Electrochromic device  
Non-stoichiometric Ni<sub>1-x</sub>O  
Reactive DC magnetron sputtering

## ABSTRACT

Non-stoichiometric Ni<sub>1-x</sub>O thin films were prepared on glass substrate by direct current reactive magnetron sputtering in a large range of oxygen partial pressure ( $0 \leq p_{O_2} \leq 1$  Pa). The dependence of the deposited film structure and properties on oxygen stoichiometry were systematically analyzed by X-ray diffraction, X-ray reflectivity, X-ray photoemission spectroscopy, Raman spectroscopy, atomic force microscopy, UV-vis measurements and electrical transport properties measurements. The deposition rates, surface morphology and opto-electrical properties are very sensitive to the oxygen partial pressure lower than 0.05 Pa due to the presence of metallic nickel cluster phase determined by X-ray diffraction, X-ray reflectivity and XPS spectroscopy. Presence of nanocrystallized NiO phase was highlighted even for  $p_{O_2} = 0$  Pa. For  $p_{O_2} > 0.05$  Pa, only the NiO phase was detected. Progressive appearance of Ni<sup>3+</sup> species is characterized by a fine increase of the lattice parameter and (111) preferred orientation determined by grazing angle X-ray diffraction, fine increase of the X-ray reflectivity critical angle, displacement of the Ni 2p<sub>3/2</sub> signal towards lower energy, significant increase of the electrical conductivity and decrease of the total transmittance. Quantification of Ni<sup>3+</sup> by XPS method is discussed. We also showed that the use of Raman spectroscopy was relevant for demonstrating the presence of Ni<sup>3+</sup> in the Ni<sub>1-x</sub>O thin films.

## 1. Introduction

Nickel oxide (NiO) thin films have a wide range of applications due to their excellent chemical stability, optical and electrical properties, and other kind of properties and performances. They have been widely used and mostly studied as anodic coloration materials in inorganic smart windows and electrochromic devices [1–5]. They have been also studied as hydrogen and other gas sensor materials [6], thin film transistors [7] and capacitors [8]. As a promising candidate of p-type transparent conducting films [9], nickel oxide thin films have been investigated as hole-transport interlayers in optoelectronic devices [10] and thin film diodes [11]. Among many potential applications, nickel oxide thin films have been shown excellent properties and performances as anodic coloration materials in electrochromic devices and as p-type transparent semi-conductive materials in relevant devices.

There are several methods to prepare nickel oxide films. Among them, reactive magnetron sputtering methods including Direct Current (DC), Radio Frequency (RF), and High Power Impulse Magnetron Sputtering (HiPIMS) are the most popularly used methods [1,7,12,13]. Other methods such as chemical vapor deposition [3], electrodeposition [4], pulsed laser deposition [5], epitaxial [8], low-temperature combustion synthesis [10], sol-gel deposition [14], spray pyrolysis [15] and thermal evaporation [16] are also frequently used to prepared nickel oxide thin films according to different circumstances. All of the characterized and intensively studied properties of the nickel oxide thin films as the deposition conditions like the oxygen partial pressure showed various oxygen to nickel concentration (Ni<sub>1-x</sub>O) and multiple nickel valences.

The oxidation state of the nickel in the NiO thin films is the key factor which impacts the physical properties such as the electrical conductivity and the optical transmittance. Doping or substituting elements for nickel to improve the oxide films properties has also been investigated [17].

In this work, we have been interested in non-stoichiometric nickel oxide (Ni<sub>1-x</sub>O) thin films with two potential applications motivation: anodic coloration layers in electrochromic devices [18,19] and p-type transparent conductive films [9]. In both of the

two applications oriented properties and performances, preparation methods and deposition conditions, microstructures of the films, electrical and optical properties are all critical influential factors and closely correlated to those performances. But up to now, even if there are large amount of publications on the nickel oxide thin films, there are still many unclear properties and some understanding disparities among specific experimental results. All the deposition adjustable parameters, as for instance the different substrate materials [20], are still worthwhile to be further individually studied to advance understanding of the basic physics and chemistry and to promote the applications of the nickel oxide thin film materials.

In this work, we use DC reactive magnetron sputtering to prepare nickel oxide thin films within large range of oxygen concentration in order to induce various nickel oxidation states in the films. We use detailed structural, microstructural and spectroscopic analysis as well as electrical and optical measurements to characterize the thin films in order to obtain clear information about their properties.

