ABSTRACT.

Ongoing developments of sustainable energy technologies based on high-surface area semiconductive metal oxide electrodes operating under mild and safe aqueous conditions, requires deep understanding of proton and electron transfer/transport throughout their porous structure. To address this issue, we investigated the electrochemical reductive protonation of high surface area nanostructured amorphous TiO₂ electrodes (produced by glancing angle deposition) in both buffered and unbuffered aqueous solutions. Quantitative analysis of the two charge storage mechanisms was achieved, allowing proper deconvolution of the electrical double-layer capacitive charge storage from the reversible faradaic one resulting from the proton-coupled reduction of bulk TiO₂. We evidence that this later process occurs reversibly and extensively (up to an intercalation ratio of 20%) not only under strongly acidic pH conditions but also, more interestingly, under neutral pH with the intercalated proton arising from the buffer rather than water. Moreover, we show that in comparison with reductive Li⁺ intercalation, the proton-coupled electron charge storage occurs more rapidly (in a few seconds). This important finding suggests that a high-rate and high-power charge storage device could potentially be achieved with the reversible H⁺-coupled charge/discharge process in TiO₂ at neutral pH, opening thus new opportunities to the development of eco-friendly batteries for electrical energy storage.

INTRODUCTION

TiO₂-based mesoporous semiconductive electrodes have attracted exponentially-increasing attention in the past decades. The unique electrical, optical, and chemical properties of TiO₂ (including low-cost, high availability, low toxicity, and excellent chemical/photochemical stability) makes it a prime candidate in the large-scale fabrication of transparent high-surface area electrodes, and also enables an increasing range of applications in which mesoporous TiO₂ electrodes play a central role.^{1,2} Among the most promising applications are the dye-sensitized solar cells (DSSC),³ rechargeable lithium-ion batteries,^{4,5} gas sensors,⁶ electrochromic smart windows, ⁷ self-cleaning surfaces, ⁸ and photo(electro)catalytic processes for fuel generation ^{9,10} or pollutant remediation. 11 A large fraction of these applications typically require operation in dry, aprotic organic solvents (e.g. DSSC or lithium-ion batteries), which leads to issues for the environment and safety, and in some cases for long-term stability. With the increasing demand for eco-friendly and sustainable technologies, there is thus a need to work toward systems operating in aqueous electrolytes and ideally under non-corrosive conditions. Consequently, growing efforts have been made recently towards the design of TiO₂-based aqueous DSSCs^{12,13} and aqueous ion-insertion batteries, 14,15 but also the development of TiO₂-based photoelectrocatalytic aqueous cells for water-splitting, CO₂ reduction, biocatalysis, and biosensing.¹⁷

Significantly, many of the above applications incorporate complex processes of charge carrier generation, separation, transport and recombination in the metal oxide films which are currently not fully understood and predictable. This is particularly true for mesoporous TiO₂ electrodes operating in aqueous media, wherein the complex interplay between electron and proton transfer/transport strongly influences the material's behavior. It is indeed well-admitted that upon

applying negative bias to a TiO_2 electrode in strongly acidic conditions (pH < 2), protons have the ability to not only adsorb at the TiO_2 /solution interface, but also to intercalate within the metal oxide lattice according to reaction 1.

$$TiO_2 + x e^- + x H^+ \longleftrightarrow H_x TiO_2$$
 (1)

This process is also often referred to as electrochemical doping of the semiconductor. It has been reported over a wide range of TiO₂ film morphologies and crystallinities, mostly anatase nanocrystalline films¹⁸ or nanotube arrays, ^{19–21} but also rutile, ²² mixed anatase-rutile, ^{23,24}

(where x is the maximal mole fraction of protons that can be inserted in the metal oxide lattice)

nanostructured films and amorphous TiO_2 nanotube arrays. ²¹ Accordingly, proton

insertion/intercalation appears as a general feature of mesoporous TiO2 films

By analogy to Li⁺ intercalation in TiO₂, proton intercalation is assumed to result from local compensation of the loss of charge that is generated during the formal reduction of Ti^{IV} sites into Ti^{III} in the bulk material,²⁴ a process associated to a strong electrochromic effect which interpretation is still a matter of debate.^{18,22,24–26} Proton intercalation can thus be expected, similarly to Li⁺, to lead to a strong increase of the electron storage capacity of TiO₂ under accumulation conditions.^{27,28} In contrast to Li⁺ intercalation in TiO₂ that has been the subject of intense research due to its fundamental role in lithium-ion intercalation batteries,⁵ H⁺ insertion in TiO₂ has been much less investigated and many questions remain unanswered. For instance, the insertion speed, reversibility and long-term cyclability have not been determined. It is moreover not clear which parameters influence the extent of proton insertion, at which potential it occurs and if strongly acidic condition is a necessary prerequisite.

The purpose of the present work is to answer these questions by investigating the electrochemical reductive protonation of nanostructured films of amorphous TiO₂ in aqueous

solution in the presence of either a strong acid (HCl) in an unbuffered solution or a weak acid in a neutral buffered solution (HEPES buffer). Nanostructured TiO₂ films were prepared by glancing angle deposition (GLAD) on planar ITO conductive substrates, a vacuum-based physical vapor deposition method allowing well-controlled and reproducible batch-to-batch sample fabrication.²⁹ GLAD-TiO₂ films also have the advantage of an open, solution-accessible porosity, allowing a relatively free and fast diffusion of chemical species throughout the void volume of the film. These nanostructured transparent TiO₂ electrodes are thus quite advantageous for quantitative analyses of factors that may affect the coupled proton-electron transfer/transport in TiO₂ using combined optical/electrochemical techniques such as cyclic voltabsorptometry.³⁰ As will be shown in the present work, we were able to clearly distinguish between two charge storage mechanisms. The first is purely capacitive and related to charging of the electrical double-layer capacitance when the electrode is converted to its fully conductive state at negative bias potentials. The second storage mechanism occurs at a well-defined formal potential, negative with respect to the conduction band, and corresponds to a faradaic process associated with reductive proton intercalation in the solid phase of TiO₂. We demonstrate that this faradaic electron storage process is fast, electrochemically reversible, diffusion controlled, and occurs extensively at a well-defined potential not only under unbuffered strong acidic conditions but also, more remarkably, under neutral pH conditions in a buffered solution.

MATERIALS AND METHODS

Chemicals and Materials. HEPES, HEPES sodium salt (puriss. p.a.), and lithium perchlorate (puriss. p.a.) were purchased from Sigma-Aldrich. Potassium chloride (Merck & Co., puriss. p.a.) and HCl (VWR prolabo, 37%) were used as received. All aqueous solutions were prepared

with highly purified water (18.2 M Ω ·cm) obtained from a TKA MicroPure UV purification system.

