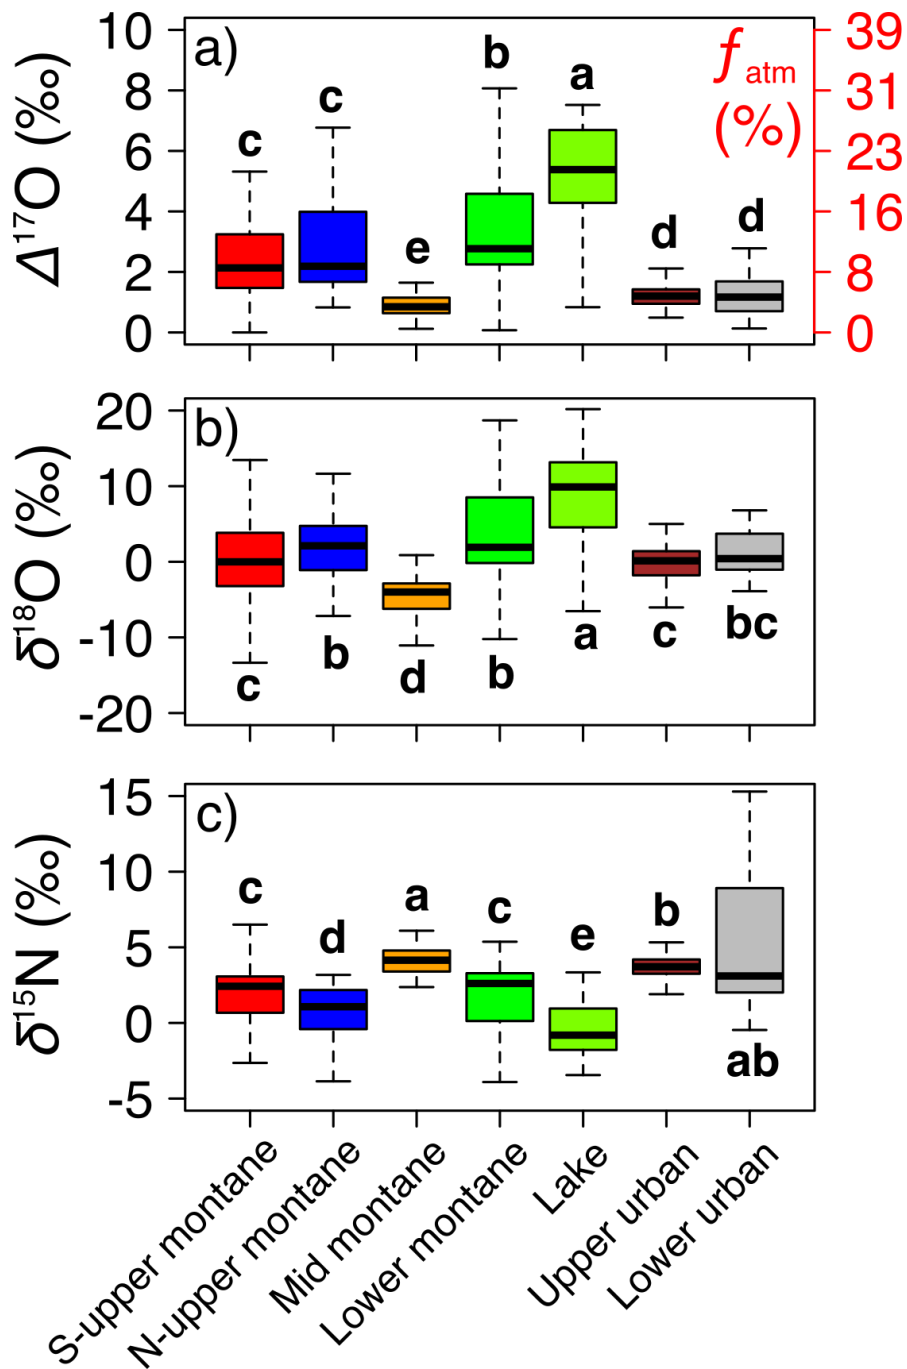

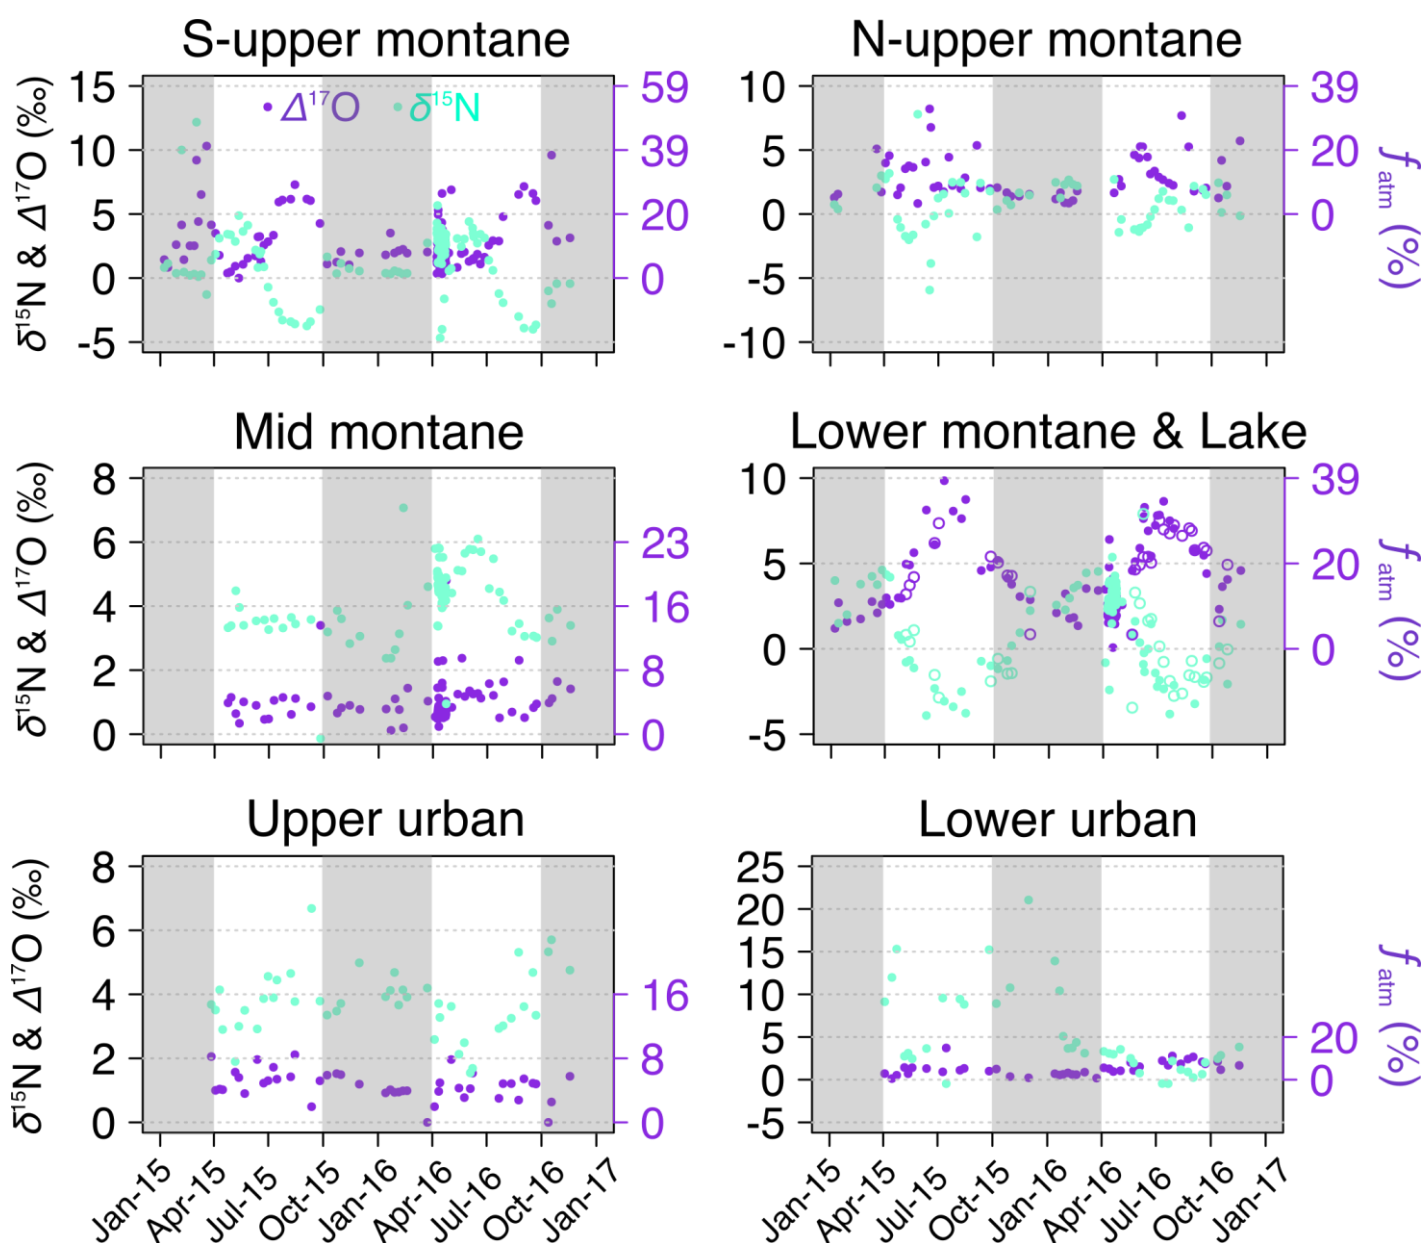

Figure 1 Two years solute concentrations in streams, with a) [NO₃⁻] (mg L⁻¹), b) [SO₄²⁻] (mg L⁻¹), c) [Cl⁻] (mg L⁻¹) and d) [Ca²⁺] (mg L⁻¹). Different letters denote significant differences in NO₃⁻ isotopic composition across sites. (e.g., a site with *ab* letters is significantly different from sites with letters from *c* onwards, but not significantly different from sites with *a* or *b* letters).