## 2. Experimental details

Many Ni<sub>1-x</sub>O thin films were deposited on the soda lime glass substrate at room temperature using DC reactive magnetron sputtering by introducing various Ar/O<sub>2</sub> mixture gas flow, which can be converted into different oxygen partial pressures  $p_{O_2}$  ( $p_{O_2} = (\text{flow}_{O_2} / (\text{flow}_{O_2} + \text{flow}_{Ar}) \times p_{\text{tot}})$ ) whereas the total pressure of deposition  $p_{\text{tot}}$  was kept the same for all films deposition at about 2 Pa. 60 mm in diameter round plate nickel metal target of 99.99% purity was used and distance between the target and the substrate was kept at about 100 mm. By controlling the deposition time and rate, we prepared a series of thin films with roughly similar thickness of around 300 nm under different oxygen partial pressures. The preparation conditions of Ni<sub>1-x</sub>O thin films numbered from #01 to #13 are listed in Table 1.

Before the deposition of the Ni<sub>1-x</sub>O films, all the glass substrates were cleaned in acetone, ethanol and deionized water with ultrasonic wave cleaning machine successively for 20 mins and then dried with nitrogen gas. Using a turbo molecular pump combined with a rotary pump, the sputtering chamber background vacuum reaches less than  $3 \times 10^{-3}$  Pa for each sample before its deposition. The sputtering gases flow input is mixed with argon (99.99%) and oxygen (99.99%) and the flow rates were controlled with mass flow controllers separately. Metal nickel target was pre-sputtered in an argon atmosphere for 5 min to remove the contaminations on surface before each new deposition. The thickness of the deposited films was measured using a Dektak 3030ST mechanical profilometer along a step made through a shadow mask during

the deposition. The crystal structural properties and the accurate thickness and density of the samples were analyzed by Grazing Incidence X-ray diffraction (GI-XRD) and X-Ray Reflectivity (XRR) using a Bruker-AXS D8-Advance X-ray diffractometer equipped with a copper source ( $\lambda_{CuK_{\alpha 1}} = 1.5405 \text{ \AA}$  and  $\lambda_{CuK_{\alpha 2}} = 1.5445 \text{ \AA}$ ), a Göbel mirror and Bruker LynxEye detector used in 0D/1D mode. The GI-XRD data were analyzed with the Bruker-EVA software, JC-PDF database and refined with the Rietveld method implemented in the FullProf-Suite program. The XRR data were treated with the Bruker-LEPTOS software. The surface morphologies were analyzed by Atomic Force Microscopy (AFM) with a NanoScope III Dimension 3000 microscope. A Thermo Scientific K-Alpha apparatus was used for X-ray photoelectron spectroscopy (XPS) measurements, using a monochromatic Al K $\alpha$  radiation (1486.6 eV) with a 400  $\mu\text{m}$  spot size. Peaks were scanned at 50 eV pass energy. The spectrometer was equipped with ions gun which has been used to clean the surface of the sample (200 eV during 180 s). The binding energies (BE) have been referenced to the 1 s carbon peak (atmospheric contamination) at 284.9 eV. Raman spectra were collected by using a LabRAM HR 800 Jobin Yvon spectrometer with a laser operating at 532 nm. Spectra acquisition was carried out with a  $\times 100$  objective lens and 600  $\text{g mm}^{-1}$  grating. The electrical conductivity at room temperature of the films was measured in four probes mode using the line configuration with a spacing between probes of 1.6 mm. The sizes of the film were used to calculate the shape factor correction (S) [21]. The optical transmittance and reflectance spectra were measured using a Bentham PVE300 sphere integrated UV-vis spectrophotometer over a wavelength range of 300–1100 nm at the room temperature.