GLAD-TiO₂ mesoporous electrodes. Mesoporous 1-µm TiO₂ thin films were prepared on commercial tin-doped indium oxide (ITO) conducting glass (Delta Technologies, 8-12 Ω/\Box) by the glancing angle deposition (GLAD) method followed by thermal treatment. Briefly, TiO₂ films were deposited from TiO₂ evaporant (Cerac, 99.9% pure rutile) in an electron-beam physical vapor deposition system (Axxis, Kurt J Lesker). Throughout the deposition, substrates were maintained at a 72° angle with respect to impinging evaporant flux while rotating as a feedback-controlled function of the deposition rate. Following deposition, TiO₂ was annealed at 100 °C for 24 h to ensure stoichiometric TiO₂ films and as a result, to enhance and stabilize the optical transmission of the film. Prior to electrochemical experiments, the electrodes were treated with UV/O₃ (UV/O₃ ProcleanerTM plus, Bioforce nanosciences) for 15 min, and further cleaned by subsequent immersion at room temperature in acetone and ethanol for 15 min and 30 min, respectively. A portion of the TiO₂ surface was then delimited with an insulating layer to define square working electrode areas of 0.30 ± 0.02 cm² (evaluated from a set of N = 10 independent electrodes). In the case of experiments conducted in HEPES buffer, GLAD-TiO2 electrodes were first washed in water and then pre-equilibrated in a 50 mM HEPES buffer solution (including 0.3 M KCl, pH 7.0) overnight before use.

Spectroelectrochemistry. The spectroelectrochemical experiments were performed in a one-compartment electrochemical cell using an Autolab PGSTAT-12 potentiostat controlled by GPES-4 software and coupled to a TORUS UV-visible spectrophotometer (Ocean Optics) equipped with optical fibers and a balanced deuterium tungsten source (Micropack). During

experiments, the electrochemical cell was thermostated at a constant temperature of 25°C using a dedicated Peltier-heater (Quantum Northwest). The potentiostat and spectrophotometer were synchronized through an input trigger signal generated by the potentiostat, thus allowing simultaneous recording of the optical absorbance and current as a function of the time-varying potential applied to the working GLAD-TiO₂ electrode. Electrodes were inserted in a 1 cm pathlength quartz cell, and the working TiO₂-coated ITO electrodes were positioned perpendicular to the optical path in the cell. The cell was filled with 1.2 mL buffer solution and thoroughly degassed by bubbling argon (for at least 20 min) prior to each experiment. An Ag/AgCl electrode in 3 M KCl (WPI, Dri-Ref, +0.2 V vs. NHE at 25°C) was used as the reference electrode, and a Pt wire was used as the counter electrode. Unless otherwise stated, all noted potentials are with respect to the Ag/AgCl reference electrode. Integration time was fixed to 3 ms and satisfactory signal-to-noise ratios were obtained by averaging 7 scans for experiments performed at 50 mV·s⁻¹ and 100 mV·s⁻¹, or 4 scans for experiments performed at 200 mV·s⁻¹ – 1 V·s⁻¹. The average value of ohmic drop compensation was $45 \pm 9 \Omega$ (N = 12). During experiments, argon was continuously flowed over the solution. Experimental reproducibility is attested by the good overlap of cyclic voltamograms recorded under identical experimental conditions for different GLAD-TiO₂ electrodes arising from different GLAD deposition batches (Figure S1, relative standard deviation RSD < 5%, N = 7). The reproducibility of the corresponding cyclic voltabsorptograms was not as good (RSD < 40%), suggesting a higher sensitivity of the absorbance measurement to batch-to-batch variations in the GLAD-TiO₂ samples. Experimental derivative cyclic voltabsorptograms were smoothed using a second order Savizky-Golay algorithm.

RESULTS AND DISCUSSION

GLAD-TiO₂ films. All experiments were carried out with 1-µm-thick amorphous TiO₂ mesoporous films deposited by glancing angle deposition (deposition angle of 72°) on flat conductive ITO surfaces (Figure 1). Nanostructured GLAD-TiO₂ films exhibit a high density of vertically aligned nanosized columnar structures, with a well-opened mesoporosity and controlled film thickness. From the volumetric mass density of the film (i.e. 2.5 g cm⁻³) and the bulk density of compact amorphous GLAD-TiO₂ film (3.8 g cm⁻³ for a TiO₂ film prepared with a 0° deposition angle)²⁹, a film porosity P of 0.34 can be estimated. A film surface area enhancement (SA) of 540 per µm film thickness was deduced from BET krypton gas adsorption isotherms.²⁹ It has been previously established that SA increases linearly with film thickness,^{29,31} while nanorod diameter and intercolumn spacing follow power-law growth patterns.³² In order to estimate the mean nanorod diameter (that is difficult to infer from Figure 1), we have considered a simplified geometrical representation of the GLAD films by assuming an array of uniform cylindrical nanorods homogeneously distributed perpendicular to the underlying flat ITO surface. According to this simplified picture, the mean nanorod diameter d and nanorod surface density δ were roughly estimated from both P and SA by solving the following set of two linear equations: $SA = \pi d \left(10^{-4} + d/4\right) \delta$ and $1 - P = \pi d^2 \delta/4$. Using the experimentally determined values of P and SA, the mean nanorod diameter and number density of 5 nm and 3.3×10^{12} cm⁻² were calculated, respectively.

Spectroelectrochemical studies in aqueous solution. GLAD-TiO₂ electrodes were investigated by the coupled techniques of cyclic voltammetry and cyclic voltabsorptometry, which allow simultaneous monitoring of electrical current and optical absorbance changes for TiO₂ electrodes