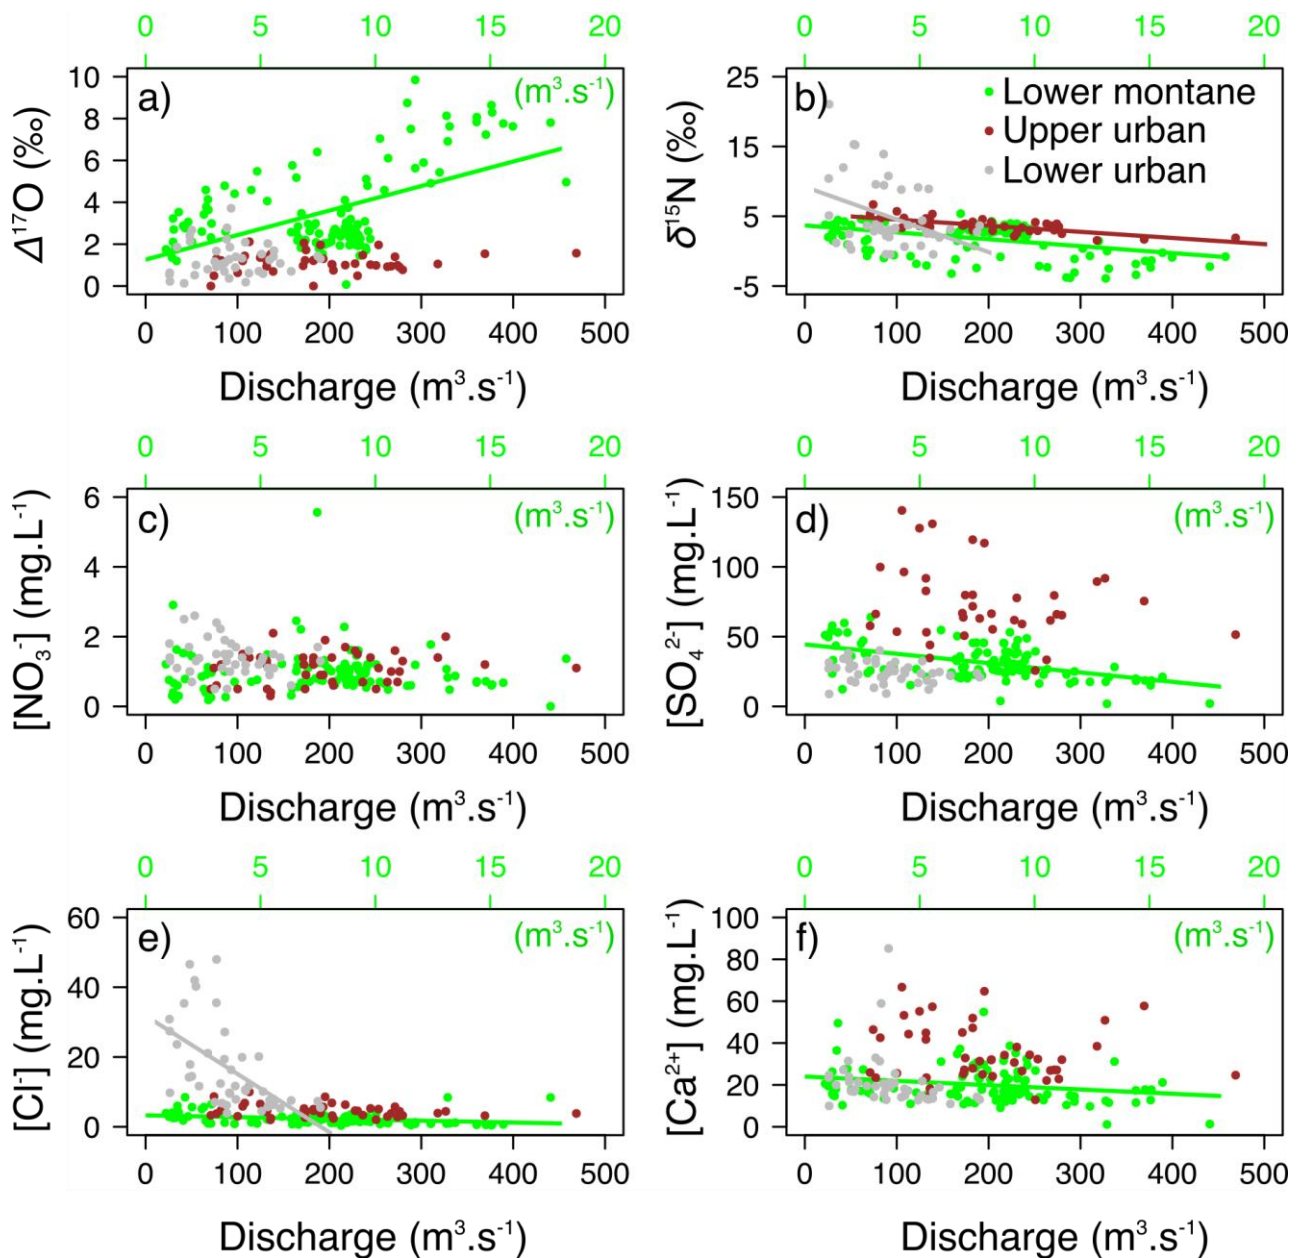

1117 **Figure 2** Two years isotopic composition of NO_3^- in streams, with a) $\Delta^{17}\text{O}$ (‰) (and
 1118 corresponding f_{atm} (%) on the red y-axis), b) $\delta^{18}\text{O}$ (‰) and c) $\delta^{15}\text{N}$ (‰). Different
 1119 letters denote significant differences in NO_3^- isotopic composition among sites (e.g., a
 1120 site with *ab* letters is significantly different from sites with letters from *c* onwards, but
 1121 not significantly different from sites with *a* or *b* letters).