## 3. Results and discussion

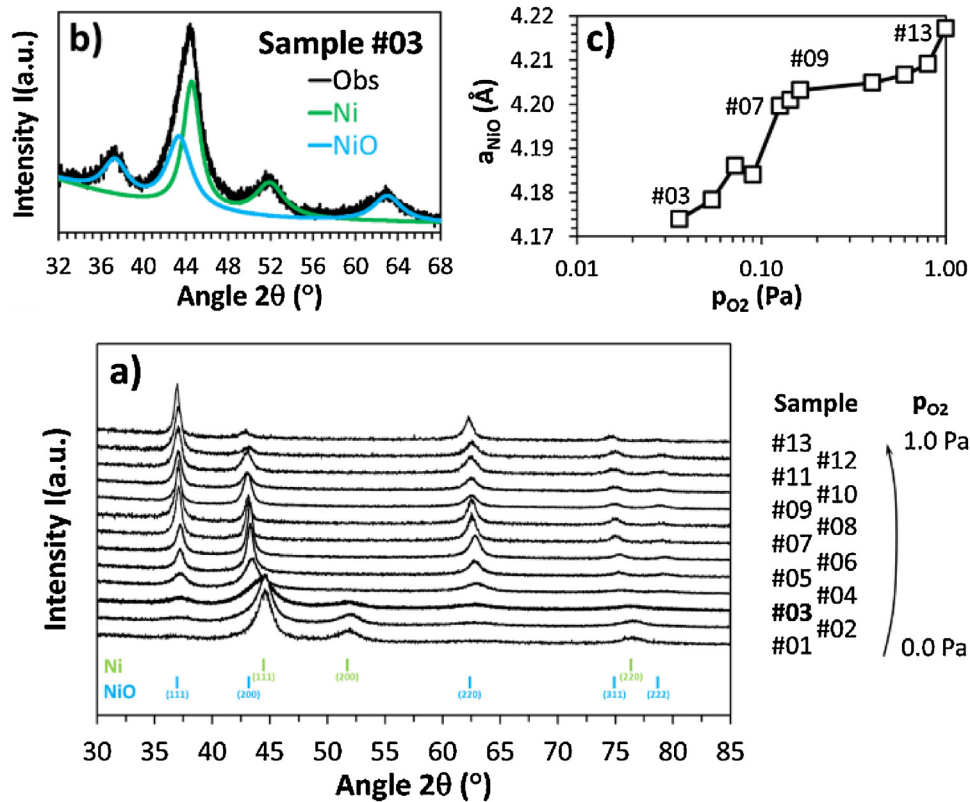

### 3.1. Deposition rate

As for the design of the experiment, the condition of the film deposition, like the deposition time, the power and the pressure of oxygen were fixed. The film thicknesses are systematically measured by profilometry and reported in Table 1. According to the fixed deposition time, the deposition rate has been calculated and also reported in Table 1 for each oxygen partial pressure ( $p_{O_2}$ ). The deposition rate is strongly dependent on  $p_{O_2}$  and it can be divided into two parts. In the first part whereas  $p_{O_2} < 0.1 \text{ Pa}$ , i.e. for samples #01 to #06, the deposition rate grows up to the maximum rate of 20.7 nm/min with the gradually increasing oxygen partial pressure. This phenomena is well known in reactive sputtering process [22–24] and is due to the progressive incorporation of oxygen in the metallic growing layer when  $p_{O_2}$  is increased. In the second part whereas  $p_{O_2} > 0.1 \text{ Pa}$ , i.e. for samples #07 to #13, we can observe that the deposition rate decreases dramatically in two steps when the oxygen partial pressure increases. It can be explained by the reaction of the oxygen with the target erosion zone which lead to the formation of less conductive oxide layer at the surface of the metallic nickel and a strong decrease of the target voltage associated to a decrease of the deposition rate.

### 3.2. Structural properties

The GI-XRD patterns of the films deposited at different oxygen partial pressures (samples #01 to #13) are presented in Fig. 1a.

The variation of the oxygen partial pressure induces big difference on the structure of the deposited films. For the lower  $p_{O_2}$ , i.e. for samples #01 and #02, characteristic (111), (200) and (220) Bragg's peaks of Ni metal (space group F m-3 m with  $a \approx 3.523 \text{ \AA}$ ) are clearly visible. With the increase of  $p_{O_2}$ , the NiO face-centered cubic rock salt structure (space group F m-3 m with  $a \approx 4.2 \text{ \AA}$ )

**Fig. 1.** a) GI-XRD patterns of samples #01 to #13 deposited at different oxygen partial pressure  $p_{\text{O}_2}$ . b) Zoom of the GI-XRD pattern of sample #03 which exhibit the Ni and NiO phases mixture as determined by Rietveld refinement. c)  $\text{Ni}_{1-x}\text{O}$  lattice parameter versus  $p_{\text{O}_2}$  deduced from Rietveld refinement.

appears notably through the increase of the (111), (200), (220), (311) and (222) Bragg's peaks between  $30^\circ$  and  $85^\circ$  in the  $2\theta$  range. Even for the very low  $p_{\text{O}_2}$  deposition conditions (sample #02 deposited at  $p_{\text{O}_2} = 0.02$  Pa but also for sample #01 deposited in pure Ar), very weak and broad peaks located at  $2\theta \approx 37.3$  and  $63.0^\circ$  are visible indicating that a few amount of nanocrystallized NiO could already be present in these samples. In these cases, the NiO phase is not really quantifiable due to the weaknesses of the peak and was noted as  $\varepsilon$  in Table 1. For sample #03 (Fig. 1b), both Ni and NiO phases are present and quantifiable in the 45%<sup>w</sup> to 55%<sup>w</sup> ratio respectively. Ni metal is still detectable for sample #04 at 14%<sup>w</sup> but completely vanishes for samples #05 ( $p_{\text{O}_2} = 0.07$  Pa) and all the other films deposited at higher  $p_{\text{O}_2}$ .