during cyclic potential scans at the semiconductive films.³⁰ Experiments were conducted in aqueous solutions containing a fixed concentration of KCl (0.3 M) as a supporting electrolyte.³³ The influence of different concentrations of two soluble proton donors were studied, either (i) free protons (i.e. H₃O⁺) resulting from the addition of HCl in water (pH values ranging from 7 to 1.85, equivalent thus to [H₃O⁺] concentrations ranging from 10⁻⁷ to 0.014 M), or (ii) the acidic AH form of the HEPES buffer at pH 7 (the concentration of which was altered by changing the buffer concentration C_B from 0 to 0.86 M with [AH] = $C_B/1.3$ at pH 7). The simultaneously recorded cyclic voltammograms (CVs) and cyclic voltabsorptograms (CVAs, monitored at 780 nm) under different proton donor concentrations and pHs are reported in Figures 2, S2 and S3. Cyclic scans were systematically initiated at anodic potentials where the semiconductive TiO₂ films were insulating. The potential was then increased to sufficiently cathodic potentials where TiO₂ was fully converted into a metal-like conductive film, and then the potential sweep was reversed to recover the initial insulating state. During the charging process (forward scan), all CVs and CVAs share some common features (Figures 2, S2, and S3). First of all, the current recorded at the beginning of the forward cathodic scan is very small and nearly constant, engendering no significant absorbance change at 780 nm. These observations indicate that TiO₂ behaves as an insulator within this potential window, and that the small recorded current on the CVs only arises from the double-layer charging capacitance of the underlying exposed ITO surface. At negative potentials to -0.60 V at pH 7.0 (or -0.30 V at pH 1.85), the exponential increase of current in CVs reflects both the progressive filling of electronic states that are localized in traps distributed in the band gap of TiO₂ and the filling of extended conduction band states when the applied potential becomes sufficiently negative (i.e., when it is raised close to the TiO_2 conduction band edge potential of $E_{CB} \sim -0.75$ V vs. Ag/AgCl at pH 7.0 or -0.45 V vs.

Ag/AgCl at pH 1.85).²⁵ This transition thus characterizes the increase of the Fermi level of electrons in the TiO₂ film and also the transition from an insulating to a conductive state by increasing the chemical capacitance (C_{chem}) of the semiconductive material. (To preserve the electrical neutrality, negative charges accumulated in TiO2 are assumed to be compensated by electrosorption of cations at the metal oxide interface). 1,34 This process is associated with a simultaneous increase of the TiO₂ film absorbance monitored at 780 nm. Accumulated electrons can thus be quantitatively analyzed in CVs through the exponential increase of current occurring from an onset potential less negative than E_{CB} , but also in CVAs through absorbance increase in the near-IR region from the same onset potential (an increase which linearly scales with the amount of electrons accumulated in the semiconductive material). 18,26 As attested by complete restoration of the initial metal oxide transparency upon scanning the potential back in the anodic direction, the charging/discharging process is fully reversible under the present experimental conditions, indicating complete removal of all injected charges. The onset potential at which both current and absorbance start to increase is pH dependent, showing a 60 mV anodic shift per unit of pH decrease, fully consistent with the reported Nernstian pH dependence of the TiO₂ conduction band edge. 35,36 The potential at which the amorphous GLAD-TiO₂ electrode becomes fully degenerate at pH 7.0 (i.e., at E < -0.75 V vs. Ag/AgCl, corresponding also to the transition from the exponential growth of the current to a constant double-layer capacitive current) is also consistent with the E_{CB} reported for sintered nanoparticulate films of anatase at the same pH (-0.8 V vs. SCE).²⁵ One may however notice that the onset potential at which the film transitions from an insulating to a conductive state is steadily downshifted as the scan rate is increased, suggesting a transition process which does not occur at thermodynamic equilibrium within the range of scan rates explored (0.05 to 0.5 V·s⁻¹). It seems thus that there is a kinetic barrier in the

delivery of electrons to the semiconductive material that for the moment we cannot clearly interpret and which is beyond the scope of this work.

Once the applied potential lies within the potential window corresponding to the fully conductive state of TiO₂, shapes and magnitudes of both CVs and CVAs exhibit strong differences and changes as a function of the proton donor concentration (Figures 2, S2, and S3). Two distinct behaviors can be clearly identified as detailed below.

Low proton donor concentrations (unbuffered aqueous solutions of pH > 3.5 or poorly buffered aqueous solutions with [AH] < 5 mM). For very low acid concentrations and for potentials more negative than the conduction band edge of TiO₂, CVs display a rectangular-shaped current response almost independent of the applied potential and scaling linearly with the scan rate (Figures 2 and also Figures S2, S3 wherein CVs are normalized to the scan rate). This behavior is typical of the double-layer capacitive charging current that can be recorded at a high surface area electrode immersed in an inert supporting electrolyte (differing from the chemical capacitive charging current by its independence from the applied potential). This is corroborated in CVAs by the near overlap of absorbance change between the forward and backward potential scans at 0.1 V·s⁻¹ (absence of significant hysteresis), a behavior that is reminiscent of a fast charging/discharging of a double-layer capacitive current. Since the double-layer capacitance (C_{dl}) is connected in series with the chemical capacitance, it can only be assessed when C_{chem} >> C_{dl} (i.e., at potentials more negative than the E_{CB} of TiO₂). ^{30,34}

It is worth mentioning that CVs normalized to v at neutral pH (Figures S2) do not all completely overlap in the lowest range of negative potentials; under -1.1 V, a small rise of current is observed and accompanied by a concomitant increase in absorbance at 780 nm. We assume that

this arises not from the hydrogen evolution reaction (HER) as often assumed, but from the reductive coloration of the underlying ITO substrate, a phenomenon that was recently ascribed to the reductive formation of metallic nanoparticles of indium and tin at the ITO surface and which strongly depends on the electrolyte composition and pH. ^{37,38} Control CV experiments were thus performed at bare ITO electrodes under the same experimental conditions as those for GLAD-TiO₂ electrodes, and the same increases in current and absorbance were observed at potentials more negative than -1.0 V (not shown).

The above results allowed us to conclude that when the applied potential is more negative than E_{CB} and when there is no significant concentration of free protons or weak acid in solution, the GLAD-TiO₂ electrode behaves like a high surface area electrical capacitor. Assuming that at low proton donor concentration the CV current is purely capacitive at pH 7.0 in the potential window -0.7 to -1.1 V, an average electrical capacitance density of 18 ± 2 mF·cm⁻² (i.e. normalized to the geometric electrode area) can be inferred (which also corresponds to a specific double-layer capacitance of 72 F·g⁻¹), which is far more than expected for a standard flat conductive electrode in an electrolyte solution (10-40 µF·cm⁻²).^{39,40} The value is, however, consistent with the large specific surface area generated by the quasi-metallic GLAD-TiO2 films at these potentials. Once corrected for film surface area enhancement (i.e. 540 µm⁻¹), an intrinsic capacitance density of 33 $\mu F \cdot cm^{-2}$ was found for the degenerate semiconductive film, a value that is close to the theoretical one (10-20 μF·cm⁻²) calculated for a flat conductive surface in an aqueous electrolyte solution. 41 The measured capacitance density, however, is in the lower end of values previously reported for nanocrystalline films of TiO_2 in aprotic solvents (30-120 $\mu F \cdot cm^{-2}$), ⁴²⁻⁴⁴ which is unsurprising in light of the fact that all of the previously-reported intrinsic capacitances were determined in the presence of lithium cations. These cations complicate the accurate estimation

of the true capacitive contribution on account of their intercalating faradaic contribution to the current. Another factor that can also significantly affect a reliable evaluation of the intrinsic capacitance density is the extent of correlation between the inner surface area of the nanostructured electrode (i.e., measured using the BET measurement, see Materials and Methods section) and the effective electroactive surface area.

