31 **Introductory paragraph:**

32 Assessing the impact of variation in chloroplast and mitochondrial DNA (collectively termed the
33 plasmotype) on plant phenotypes is challenging due to the difficulty in separating their effect from
34 nuclear derived variation (the nucleotype). Haploid inducer lines can be used as efficient plasmotype
35 donors to generate new plasmotype-nucleotype combinations (cybrids) (Ravi et al., 2014). We
36 generated a panel comprising all possible cybrids of seven *Arabidopsis thaliana* accessions and
37 extensively phenotyped these lines for 1859 phenotypes under stable and fluctuating conditions. We
38 show that natural variation in the plasmotype results in additive as well as epistatic effects across all
39 phenotypic categories. Plasmotypes which induce more additive phenotypic changes also cause more
40 significant epistatic effects, suggesting a common basis for both additive and epistatic effects. This
41 quick and precise method allows accurate assessment of the phenotypic effects of natural variation in
42 organellar genomes on plant performance and efficient screening for favourable nucleotype-
43 plasmotype combinations and thus improve plant performance.

44 Chloroplasts and mitochondria play essential roles in metabolism, cellular homeostasis and
45 environmental sensing (Chan et al., 2016). Their genomes contain only a limited set of genes whose
46 functioning requires tight coordination with the nucleus through signaling pathways that modulate
47 nuclear and organellar gene expression (Kleine and Leister, 2016). Plasmotype variation can be
48 strongly additive, such as in the case of chloroplast encoded herbicide tolerance (Flood et al., 2016),
49 or can manifest in complex cytonuclear interactions as non-additive, non-linear effects (epistasis),
50 such as found for secondary metabolites (Joseph et al., 2013). The phenotypic consequences of
51 epistasis can be detected when a plasmotype causes phenotypic effects in combination with some,
52 but not all nuclear backgrounds. Recent studies suggest that cytonuclear epistasis is the main route
53 through which variation in the plasmotype is expressed (Zeyl et al., 2005; Montooth et al., 2010;
54 Joseph et al., 2013; Joseph et al., 2013; Tang et al., 2014; Roux et al., 2016; Mossman et al., 2019)
55 and that additive effects are both rare and of small effect.

56 Plasmotypic variation is relevant from an agricultural as well as evolutionary perspective
57 (Levings, 1990; Bock et al., 2014; Dobler et al., 2014), but to understand, or utilize it, it is necessary to
58 separate nuclear from mitochondrial and chloroplastic effects. Reciprocal-cross designs, where
59 nucleotypes segregate in different plasmotypic backgrounds, have been used to identify plasmotype-
60 specific quantitative trait loci (Joseph et al., 2013; Tang et al., 2014), but are limited to just two

61 plasmotypes. A larger number of plasmotypes can be studied using backcross designs where
62 plasmotypes are introgressed into different nuclear backgrounds (Dowling et al., 2007; Sambatti et al.,
63 2008; Miclaus et al., 2016; Roux et al., 2016), but backcross approaches are lengthy and any
64 undetected nuclear introgressions may confound the results.

65 To precisely and rapidly address the contribution of organellar variation to plant phenotypes,
66 we explored the use of a haploid inducer line available in *Arabidopsis* (*GFP-tailswap*) (Ravi and Chan,
67 2010; Ravi et al., 2014). When pollinated with a wild-type plant, the *GFP-tailswap* nuclear genome is
68 lost from the zygote through uniparental genome elimination. This generates haploid cybrid offspring
69 with a paternally derived nuclear genome and maternally (*GFP-tailswap*) derived mitochondria and
70 chloroplasts (Fig. 1B). These haploid plants produce stable diploid (doubled haploid) offspring
71 following genome duplication or restitutional meiosis (Ravi and Chan, 2010). We set out to test the use
72 of this approach to investigate how plasmotypic variation affects plant phenotypes and to what extent
73 this variation manifests itself as additive variation or as cytonuclear epistasis.

74 Seven different *Arabidopsis* accessions were selected for our experiment: six that represent a
75 snapshot of natural variation (Bur, C24, Col-0, Ler-0, Shah, WS-4) and Ely, an accession with a large-
76 effect mutation in the chloroplast-encoded *PsbA* gene (El-Lithy et al., 2005). This mutation results in
77 reduced photosystem II efficiency (El-Lithy et al., 2005; Flood et al., 2014) and was included to
78 evaluate the consequence of a strong plasmotype effect in our test-panel. We first generated haploid
79 inducers for all seven plasmotypes (Fig. 1A) and then used each inducer to generate cybrid offspring
80 for all seven nucleotypes (Fig. 1C). Wild-type nucleotype-plasmotype combinations were also
81 regenerated in this way (hereafter referred to as self-cybrids) to later compare these with their wild-
82 type progenitors. The genomes of all haploid cybrids were resequenced for genotype verification,
83 resulting in the exclusion of Bur^{C24}, (a Bur nucleotype with a C24 plasmotype) and Bur^{Bur} (see Online
84 methods; Supplementary Fig. 1). With the exception of Ely^{Sha} for which we obtained seeds at a later
85 stage, we obtained doubled haploid seeds from all haploid cybrids resulting in a testpanel of 46
86 cybrids and 7 wildtype progenitors. To visualize the genetic variation between lines within our panel
87 we generated neighbor joining trees for the nuclear, mitochondrial and chloroplast genomes
88 (Supplementary Fig. 2 to 5). The nucleotypes were found to be approximately equidistant, while the
89 Ler, Ely and Col plasmotypes appear to be more closely related to each other than the other
90 plasmotypes.