With the increase of the oxygen partial pressure during the deposition process, the lattice parameter of the  $\text{Ni}_{1-x}\text{O}$  phase ( $a_{\text{NiO}}$ ) continuously evolves as shown in Fig. 1c. A large change is first observed from sample #03 ( $a = 4.174(2)$  Å) to sample #07 ( $a = 4.1996(6)$  Å) and then followed by a smoother increasing up to sample #13 ( $a = 4.2172(1)$  Å). The first increase corresponds to the stabilization of the stoichiometric bunsenite NiO phase in low oxygen partial pressure.  $\text{Ni}^0$  tends to be fully oxidized in  $\text{Ni}^{2+}$  as demonstrated by the disappearance of Ni metallic phase after  $p_{\text{O}_2} \approx 0.07$  Pa (sample #05). Lattice parameter of sample #07 is close to the one of the bulk reference [25]. The second increase from sample #07 to sample #13, i.e. for  $p_{\text{O}_2} > 0.13$  Pa, could be attributed to the increase of nickel vacancies and concomitant introduction of  $\text{Ni}^{3+}$  species (even if ionic radii of  $\text{Ni}^{3+}$  is smaller than the one of  $\text{Ni}^{2+}$  in 6-fold octahedral coordination) as previously reported by many authors [26,27]. This phenomenon expands for the highest  $p_{\text{O}_2}$ . One can note that the peak of  $\text{Ni}_2\text{O}_3$  is never observed as crystalline phase in this work.

No specific preferred orientation is observed for the NiO phase in sample #07, but a (111) preferred orientation tends to increase

**Fig. 2.** XRR spectra of selected samples and evolution of the critical angle as a function of the oxygen partial pressure in inset.

from sample #07 to sample #13 (i.e. for  $p_{\text{O}_2} > 0.13$  Pa) as previously observed in similar films [28,29]. In the cubic NiO rock salt structure, the (111) plane corresponds to the pure compact plane of oxygen. With the oxygen partial pressure increasing, the {111} family plane shift away might be due to excess oxygen segregation at the grain boundaries [30]. Given by Seo et al. [26], this phenomenon is relevant with the increasing nickel vacancies because oxygen content is raised.

In addition to GI-XRD analysis, the surface-sensitive analysis of all the  $\text{Ni}_{1-x}\text{O}$  films have been carried out by specular X-Ray Reflectivity (XRR) and presented in Fig. 2 for selected samples.

In the XRR spectra, thickness oscillations of X-ray intensity are not visible due to the high thickness of the samples. A simple model made of glass substrate (infinite thickness,  $\rho_{\text{Glass}} = 2.38$  g cm<sup>-3</sup> and

roughness <1 nm independently characterized) and NiO layer was implemented in the Bruker-Leptos program. For each deposited film, experimental XRR data were fitted with the genetic method and allow to refine the thickness, roughness and density ( $\rho$ ) variables of the film. The critical angle ( $\alpha_c$ ) which is directly proportional to the electron density ( $\alpha_c \propto \sqrt{\rho_e}$ ) and deduced from this refinement, is reported for all the samples in the inset of Fig. 2.

The critical angles obtained for films deposited under different oxygen partial pressures are very different. The dense nickel metal leads to the large critical angle under lower oxygen partial pressure. From sample #01 to #06, i.e. in the  $0.0 \leq p_{O_2} \leq 0.09$  Pa range, the critical angle rapidly decreases from  $\alpha_c = 0.67^\circ$  down to  $0.54^\circ$ . With nickel reacting to the oxygen, the critical angle gets smaller due to the decrease of the density of the film ( $\rho_{Ni} = 8.91 \text{ g cm}^{-3}$ ;  $\rho_{NiO} = 6.72 \text{ g cm}^{-3}$ ). This behavior is also in good agreement with the increase of the deposition rate (Table 1) and the concomitant disappearance of the metallic Ni phase previously observed by GI-XRD (Fig. 1) in this  $p_{O_2}$  range.

For  $p_{O_2} > 0.10$  Pa, i.e. for sample #09 up to sample #13, the critical angle is quite stable at around  $\alpha_c \approx 0.56^\circ$ . One can note a constant increase of the critical angle for the three samples deposited with the highest oxygen partial pressure. This could be correlated to the increasing of the nickel vacancies as the formation of one nickel vacancy is accompanied by transition of two  $Ni^{2+}$  ions to  $Ni^{3+}$  ions (if it supposed that all  $Ni^{3+}$  ions are resulted from the formation of Ni vacancies) [31]. However the true nature of the non-stoichiometry taking place in nickel oxide based thin films when  $p_{O_2}$  increases, i.e. when an increase in  $Ni^{3+}$  concentration occurs, showing an increase in the critical angle still needs to be clarified.

For a better understanding of this behavior, NiO thin films deposited under various oxygen partial pressures were examined by X-ray Photoelectron Spectroscopy (XPS) and Raman spectroscopy. A commercial oxygen-rich “black” NiO powder was also analyzed for comparison. The corresponding XPS and Raman spectra are presented in Fig. 3.