High proton donor concentrations (unbuffered aqueous solutions with pH < 3.5 or buffered aqueous solutions with [AH] > 5 mM). Upon either increasing the buffer concentration (up to 860 mM at pH 7) or decreasing the pH below pH 3, the shapes and magnitudes of current/absorbance changes in CVs/CVAs are strongly modified and increased for cathodic potentials wherein TiO₂ is conductive (Figures 2, S2 and S3). The strong increase in current is linked to the growth of a broad reversible wave on top of the capacitive current. Depending on the pH, this reversible wave is centered on formal potentials ($E^{0'}$) of -1.06 V vs. Ag/AgCl at pH 7.0 (0.1 M HEPES) and -0.68 V vs. Ag/AgCl at pH 1.85 (Figure 2 and Table S1), exhibiting thus a shift of -74 mV per unit of pH, which is again reminiscent of the -60 mV pH dependence of the E_{CB} of TiO₂. ^{1,36} The current of this reversible wave is clearly not proportional to the scan rate as shown from CVs normalized to v in Figure S2 and S3. In order to further analyze this wave, CVs recorded at different proton donor concentrations were systematically corrected for the electrochemical double-layer capacitance contribution by subtracting the CVs obtained under negligible proton donor concentration (i.e. by subtracting the CVs in 0.3 M KCl). Once corrected for capacitive current and normalized to \sqrt{v} , the resulting CVs gathered in Figure S4 show good overlap, especially in terms of magnitudes of cathodic and anodic peaks. These results clearly demonstrate that the reversible wave is proportional to \sqrt{v} over the entire range of buffer concentrations and pHs investigated in this work (Figure 3), a behavior that strongly supports the

occurrence of a reversible faradaic process rate-limited by diffusion-controlled mass transport. On account of its $E^{0'}$ position, strong dependence on proton donor concentration, and also diffusion-controlled response, the reversible wave can be reasonably ascribed to the reversible faradaic reduction of Ti^{IV} sites in the metal oxide lattice coupled with proton uptake for local charge compensation. Depending on the experimental conditions, this proton-coupled electron transfer reaction, when fast, can be assumed to be rate-limited either by the solid-state diffusion of protons inserted within the TiO₂ lattice or by the solution diffusion of proton donors in the bulk electrolyte. This process is formally equivalent to the Li⁺-coupled electron transfer reaction occurring in intercalation metal oxide materials, a process that has been and continues to be widely studied based on its great importance in the field of Li-ion batteries.^{4,5} Compared to the CVs reported in literature for Li⁺ intercalation in nanocrystalline TiO₂ films, it is remarkable here to note the rather high electrochemical reversibility of proton intercalation (characterized by a small potential separation between the anodic and cathodic peaks, i.e. $\Delta E_p < 0.23 \text{ V}$ at 0.1 V·s⁻ ¹, see Table S1), as compared to corresponding reports for Li⁺-intercalation in nanocrystalline TiO₂ films ($\Delta E_p > 0.4 \text{ V}$ at CV scan rates < 10 mV·s⁻¹).^{43–45} The poor reversibility of lithium ion intercalation is often associated with crystallographic phase changes during the faradaic process, so the good electrochemical reversibility we observed here for H⁺ intercalation suggests that crystallographic variations may not be a major issue. The disordered structure and defects in amorphous TiO₂ may also contribute to facilitate the interfacial proton-coupled electron transfer reaction.

In order to get deeper insights into the diffusion-limited faradaic charge storage process, the electron flux density of the cathodic peak $\phi_{f,p}$, normalized to \sqrt{v} , was plotted as a function of the proton donor concentration (Figure 3). Provided that the proton donor concentration in solution

remains low, the data clearly show a linear relationship which is indicative of a process ratecontrolled by the diffusional mass transport of proton donors in the electrolyte. Upon further increasing the proton donor concentration (i.e. > 100 mM), a progressive deviation from linearity with a tendency to asymptotically reach a maximal value at high buffer concentrations is welldiscerned at pH 7.0. That the diffusion-controlled cathodic peak current is independent of the proton donor concentration at high buffer concentrations, but still proportional to \sqrt{v} , allows us to conclude that the faradaic process is now rate-controlled by the solid-state diffusion of protons within the TiO₂ lattice, rather than by the mass transport of proton donor in solution (the latter being sufficiently fast to support the redox process at the interface under these conditions). Such a transition from one limiting case to the other was unfortunately not observable under acidic pH conditions for the reason that we were unable to perform CV experiments at pH < 1.0 without generating an irreversible loss of the electrical properties of TiO₂ together with a concomitant and permanent coloration of the metal oxide film. (This blue/black coloration was observed after exceeding a certain charge accumulation threshold or upon scanning the potential into excessively negative values). Such an abrupt alteration of the physico-chemical properties of TiO₂ might be related to a significant structural/morphological change of the metal oxide lattice, which under strong electron/proton accumulation may lead to delamination or breakage/collapse of the GLAD-TiO₂ film.

From the above experimental observations, it can be concluded that the charging/discharging process related to the reversible proton-coupled reduction of Ti^{IV} ions can, depending on the experimental conditions, be rate-limited by any of (i) the mass transport of proton donor in solution, (ii) the solid-state diffusion of protons in the TiO₂ lattice, (iii) the interfacial proton-coupled electron transfer, or (iv) a mixed control of these different processes (Scheme 1).

Another important finding from the above results is that the aqueous solvent is an ineffective proton donor in comparison to the acidic form of HEPES or H_3O^+ . This might be explained by the very low acidity of water ($pK_a = 14$ which is 6.5 orders of magnitude higher than the pKa of the HEPES buffer), which would suggest that the thermodynamic ease with which the proton donor can deliver a proton to the metal oxide is a key factor in the proton intercalation mechanism.