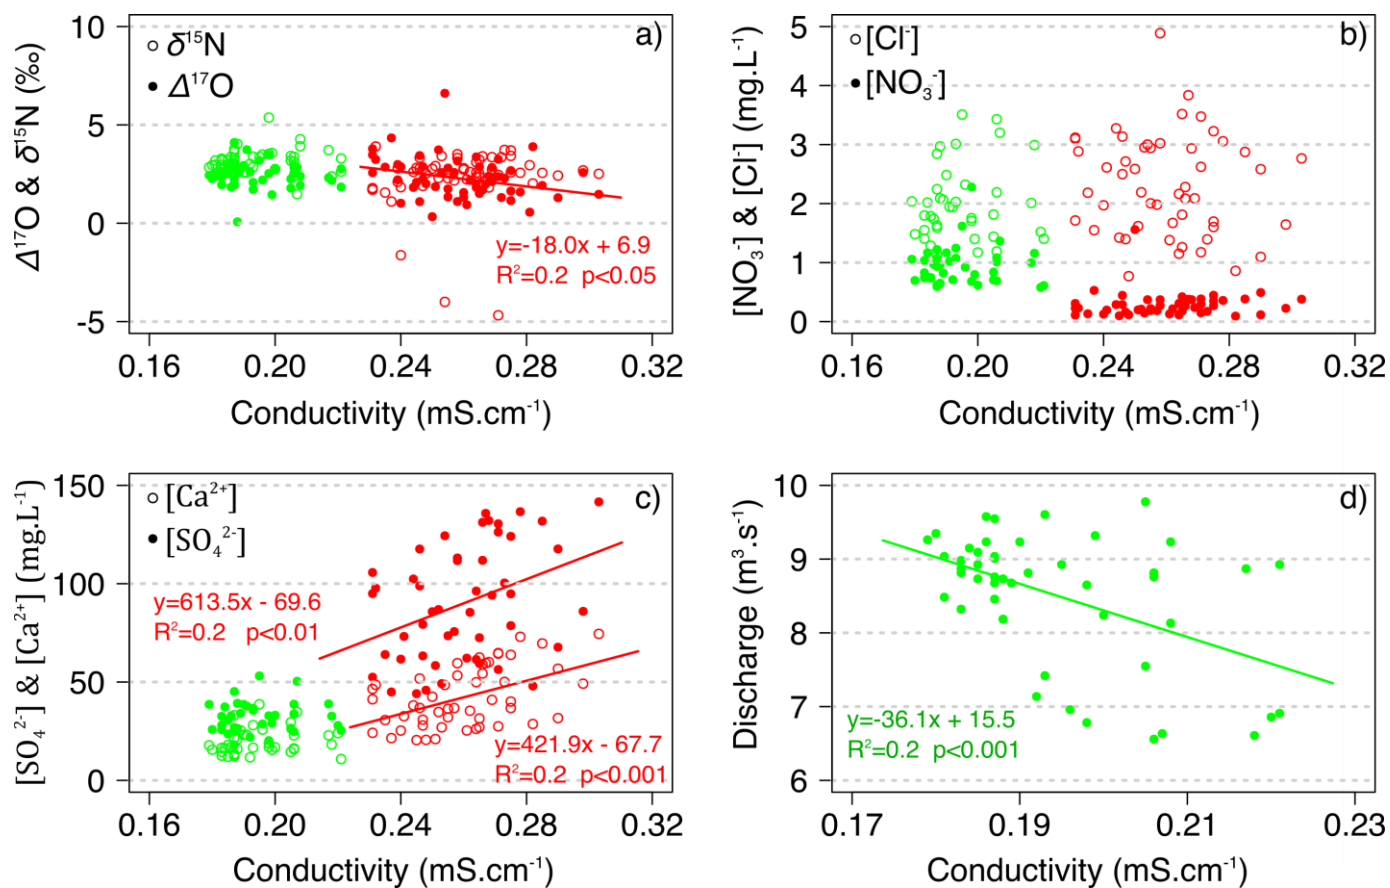

1122 **Figure 3** Seasonal variations of $\Delta^{17}O\text{-NO}_3^-$ and $\delta^{15}N\text{-NO}_3^-$ (‰) in streams. Point
 1123 colors denote isotopes as indicated in legend. Range of corresponding f_{atm} (%) is
 1124 indicated on the secondary y-axis. on the red y-axis). Highlighted in grey is the
 1125 dormant season (October-April). Note the different y-axes scales across the different
 1126 panels.

	Mean discharge-weighted annual [NO ₃ ⁻] (mgL ⁻¹)		Mean discharge-weighted f_{atm} (%) based on $\Delta^{17}O$ (‰)		Total NO ₃ ⁻ flux (kg N ha ⁻¹ yr ⁻¹)		Total NO ₃ ⁻ _{atm} flux (kg N ha ⁻¹ yr ⁻¹)	
	2015	2016	2015	2016	2015	2016	2015	2016
Lower montane	1.0	0.9	22	19	1.9	1.4	0.4	0.3
Upper urban	1.0	1.2	5	4	2.0	2.6	0.1	0.1
Lower urban	1.7	1.3	4	5	4.8	2.1	0.2	0.1