Fig. 3a shows the XPS spectra of four specific films (not listed in Table 1) deposited in identical condition but with different oxygen partial pressures (0.04, 0.05, 0.11 and 0.16 Pa) in the  $p_{O_2}$  range whereas the  $Ni^0$  metal is oxidized into  $Ni^{2+}$  and potentially  $Ni^{3+}$  as previously determined by GI-XRD and XRR studies with the approximate threshold pressure of  $p_{O_2} \approx 0.1$  Pa.

Many published articles related to nickel oxides attempted to determine the  $Ni^0$ ,  $Ni^{2+}$  and  $Ni^{3+}$  concentration by the assignation of oxidation states to single identifiable peak in the Ni  $2p_{3/2}$  signal (Binding Energies BE  $\approx 850$ –870 eV) obtained by X-ray Photoelectron Spectroscopy (XPS). For example Carley et al. [32] proposed assignment of BEs of 852.6, 854.6 and 856.1 eV to Ni  $2p_{3/2}$  XPS spectra for  $Ni^0$ ,  $Ni^{2+}$  and  $Ni^{3+}$  respectively. However more recent work from Biesinger et al. [33,34] shows that envelope spectra are better fitted by using multiplet splitting. Due to peak asymmetries, complex multiplet splitting, shake-up and plasmon loss structure, overlapping binding energies, it is quite difficult to determine the proportion of different Ni valences. Moreover the possible presence of residual surface contaminant like hydroxide or oxyhydroxide species after soft surface cleaning by etching can lead to additional misinterpretations on the presence of  $Ni^{3+}$  in the NiO phase. So we will conduct only a qualitative comparison.

On the one hand, no significant difference can be observed for all samples in the Ni 2p XPS spectra related to the presence of  $Ni^{2+}/Ni^{3+}$  species (BEs higher than 853 eV). This suppose that oxygen containing species localized at the surface should be present even for the lowest oxygen partial pressure deposited sample. This is also consistent with the O 1s XPS spectra (not shown here) whereas peak located at around 530 eV is visible and reflects a local electron density around O atoms.

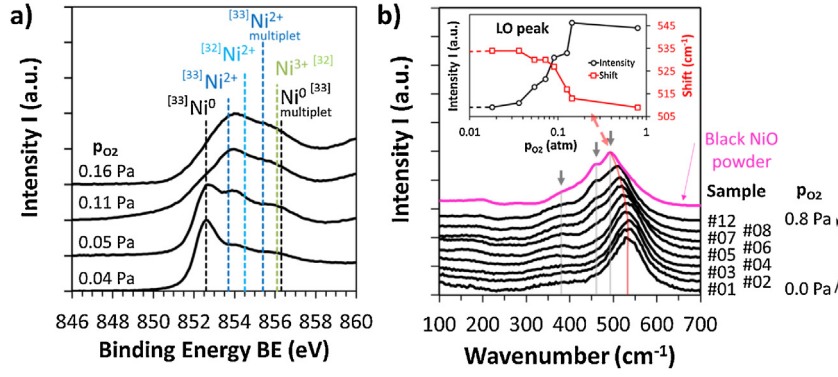

On the other hand, the spectra of the two samples deposited at the lowest oxygen partial pressure ( $p_{O_2} < 0.1$  Pa) clearly show a peak around 852.5 eV which can be definitely attributed to the presence of  $Ni^0$ . Quite logically the peak intensity for  $Ni^0$  is more pronounced in the case of the sample deposited at lower oxygen pressure. Even if they are limited in our case for the determination of the presence of  $Ni^{3+}$  species, XPS measurements confirm however the presence of nickel metal in the samples deposited at oxygen partial pressure lower than 0.1 Pa according to the X-ray experiments. It also pointed out that the sample deposited at the lowest  $p_{O_2}$  contains NiO nanocrystallized phase not quantifiable by XRD.

The Raman spectra in the 100–700 wavenumber range shows the characteristic peaks of NiO phase [35,36]. First-order Transverse Optical (TO) and Longitudinal Optical (LO) phonons modes are located at 380 and 492  $\text{cm}^{-1}$  respectively. However, black NiO which is oxygen-rich phase ( $Ni_{1-x}O$ ), presents also an additional peak that can be attributed to the non-stoichiometry. This peak is often described in the bibliography as a shoulder located in the left of the LO peak [37]. In our case, this extra peak is clearly shown in the spectra of the black NiO at 460  $\text{cm}^{-1}$ . Mironova-Ulmane et al. [38] explained the activation of the peak at 450  $\text{cm}^{-1}$  by magnetostriiction effect responsible for a slight rhombohedral distortion in NiO.