Intercalation process. The proton-coupled reduction of Ti^{IV} is assumed to be induced at the metal oxide/electrolyte interface. It thus involves the soluble proton donor locally available at this interface, which according to the experimental conditions, can be either free protons in solution or the acidic form [AH] of the buffer (in the present case, the zwitterionic protonated form of HEPES). We can thus write the following electron transfer reactions at the metal oxide interface for each proton donor:

$$Ti^{IV}O_2 + e^- + H_3O^+ \longrightarrow Ti^{III}(O)(OH) + H_2O$$
 (2)

$$Ti^{IV}O_2 + e^- + AH \longrightarrow Ti^{III}(O)(OH) + A^-$$
 (3)

These reactions are expected to occur more favorably at grain boundaries where interfacial Ti^{IV} sites are more accessible and solvent-exposed. According to the high specific surface area of GLAD-TiO₂ electrodes and the high surface concentration of Ti^{IV} ions, these reactions are assumed to provoke massive consumption of the proton donor present at the metal oxide/electrolyte interface (i.e., in the void volume of the porous film). Under these circumstances, consumption is sufficient to rapidly induce rate-limitation by the mass transport of proton donor from the bulk solution. This is especially true when the working concentration of

proton donor is low, thus leading to a current response of the diffusion-controlled reversible wave linearly dependent on the soluble proton donor concentration.

Once surface Ti^{IV} sites are reduced and charge compensated by protonation, we can assume that the paired electron/proton couple (e⁻/H⁺) can be transferred between adjacent titanium ions localized in the sub-surface region of the amorphous TiO₂ material, formally according to the following electron-proton transfer reaction:

$$Ti^{IV}O_2 + Ti^{III}(O)(OH) \rightleftharpoons Ti^{III}(O)(OH) + Ti^{IV}O_2$$
 (4)

This mechanism of charge transfer propagation throughout the metal-oxide lattice can be assumed to be equivalent to a diffusion-like process considering an isotropic random walk of e^{-}/H^{+} throughout the TiO_2 lattice. (It is worth noting that in this process, electrons may not originate from hopping electron transfer reactions between adjacent titanium ions, but rather from transfer with electrons accumulated in the delocalized states of the conduction band. Therefore during this e^{-}/H^{+} migration, only protons can truly be considered to hop between adjacent titanium sites.) To determine the rate of this solid-state diffusion-like process, it is essential to ensure that the mass transport of proton donor in solution does not play a role. Such a situation is encountered in Figure 3 when the magnitude of the reversible wave is nearly independent of the proton donor concentration.

The linear relationship observed between $\phi_{f,p}/v^{1/2}$ and the soluble proton donor concentration, [H], at low and intermediate concentrations, in Figure 3 (i.e., < 100 mM) is typically associated with the first situation where the diffusion-controlled reversible current response is limited by mass transport of the proton donor. If we assume a Nernstian interfacial reaction (i.e., a fast

reversible proton-coupled electron transfer reaction), the following Randles-Sevcik equation can applied for both reactions 2 and 3 at low proton donor concentrations:^{40,47}

$$\frac{\phi_{f,p}}{v^{\frac{1}{2}}} = \frac{i_{f,p}}{FSv^{\frac{1}{2}}} = 0.4463\sqrt{\frac{F}{RT}}\sqrt{D_{H,out}}[H]$$
 (1)

where $\phi_{i,p}$ and $i_{f,p}$ are the faradaic peak flux density (C·mol⁻¹·cm⁻²) and peak current (A), respectively, v is the scan rate (V·s⁻¹), S is the delimited geometric electrode area (or projected electrode area, cm²), $D_{H,out}$ is the diffusion coefficient of proton donor in the bulk aqueous solution (cm²·s⁻¹), and [H] is the concentration of proton donor in solution (mol·cm⁻³). The geometric electrode area is utilized in this equation due to the fact that the diffusion layer thickness of soluble proton donor is much larger than the 1-µm film-thickness of GLAD-TiO₂ within the range of scan rates used in the present study. From the linear regression fit of eq 1 to the linear part of experimental plots in Figure 3, it becomes possible to determine the diffusion coefficient $D_{H,out}$ of each proton donor we have investigated. Diffusion coefficients of 3 × 10⁻⁵ cm²·s⁻¹ and 1.5 × 10⁻⁶ cm²·s⁻¹ were found for H₃O⁺ and the protonated form of HEPES, respectively. These values are in good agreement with the diffusion coefficient values reported in the literature (i.e. 2.3×10^{-5} cm²·s⁻¹ for H₃O⁺ ^{48,49} and 6.2×10^{-6} cm²·s⁻¹ for HEPES, ⁵⁰ both at 25°C).

In highly concentrated solutions of proton donor, it was not possible to definitely reach the limiting case where $\phi_{f,p}$ is uniquely rate-controlled by the apparent diffusion of H⁺ in TiO₂, however, the apparent diffusion coefficient of protons within the metal oxide lattice could be estimated from the maximal electron flux density that was extrapolated at high buffer concentrations in Figure 3 (dotted black line). Under this limiting case, eq 1 no longer applies

and must be modified to consider reaction 4 as the rate-limiting diffusion-like process. On account of the small solid-state diffusion coefficients reported for cations in TiO_2 ($10^{-13}-10^{-17}$ cm²·s⁻¹), ^{42-44,51-55} the diffusion length of H⁺ within the bulk metal oxide is expected to be much smaller than the smallest dimension of nanorods (5 nm diameter) such that the proton gradient can be considered as a semi-infinite linear diffusion-like process occurring normal to the metal oxide interface (i.e., normal to the vertical walls of the nanorods). Under these conditions, the following Randles-Sevcik equation can be used (assuming again a Nernstian redox reaction):

$$\frac{\phi_{f,p}}{v^{\frac{1}{2}}} = \frac{i_{f,p}}{FSv^{\frac{1}{2}}} = 0.4463\sqrt{\frac{F}{RT}} \frac{S_e}{S} \sqrt{D_{H,in}} x C_{Ti}^0$$
(2)

where S_e (in cm²) is here the specific electroactive surface area of the mesoporous electrode, $D_{H,in}$ (in cm²·s⁻¹) is the apparent diffusion coefficient of H⁺ within the metal oxide lattice, C_{Ti}^0 (0.048 mol·cm⁻³) is the maximal concentration of titanium ions in amorphous TiO₂, and x is the maximal mole fraction of protons that can be inserted in the fully reduced phase H_xTiO₂. This equation can thus be used to calculate the diffusion coefficient of H⁺ within the TiO₂ lattice using the limiting value of $\phi_{fp}/v^{1/2}$ extrapolated in Figure 3 (dotted black line, $\phi_{fp}/v^{1/2} = 1.1 \times 10^{-6}$ mol cm⁻²·s^{-1/2}·V^{-1/2}). Two issues must, however, be considered. First, an appropriate estimate of the maximal value of x must be available. Unfortunately, we were experimentally unable to reach full reduction of TiO₂ before permanent failure of the GLAD-TiO₂ electrode. The second issue is related to the difficulty of reliably evaluating the true specific electroactive surface area, S_e , through which the proton-coupled charge transfer occurs, an area which does not necessarily correspond to that determined by BET. This is indeed supported by the idea that ion-insertion may not occur homogenously at the electrolyte/metal oxide interface but preferentially via

percolation channels within single grains, as it has been recently demonstrated by nanoscale imaging of a lithium titanate surface at various states of Li⁺ intercalation.⁵⁶ Consequently, the diffusion coefficient for ion intercalation determined from eq 2 is an apparent value (one can finally hardly deconvolute the two parameters contained in the $S_e \sqrt{D_{H,in}}$ product).