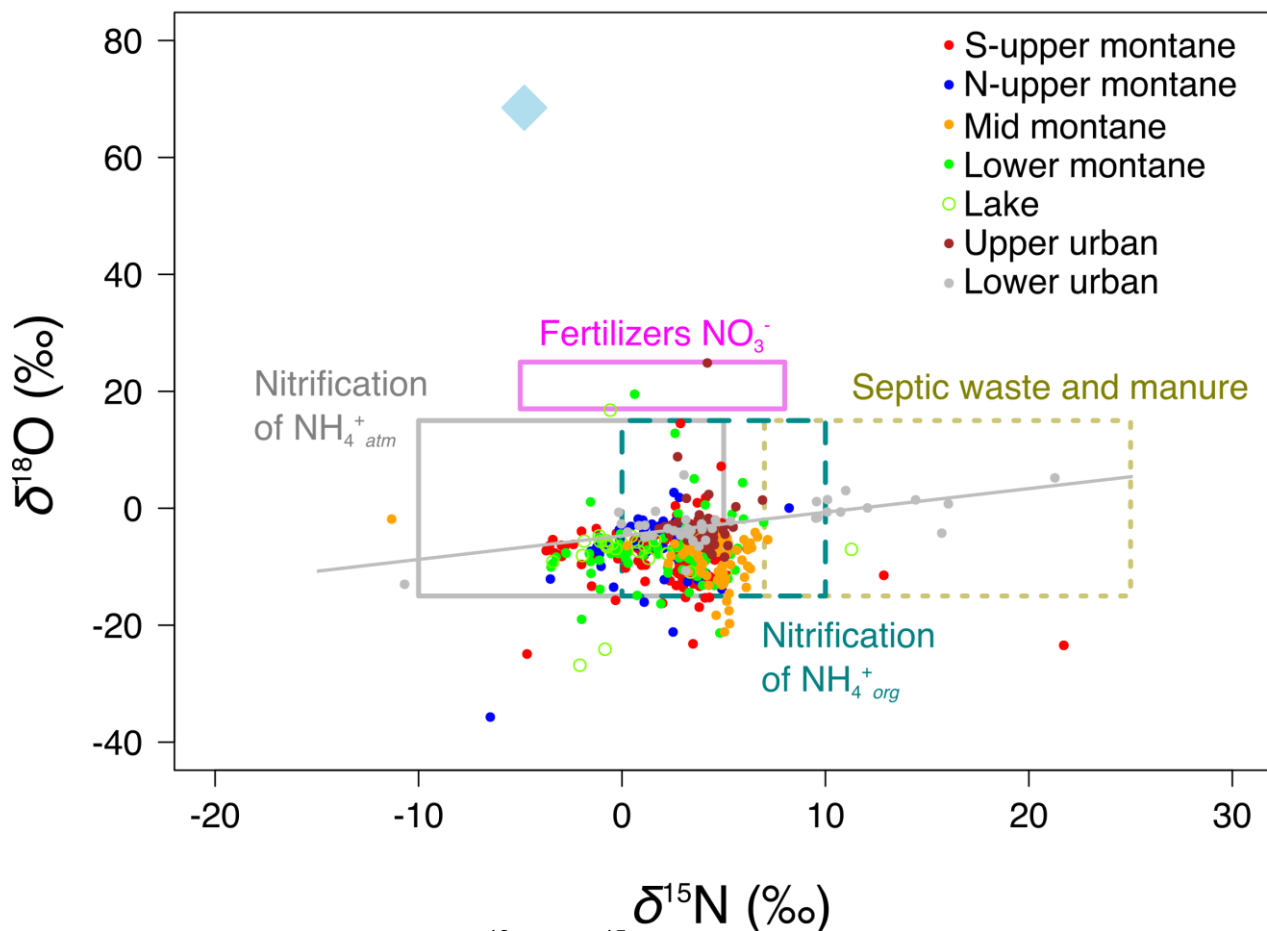

1127 **Table 2** Mean discharge-weighted annual [NO₃⁻] and associated (mgL⁻¹) and f_{atm}
1128 (%), annual fluxes of total NO₃⁻ and total NO₃⁻_{atm} in streams and deduced annual
1129 contribution of NO₃⁻_{atm} yield to the total NO₃⁻ flux at three sites along the montane to
1130 urban gradient for years 2015 and 2016.