From this characterization complementary to GI-XRD, XRR and XPS, we can deduce that, even for samples deposited without oxygen, a small quantity of NiO is formed inside the metallic nickel matrix. The spectra shown in Fig. 3b are normalized for comparison but the values of the real intensities of the LO peaks are given in the inset of Fig. 3b. Below  $p_{O_2} = 0.04$  Pa, this oxide is probably nanocrystallized and then cannot be correctly observed in XRD patterns. From the variation of the intensity of the LO Raman peak, the quantity of NiO phase even for the lower oxygen deposition pressures doesn't seem to be negligible. The formation of NiO when no oxygen is used during the deposition may originate from the background gas before process gas introduction, the different micro-leaks compensated by pumping system, and from the argon gas bottle. Raman shift of LO peaks stays nearly constant in the 530–535  $\text{cm}^{-1}$  range below 0.1 Pa due to the presence of stoichiometric NiO. For higher pressures and particularly above around  $p_{O_2} = 0.1$  Pa (sample #06–#07), Raman shift increases significantly and approaches the value of the “black” NiO due to  $Ni_{1-x}O$  being more and more oxygen-rich when the oxygen deposition pressure increased. Above  $p_{O_2} = 0.14$  Pa, the evolution of Raman shift of LO peak still continues but becomes slower. Above  $p_{O_2} = 0.13$  Pa, the growth of the peak at 460  $\text{cm}^{-1}$  confirms that an oxygen-rich phase is deposited. In conclusion, the films deposited around  $p_{O_2} = 0.1$  Pa are closed to the NiO stoichiometry. Below this partial pressure threshold, the amount of oxygen is too low to form a pure NiO phase and a mixture of Ni metal and stoichiometric NiO is obtained. Above this pressure threshold, an oxygen-rich phase  $Ni_{1-x}O$  is precipitated due to the excess of oxygen in the gas mixture.

### 3.3. Surface morphology

The atomic force microscope (AFM) isoscale images of three representative films (samples #01, #07 and #13 deposited at  $p_{O_2} = 0.00$ , 0.13 and 1.00 Pa respectively) using the tapping mode are shown in Fig. 4. The bright regions of the images reflect the strong fluctuation which means there are high peaks and deep valleys on surface [12,30]. The dark regions are opposite. At  $p_{O_2} = 0.00$  Pa, the nickel and argon ions hit with each other very strongly and easily lead to the formation of crystalline phase [39]. Hence, for sample #01, the grain size are around 60 nm in diameter and film surface is rough with  $R_a = 9.1$  nm. When the oxygen partial pressure increases up to  $p_{O_2} = 0.13$  Pa, the roughness decreases as well as the grain size but in lesser proportion. At  $p_{O_2} = 1.00$  Pa,

**Fig. 3.** XPS and Raman analysis spectra of the Ni-O thin films sputtered under different  $p_{O_2}$  atmospheres: a) Ni 2p3/2 XPS spectra and comparison with bibliographical data from refs. [32] and [33]. b) Raman spectra in the 100–700  $\text{cm}^{-1}$  range. LO Raman peak intensity and shift position are reported as function of  $p_{O_2}$  in inset.

**Fig. 4.** AFM micrograph and roughness (Ra) of samples #01, #07 and #13.

**Table 2**

Ni<sub>1-x</sub>O thin film opto-electrical properties: electrical conductivity, average absorption coefficient in the 400–800 nm range and optical bandgap.

Sample No.	$p_{O_2}$ (Pa)	$\rho$ (S/cm)	$\alpha$ ( $\text{cm}^{-1}$ )	$E_g$ (eV)
#01	0.00	$2.16 \times 10^2$	$2.32 \times 10^7$	1.81
#02	0.02	$2.45 \times 10^2$	$2.88 \times 10^7$	1.81
#03	0.04	$4.00 \times 10^1$	$2.47 \times 10^7$	1.75
#04	0.05	$3.10 \times 10^{-4}$	$5.07 \times 10^6$	3.55
#07	0.13	$3.01 \times 10^{-6}$	$2.74 \times 10^5$	3.71
#08	0.14	$6.15 \times 10^{-6}$	$5.38 \times 10^5$	3.72
#11	0.60	$2.78 \times 10^{-5}$	$1.04 \times 10^6$	3.69
#12	0.80	$5.70 \times 10^{-5}$	$1.52 \times 10^6$	3.69

the film exhibits smoother surface. When the deposition process is conducted under an oxygen-enriched atmosphere,  $O\bullet$  species are generated and accelerated to the substrate by promoting an increase of the bombardment of the growing layer and then, a smoothing of the surface. It may be also attributed to the increase of nickel vacancies. With the  $p_{O_2}$  increasing, the  $Ni^0$  species tend to disappear due to the combination of the nickel atoms with the free oxygen atoms. In conclusion, the variation of the oxygen partial pressure has a big influence on the surface morphology. Nevertheless, no significant influence of the oxygen pressure on the grains size has been noticed.