Assuming a S_e value of 540 cm² (estimated from BET) for the 1- μ m thick GLAD-TiO₂ film and a mole fraction x = 0.5 by analogy to that usually reported for Li⁺ in anatase, ^{5,52} an apparent solid-state proton diffusion coefficient of $D_{H,in} = 10^{-15}$ cm²·s⁻¹ is obtained. From such a value, the penetration length, l, of protons within the metal oxide lattice during the time course of a typical CV experiment can be estimated using eq 3, where t is the charging time of the experiment.

$$l = \sqrt{\pi D_{H,in}t} \tag{3}$$

At the slowest scan rate (0.1 V·s⁻¹) we have used and for the highest buffer concentration (860 mM HEPES at pH 7), a proton penetration length *l* of 1.25 nm was calculated. This diffusion length is less than the smallest dimension of GLAD-TiO₂ nanorods (~5 nm) we have roughly estimated from our simple model in Figure 1, a result which therefore justifies *a posteriori* the validity of eq 2 and, therefore, the assumption of 1D semi-infinite linear diffusion. It also suggests that for the strongest accumulation conditions we were able to reach, the concentration gradient layer of reduced Ti^{IV} extends from the TiO₂ nanorod walls up to ~40% of the total metal oxide volume.

Comparative study with lithium intercalation. With the aim of directly comparing proton-ion versus lithium-ion insertion in a 1-µm thick amorphous GLAD-TiO₂ film, a series of CV and CVA experiments were performed in aqueous electrolytes containing either 76 mM Li⁺ (pH ~

6.5) or 76 mM acid form of HEPES (pH 7.0) for a set of scan rates (Figure S5). The marked differences between the shapes of CVs (and also CVAs) recorded in the presence of a proton ion donor and those recorded in the presence of lithium ion, suggests that Li⁺ intercalation does not proceed as fast as proton intercalation under the selected conditions. One may argue that at the low Li⁺ concentration used, the lack of discernable lithium intercalation within GLAD-TiO₂ films would result from a slow diffusion rate of Li⁺ in the bulk of solution, leading thus to a low faradaic current response according to eq 1. This is however unlikely because the diffusion coefficient of Li⁺ in aqueous solution is quite high (~10⁻⁵ cm²·s⁻¹),⁵⁷ and so its diffusion rate in water is even faster than the AH form of HEPES. Still, an additional CV experiment was performed at a much higher concentration of Li⁺ (1 M) (Figure S5), but again the small increase of current compared with that obtained with a proton donor such as the protonated form of HEPES at 0.66 M definitely indicates the much slower insertion of Li⁺ than H⁺ in the amorphous film of GLAD-TiO2. One should note that the broad and small reversible waves we observed here for Li⁺ intercalation in amorphous GLAD-TiO₂ are in line with previous reports of Li⁺ intercalation in other types of amorphous mesoporous TiO₂ films in aprotic solvents, exhibiting a similar broad and small reversible wave in CV, much smaller and less well-defined than for Li⁺ intercalation in mesoscopic films of pure anatase. 51,58 All of these observations allow us to conclude that, under our conditions, proton ion insertion occurs in amorphous mesoporous GLAD-TiO₂ films immersed in a neutral aqueous buffer solution through a remarkably faster and more favorable process than lithium ion insertion.

On account of the above observations, it is interesting to return to the value we have determined for the solid-state diffusion coefficient of protons in GLAD-TiO₂ ($D_{H,in} = 10^{-15} \text{ cm}^2 \cdot \text{s}^{-1}$) because it is the key parameter governing the proton charge storage dynamics in TiO₂ relative to lithium.

Analyzing in detail the solid-state diffusion coefficients of Li⁺ reported in literature (in particular those obtained at nanoporous TiO₂ films made of 7-8 nm anatase particles) allows us to identify consistent values in the range of 1×10^{-17} to 6×10^{-17} cm²·s⁻¹. ^{42,43,51} Assuming these data as the most relevant for direct comparison to the present value of $D_{H,in}$ in GLAD-TiO₂, we can conclude that protons diffuse 20- to 100-fold faster in amorphous TiO₂ than Li⁺ in anatase. This strong difference may explain the obvious contrast we observe between proton and lithium ion insertion in amorphous GLAD-TiO₂ electrodes.

Charge Storage. One great advantage of cyclic voltabsorptometry lies in the correlation that can be done between electrochemical and spectroscopic data. In the present study, it allows for real-time analysis of the spectroscopic features of TiO_2 films during the electrochemical charging process. Assuming that all injected electrons give rise to absorbance at 780 nm, cyclic voltabsorptograms can be converted to derivative cyclic voltabsorptograms (DCVA) according to eq 4 (where both current and absorbance are expressed in flux density ϕ in mol·cm⁻²·s⁻¹) and directly compared to each other.

$$\phi = \frac{1}{1000\varepsilon_{780}} \frac{dA_{780}}{dt} = \frac{i}{FS} \tag{4}$$

where A_{780} is the absorbance monitored at 780 nm and ε_{780} , in M⁻¹·cm⁻¹, is the extinction coefficient of the stored electron.

As shown in Figure S6, when using an extinction coefficient value of 800 or 1200 $M^{-1} \cdot cm^{-1}$ at 780 nm, depending on the electrode batch, a perfect overlap of the DCVAs and CVs is obtained over the entire potential window, regardless of the pHs and buffer concentrations. The independence of ε_{780} from both the applied potential as well as the proton provider is *a priori*

surprising since it indicates that all electrons stored within the material share common spectroscopic features in the visible range, regardless of their origin or nature (i.e., either the electrons are associated with the filling of electronic states in the band-gap and/or conduction band, or stored in the double-layer capacitance at the TiO_2 -electrolyte interface, or associated with the faradaic charging process leading to the reductive protonation of Ti^{IV} ions within the TiO_2 lattice). Such an observation seems to contradict a previous report in literature suggesting that electrons associated with lithium ion insertion in TiO_2 have a marked increase in average extinction coefficient (in the near-IR range) with respect to electrons accumulated in the conduction band.³⁵ This previous report, however, was performed under strong accumulation conditions, which are known to lead to a long lasting coloration of the metal oxide film. In the present study, such strong accumulation conditions are not encountered. The extinction coefficient values used in the present study, $900 \pm 300 \text{ M}^{-1} \cdot \text{cm}^{-1}$, are in good agreement with those previously found under different experimental conditions and for different types of mesoporous TiO_2 films.^{18,25,35}