1131 **Figure 4** Relationships of nitrate isotopes and solutes concentration with discharge
 1132 at three sites along the montane to urban gradient. Linear correlations were plotted
 1133 only if significant. Note the differences in the y-axis scales among the panels, and the
 1134 specific x-axis for discharge at the lower montane site (in green). Point colors denote
 1135 sites as indicated in legend.

1136 **Figure 5** Relationships of NO_3^- isotopes, solute concentration and discharge with
 1137 conductivity during snowmelt (April 8 to April 24 in 2016) at the S-upper montane (in
 1138 red) and the lower montane (in green) sites. Linear regressions were plotted only if
 1139 significant. Full or open circles feature either a) different NO_3^- isotopes or b) and c)
 1140 different solute concentrations.

1141 **Figure 6** Dual isotopes plot ($\delta^{18}\text{O}$ vs $\delta^{15}\text{N}$) illustrating the mixing between distinct
 1142 sources of $\text{NO}_3^-_{ter}$ (non-atmospheric) in streams. All isotopic values were obtained by
 1143 the $\Delta^{17}\text{O}$ transform of NO_3^- collected at all sites (see *Methods*). The colored boxes
 1144 represent the reported range for NO_3^- terrestrial sources, featuring atmospheric
 1145 ammonium ($\text{NH}_4^+_{atm}$) in grey, mineralized ammonium ($\text{NH}_4^+_{org}$) in turquoise, manure
 1146 or sewage derived NH_4^+ in beige and fertilizers NO_3^- in violet (Kendall et al., 2007).
 1147 Linear regressions were plotted only when significant. The blue diamond reflects the
 1148 isotopic composition of $\text{NO}_3^-_{atm}$ as measured in this study. Point colors denote sites
 1149 as indicated in legend.

	Mean annual $\delta^{18}\text{O}-\text{NO}_3^-$ (‰)	Mean annual $\delta^{18}\text{O}-\text{NO}_3^-_{ter}$ (‰) and deduced % $\text{NO}_3^-_{atm}$	Calculated $\delta^{18}\text{O}-\text{NO}_3^-_{nit}$ (‰) and deduced % $\text{NO}_3^-_{atm}$
S-upper montane	0.7 ± 6.6	-7.7 ± 4.8 11 ± 7^a	-3.3 ± 3.4 5 ± 9^b
N-uppermontane	2.8 ± 4.2	-6.3 ± 5.6 12 ± 7^a	-3.3 ± 3.4 8 ± 6^b
Mid-montane	-4.9 ± 4.1	-8.0 ± 3.7 4 ± 3^a	-3.3 ± 3.4 0 ± 5^b
Lower montane	4.1 ± 6.6	-6.8 ± 6.7 14 ± 8^a	-3.3 ± 3.4 10 ± 9^b
Lake	8.6 ± 6.2	-7.3 ± 4.8 20 ± 7^a	-3.3 ± 3.4 16 ± 8^a
Upper urban	0.9 ± 5.7	-2.8 ± 5.3 5 ± 2^a	2.3 ± 4.2 0 ± 4^b
Lower urban	1.1 ± 3.8	-2.6 ± 3.5 5 ± 3^a	2.3 ± 4.2 0 ± 6^b

1150 **Table 3** The second column gives the mean annual $\delta^{18}\text{O}-\text{NO}_3^-$ (‰) measured in
1151 streams. The third column shows the mean annual $\delta^{18}\text{O}-\text{NO}_3^-_{ter}$ (‰) after samples
1152 isotopic composition was corrected for the atmospheric imprint (see *Methods*), and
1153 the corresponding proportion of $\text{NO}_3^-_{atm}$ when using the corrected value as microbial
1154 end-member. Fourth column presents the calculated theoretical $\delta^{18}\text{O}-\text{NO}_3^-_{nit}$ when
1155 using the approach detailed in section 4.3, and the corresponding proportion of $\text{NO}_3^-_{atm}$
1156 $_{atm}$ when using this theoretical value as microbial end-member. Superscript letters
1157 indicate significant differences in the proportion of $\text{NO}_3^-_{atm}$ inferred by both methods
1158 ($p < 0.05$).