### 3.4. Electrical and optical properties

The electrical conductivities of the films were reported as the function of the  $p_{O_2}$  in Table 2.

The most conducting films are those deposited under a low oxygen partial pressures ( $p_{O_2} < 0.05$  Pa): Sample #01 and sample

#02 exhibit average electrical conductivities of  $2.3 \times 10^2$  S/cm. This high conductivity value could be explained by a current percolation through a nickel clusters in the film [40]. The fact that this value is two order of magnitude smaller than the conventional attended value ( $\sigma_{Ni} \approx 5 \times 10^4$  S/cm) of pure Ni (nanocrystalline bulk or film) [41,42] is consistent with the presence of oxidized Ni species highlighted previously.

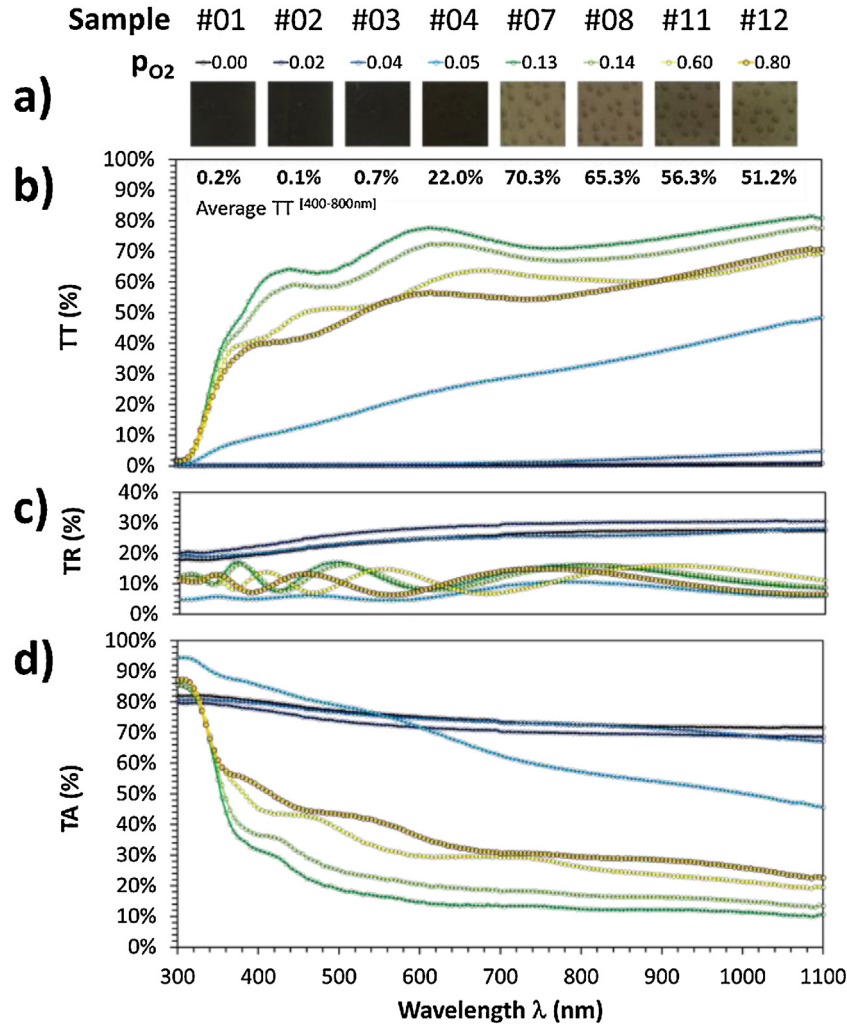

When  $p_{O_2}$  increases up to 0.14 Pa, the conductivity drastically decreases due to the increase of the NiO phase. The minimum conductivity value of  $3.0 \times 10^{-6}$  S/cm is reached at  $p_{O_2} = 0.13$  Pa for sample #07 because of the complete disappearance of the metallic nickel and the proximity of the perfect stoichiometric NiO composition which was highlighted by the previous analyses.

For higher  $p_{O_2}$  values, the conductivity slightly re-increases up to  $6 \times 10^{-5}$  S/cm when the  $p_{O_2}$  increases from the  $p_{O_2} = 0.13$  Pa to 0.80 Pa due to the appearance of nickel vacancies in the Ni<sub>1-x</sub>O material. These vacancies generate new charge carriers which contribute to the electrical conduction.