The charge density Q (in $C \cdot cm^{-2}$) stored in the 1 µm-thick GLAD-TiO₂ film can be easily determined for each electrode either from the maximum absorbance change monitored at 780 nm or integration of the charging/discharging current in CV, using eq 5.

$$Q = F \frac{\Delta A_{780}}{1000 \varepsilon_{780}} = F \int \frac{i}{S} dt \tag{5}$$

This equation was used to estimate the total charge stored at the highest tested concentration of proton donor (0.66 M AH in 0.86 M HEPES buffer, pH 7) and 0.1 V·s⁻¹ (Figure 4). A value of 78 mC·cm⁻² was obtained, corresponding thus to a total charge capacity of 310 C·g⁻¹. This total

stored charge results from the combined contributions of charges stored from faradaic reduction of TiO₂ and charges accumulated at the double-layer interface of the nanostructured metal oxide. The charge fraction associated with the faradaic contribution can be determined by subtraction of charge accumulated in the absence of significant proton intercalation (corresponding to the double-layer capacitance charge) from the total charge. From the magnitude of absorbance changes recorded at the lowest concentration of proton donor, a capacitive charge density of 18 mC·cm⁻² (or 72 C·g⁻¹) could be recovered. This implies that 23% of the total stored charge results from the double-layer capacitance of the nanoporous TiO₂ film, while the remaining 77% (i.e., 60 mC·cm⁻² or 240 C·g⁻¹ or 66 mA·h·g⁻¹) arises from the proton-coupled electron transfer reaction within the metal-oxide network (Table 1). This latter value is equivalent to 0.6 μmol·cm⁻ 2 of intercalated protons, and thus corresponds to the reductive protonation of $\sim 20\%$ of the total titanium ions in the lattice (equivalent to a x value of 0.2). As the charging process is diffusionlimited under the experimental conditions, the maximal mole fraction x is manifestly not reached. It could theoretically be attained experimentally by either decreasing the scan rate or prolonging the time the electrode is biased at negative potentials ($\leq E^{0'}$). However, the scan rate could not be decreased below 0.05 V·s⁻¹ in the present study without the strong charge accumulation condition inducing a sudden irreversible failure of the GLAD-TiO2 electrodes (see above).

Despite the inability to reach the maximum mole fraction, it is still possible to compare the total e⁻/H⁺ charges that could be reversibly stored in the 1-μm thick GLAD-TiO₂ electrode against previous reports for Li⁺-storage in various mesoporous anatase films (in aprotic solvents) (Table 1). It is remarkable to note in Table 1 that under our experimental conditions, proton ion insertion within amorphous GLAD-TiO₂ films occurs nearly as extensively as lithium ion

intercalation in mesoporous crystalline films of anatase. Moreover, this extensive proton insertion is achieved much more rapidly than reported for lithium ion insertion (the 0.2 mole fraction was attained here at a scan rate of 100 mV·s⁻¹, while for Li⁺, the 0.15 to 0.31 mole fractions were obtained at 0.5 mV·s⁻¹, see Table 1). Interestingly, in spite of completely different experimental conditions, a similarly extensive reductive protonation of TiO₂ (~16%) was obtained by prolonged UV-irradiation in toluene of amorphous nanoparticles capped with organic ligands.⁵⁹

To better characterize the long-term stability, reversibility and speed of e⁻/H⁺ charge/discharge in GLAD-TiO₂, mesoporous films were investigated by double potential-step chronoabsorptometric experiments in HEPES buffer at two different proton donor concentrations (i.e., 0.77 and 77 mM AH). To avoid excessive charge accumulation, the forward potential was stepped from 0.0 V to -1.0 V, a moderate cathodic potential only slightly more positive than the formal potential ($E^{0'}$ = -1.06 V) of the reversible proton insertion/disinsertion wave. In the absence of significant proton donor in solution, the time-course absorbance change in Figure 4 grows rapidly until it reaches a steady state value of 8.7 mC·cm² (in less than 30 s). This fast absorbance increase is representative of the electrode capacitive charging rate (i.e., the charging of both the chemical and double-layer capacitances) when there is no significant contribution of proton insertion to charge storage. At an appreciable proton donor concentration of 77 mM (0.1 M HEPES), a significantly higher limiting charge storage value of 19.3 mC·cm² (an increase of 120%) is reached after only slightly longer accumulation time (ca. 60 s). This result confirms the remarkably fast reductive protonation of GLAD-TiO2 and allows for easy estimation of the additional stored charges resulting from the faradaic proton insertion at the selected applied potential. The stationary charge accumulated after 1 min of electrode polarization at -1.0 V also

points to thermodynamic control of the accumulated charge (i.e., in equilibrium with the Fermi level of -1.0 V applied to the metal oxide film), which is here assumed governed by the Nernst's law. (This is a reasonable assumption when one considers the good electrochemical reversibility of the proton insertion/disinsertion waves on the CVs). From the maximal faradaic charge density extracted in Figure 4 (i.e., $Q = 11 \text{ mC} \cdot \text{cm}^{-2}$ after subtraction of the capacitive charge density), it can be calculated that 4% of the total Ti ions present in the metal oxide film are electrochemically reduced after only 1 min of electrode polarization at -1.0 V. Inserting this ratio into the Nernst equation and assuming the law remains valid regardless of the amount of charge injected into TiO₂ allows us to estimate an x value of 0.45 (using $E^{0'} = -1.06 \text{ V}$ and E = -1.0 V). This maximum insertion ratio is close to the mole fraction of 0.5 found for lithiated anatase (Li_{0.5}TiO₂) wherein lithium ions are randomly distributed over half of the available interstitial octahedral sites. 60 It also validates a posteriori the x value of 0.5 used in eq 2 for the calculation of $D_{H,in}$. Another important merit of the chronoabsorptometric experiments in Figure 4 is to clearly highlight the high-rate electrochemical charging and discharging processes as well as their high reversibility and cyclability as attested by the perfect overlay of the multiple double potential-step experiments repetitively recorded.