The total transmittance (TT) and reflectance (TR) as a function of the wavelength plotted for different oxygen partial pressures are reported in Fig. 5a and b. At each wavelength, the total absorbance (TA) has been calculated according to  $TT + TR + TA = 1$  and reported in Fig. 5c. Knowing the thickness of each film, the absorption coefficient ( $\alpha$ ) has been calculated according to Eq. (1) for every wavelength. An average value of  $\alpha$  in the visible range ( $400 \leq \lambda \leq 800$  nm) is reported in Table 2.

$$\alpha = \frac{1}{t} \ln \left( \frac{(1 - TR)^2}{TT} \right) \quad (1)$$

Pictures of the films placed on a medium of patterned paper and values of their average total transmittance in the 400–800 nm

**Fig. 5.** Optical properties of NiO thin films sputtered under different  $p_{O_2}$  atmosphere. a) Pictures of the films placed on a medium of patterned paper. b) Total Transmittance (TT) spectra. To illustrate the transparency of the films to natural white light, values of their average total transmittances in the 400–800 nm visible range are also indicated. c) Total Reflectance (TR) spectra. d) Total Absorbance (TA) spectra.

visible range are presented in Fig. 5a and b respectively to highlight that the optical properties drastically varies with the oxygen partial pressure.

For the thin films deposited at  $p_{O_2} < 0.05$  Pa and represented by the black and blue curves in Fig. 5: the total transmittance is very low and cannot be distinguished from the wavelength axis. The films are dark/colored and exhibit the highest reflectance of the whole series. This behavior is explained by the proportion of nickel metal (cluster) in the film which still important with these oxygen pressures.

The maximum transmittance in the visible range is obtained for sample #07, i.e. for  $p_{O_2} = 0.13$  Pa which corresponds to the mainly NiO stoichiometric composition. More than 70% of average total transmittance in the visible range is obtained. The minimum of the absorption coefficient  $\alpha$  established on the whole wavelength range has been also obtained for this film.

For the film deposited at  $p_{O_2} > 0.13$  Pa, the total reflectance of the films stays in the 10% range while the total transmittance slightly decreases. The inter-fringes present in the TT spectra are almost similar which is consistent with the lower thickness variation of the films with  $p_{O_2}$ .

The optical gap reported in Table 2 have been determined by the direct band gap Tauc's relation  $((\alpha h\nu) = A (h\nu - E_g)^{1/2})$  [43] employed from the integrated transmittance data. As shown in

Table 2, the direct band gap energy  $E_g$  increases drastically from 1.8 eV to 3.8 eV when the oxygen partial pressure increases from  $p_{O_2} = 0$  to 0.13 Pa. Once again, the presence of a band gap even for  $p_{O_2} = 0.00$  Pa prove the presence of oxidized nickel (no band gap should be obtained for pure metallic nickel phase). The maximum  $E_g$  value is equal to the 3.8 eV for  $p_{O_2} = 0.13$  Pa. The direct band gap energy is almost constant for higher oxygen pressures. This value is in agreement with those obtained in the literature [44,15,45] for the NiO phase.

#### 4. Conclusion

The  $Ni_{1-x}O$  films show apparent dependence on the variation of oxygen partial pressure  $p_{O_2}$  during the deposition process. In addition with the deposition rate analysis, a complete set of structural, microstructural and opto-electrical characterizations proves that the deposition condition used in this work allows to obtain various nickel oxidation states ( $Ni^0$ ,  $Ni^{2+}$ ,  $Ni^{3+}$ ) in the whole series.

When the  $0.00 \leq p_{O_2} \leq 0.05$  Pa, metallic nickel phase is detected by the GI-XRD, XRR and XPS technics. At the same time, GI-XRD, XRR, XPS and Raman spectrum analysis reveal that NiO is always present in these samples as minor phase. In these samples, opto-electrical properties are driven by the metallic phase (high total optical reflectance and high electrical conductivity values) but

affected in a measurable way by the small quantity of NiO formed inside the metallic Ni matrix.

Metallic nickel completely vanishes for  $p_{O_2} > 0.05$  Pa.

For higher  $p_{O_2}$ , i.e.  $p_{O_2} > 0.10$  Pa, the evolution of lattice parameter determined by Rietveld refinement as well as the preferred crystallographic orientation, XRR-critical angle, Ni 2p<sub>3/2</sub> XPS spectra, Raman Longitudinal Optical (LO) phonon modes, electrical conductivity, absorption coefficient, direct optical bandgap and surface topology (AFM) tends to prove that the stoichiometric NiO is obtained for  $p_{O_2} \approx 0.10$  Pa. Nickel vacancies and concomitant introduction of Ni<sup>3+</sup> species gradually appears for  $p_{O_2} > 0.10$  Pa without sign of additional Ni<sub>2</sub>O<sub>3</sub> phase in the films. Therefore, the as-deposited films obtained in this work can be represent as Ni +  $\epsilon$  NiO ( $0 \leq p_{O_2} \leq 0.05$  Pa), NiO ( $p_{O_2} \approx 0.10$  Pa) and Ni<sub>1-x</sub>O ( $0.13 \leq p_{O_2} \leq 1.00$  Pa).