CONCLUSION

In the present work, we demonstrate that the charge storage capacity of amorphous GLAD-TiO₂ electrodes can be strongly enhanced upon reductive protonation of lattice Ti^{IV} ions. This process is characterized by a reversible and fast faradaic proton-coupled electron transfer reaction centered at a well-defined formal potential (i.e., a well-defined localized state), energetically positioned at a value negative to the conduction band potential of TiO₂ (i.e., at a potential where

TiO₂ is fully degenerate), and that we can reasonably attribute to the Ti^{IV}O₂/Ti^{III}O(OH) redox couple. This reversible process can however only be revealed by the presence of a sufficiently large concentration of an appropriate proton donor in solution, i.e., free protons or a much weaker acid such as the acidic form of the buffer. We demonstrate moreover that reductive doping of amorphous mesoporous TiO₂ in aqueous solution is highly specific for protons and that Li⁺ insertion does not compete with proton insertion under the present experimental conditions, most likely because of the short time window used. Despite this, the total charge stored in the GLAD-TiO₂ electrode upon proton insertion falls within the range of values reported for mesoporous TiO₂ electrodes upon lithium insertion in aprotic solvent.

The present study is of special interest for the development of devices operating under mildly-aqueous conditions as it demonstrates that electron/proton accumulation within mesoporous TiO₂ films can occur massively and rapidly at neutral pH conditions. This, in turn, indicates that high-rate and high-power could be achieved for reversible proton charge/discharge storage within the material. It provides moreover an easy methodology to distinguish the faradaic current density related to proton intercalation from that associated with the classical electrical capacitance by modifying the concentration of the weak acid.

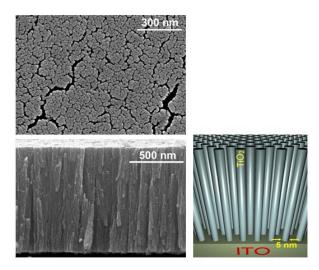

Figure 1. SEM images (top- and side-views) of the 1-μm GLAD-TiO₂ films. The right cartoon is a schematic representation of the film consisting of an array of homogenously distributed cylindrical nanorods. The indicated diameter (5 nm) was calculated based on BET measurements of surface area and characterizes the high surface area fine structure internal to TiO₂ columns grown by GLAD.

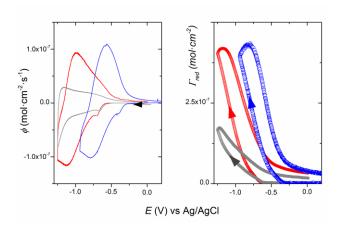

Figure 2. (Left) CVs and (right) CVAs (monitored at 780 nm) recorded simultaneously at a 1 μm-thick GLAD-TiO₂ electrode in an aqueous solution of (blue) 14 mM HCl (pH 1.85), or buffered solutions (pH 7.0) of (black) 1 mM HEPES or (red) 100 mM HEPES. All solutions also contained 0.3 M KCl as supporting electrolyte. Electrodes were scanned from 0 to -1.25 V at pH 7, and from 0 to -0.96 V at pH 1.85. CVs are expressed in flux density and CVAs in surface concentrations (i.e., $\Delta A_{780}/(1000 \cdot \varepsilon_{780})$). Scan rate: 0.1 V·s⁻¹. T = 25°C.

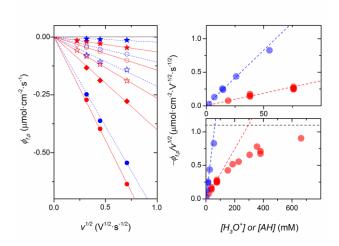

Figure 3. (Left) Cathodic peak electron flux density in CV as a function of \sqrt{v} (for scan rates ranging from 0.05 to 0.5 V·s⁻¹) and for different concentrations of (blue data) free protons, i.e. $[H_3O^+] = (\bigstar) 2.5, (\bigcirc) 7, (\bigstar) 14$ and $50 (\bigcirc)$ mM, or (red data) the acidic form of HEPES buffer, i.e. $[AH] = (\bigstar) 19, (\bigcirc) 38, (\bigstar) 77, (\spadesuit) 153$ and $(\bullet) 656$ mM. (Right) Cathodic peak electron flux density normalized to \sqrt{v} and plotted as a function of proton donor concentration: (blue) free protons and (red) the acidic form of HEPES buffer. Dashed lines correspond to the linear regression fits of eq 1 to the data determined at low proton donor concentrations. The horizontal dotted black line corresponds to the extrapolated limiting value of $\phi_{f,p}/v^{1/2}$.

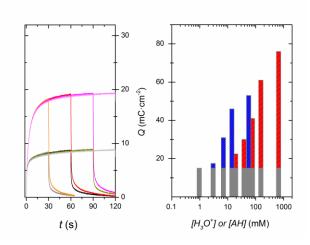

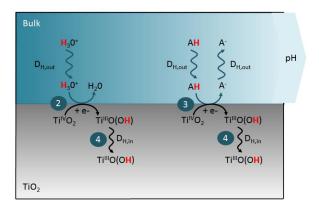

Figure 4. (Left) Double potential step chronoabsorptometric responses (the absorbance has been converted into charge per unit of geometric electrode area using eq 5) monitored at 780 nm in a 0.3 M KCl aqueous solution containing (black and grey lines) 1 mM or (orange, red, magenta, pink lines) 100 mM HEPES at pH 7. The potential was stepped from 0.0 to – 1.0 V and then back to 0.0 V (vs. Ag/AgCl). The double potential step experiment was repeated several times by progressively increasing both the cathodic and anodic polarization time from 30 to 120 s. (Right) charge contributions of the (grey) double layer charging and (blue and red) faradaic proton intercalation to the total charge stored in a GLAD-TiO₂ film during a CV performed at 0.1 V·s⁻¹. Bars in blue are for free protons, while those in red are for the acidic form, AH, of the HEPES buffer.

Scheme 1. Schematic representation of the faradaic charging processes occurring at the TiO_2 mesoporous electrodes involving concerted electron-proton transfer to solvent-accessible Ti^{IV} ions according to the interfacial reactions 2 or 3, depending on the proton provider, followed by coupled electron/proton diffusion within the TiO_2 lattice according to reaction 4.

Table 1. Structural characteristics and charge storage properties of the present GLAD TiO₂ films compared to those previously established for other mesoporous TiO₂ films.

	GLAD film	Nanoparticle films			Sol-gel film
TiO ₂ crystallinity	amorphous	anatase	anatase	anatase	anatase

- (47) Note: it is also possible to consider the case of a slow or irreversible electrochemical reaction by analyzing the peak current using the following expression

- $i_{f,p}/FSv^{1/2} = 0.4958\sqrt{F/RT}\sqrt{\alpha D_{H,out}}$ [H], where α is the transfer coefficient. If we assume $\alpha = 0.5$, it would mean that the constant 0.4463 in eq 1 is replaced by 0.3506 for an irreversible electrochemical reaction.