91

92 **Figure 1. Generation of a cybrid test panel.** A) Generation of a new haploid inducer (HI) line with a
 93 new plasmotype. The HI expresses a GFP-tagged *CENH3/HRT12* in a *cenh3/htr12* mutant
 94 background. A cross of a wild type (female) with a HI (male) results in a hybrid F1. A diploid F1 is
 95 selected in which no genome elimination has occurred. Self-fertilization generates an F2 population in
 96 the plasmotype of the wild-type mother. From this an F2 plant is selected that is homozygous for the
 97 *cenh3/htr12* mutation and carries the *GFP-tailswap* transgene. This F2 plant is a new HI line and can
 98 serve as plasmotype donor when used as female in crosses. Vertical bars represent the nucleotype,
 99 and the ovals represent the plasmotype. HI centromeres are indicated in green (signifying GFP-tagged
 100 *CENH3/HTR12* proteins as encoded by the *GFP-tailswap* construct) that cause uniparental genome-
 101 elimination. B) HI lines can function as plasmotype donors when used as a female parent. In this case,
 102 uniparental genome elimination (red arrow) leads to a haploid offspring plant with the nucleotype of
 103 the wild-type (WT) male parent, but the plasmotype of the HI mother. C) Full diallel of all nucleotype-
 104 plasmotype combinations for which cybrids were generated. The diagonal line highlights the wild-type
 105 (WT) nucleotype-plasmotype combinations that were generated by crossing wild-type plants to
 106 plasmotype donors with the plasmotype of the wild type (self-cybrids).

107

108 We phenotyped the cybrid panel under constant environmental conditions for absolute and
109 relative growth rate, biomass accumulation, epinastic leaf movement, photosystem II efficiency (Φ_{PSII}),
110 non-photochemical quenching (NPQ), and elements thereof (Φ_{NO} , Φ_{NPQ} , q_E and q_I), a reflectance-
111 based estimate of chlorophyll, flowering time, pollen abortion, germination and primary metabolites. To
112 simulate more variable conditions that are frequently encountered in the field, we also screened the
113 panel under fluctuating light for all the above-mentioned photosynthesis-related phenotypes, and
114 assayed germination rates under osmotic stress and after a controlled deterioration treatment.
115 Counting individual metabolite concentrations and single time points in the time series separately, we
116 collected in total 1859 phenotypes (Supplementary Data 1). To avoid overrepresentation of highly
117 correlated and non-informative phenotypes we selected a subset of 92 phenotypes (Online methods)
118 comprising 24 from constant growth conditions, 32 from fluctuating or challenging environmental
119 conditions and 36 primary metabolites for further analysis (Supplementary Table 1).

120 Comparison of six self-cybrids with their genetically identical wild-type progenitors for these 92
121 phenotypes did not reveal significant phenotypic differences (Supplementary Table 1) from which we
122 infer that uniparental genome elimination is a robust method to generate cybrids. To determine the
123 relative contributions of additive nucleotype and plasmotype effects, as well as their interactions
124 (epistatic effects) to the observed phenotypic variation, we estimated the fraction of the broad sense
125 heritability (H^2 ; also called repeatability (Falconer and Mackay, 1996)) explained by each. Across the
126 entire panel the average contribution to H^2 of nucleotype, plasmotype and nucleotype-plasmotype
127 interaction was 65.9%, 28.2% and 6.0% respectively (Supplementary Table 2 and 3; Supplementary
128 Data 1). Most of this plasmotype derived variation was caused by the Ely plasmotype, arising from the
129 *psbA* mutation. When this plasmotype was excluded from the analysis, the nucleotype, plasmotype
130 and their interaction account for 91.9%, 2.9% and 5.2% of the genetic variation, respectively
131 (Supplementary Table 2 and 3; Supplementary Data 1). So, while nucleotype-derived additive
132 variation is the main genetic determinant of the cybrid phenotype, variation caused by plasmotype
133 additive effects as well as epistatic effects results in substantial phenotypic differences.

134 We sought to assess whether there are general patterns in how specific nucleotypes and
135 plasmotypes interact. To this end we first assessed which plasmotype changes result in additive
136 phenotypic changes. Plasmotype replacements involving the Ely plasmotype lead to additive changes
137 in, on average, 50 (out of 92) phenotypes across the 7 nucleotypes. Changes involving the Bur

138 plasmotype lead to on average 10 significant additive effects (Table 1A), 8 of which are
139 photosynthesis-related (Supplementary Data 2). Other plasmotype changes show on average one
140 additive effect, in predominantly non-photosynthetic phenotypes. Comparison of wild-type cytonuclear
141 combinations with all their iso-nuclear cybrid lines also shows that plasmotype changes involving Ely
142 and Bur plasmotypes show the most epistatic effects (on average 43 and 6 respectively) (Table 1B).
143 The number of epistatic effects resulting from the Bur plasmotype range between 0 (Ler^{Ler} vs Ler^{Bur}) to
144 10 (Sha^{Sha} vs Sha^{Bur}), indicating high variability. Plasmotype changes involving other plasmotypes
145 show more modest numbers of significant epistatic effects that range from 0 to 6. Plasmotypes that
146 result in more additive effects also cause more epistatic effects (correlation coefficient of 0.8)
147 suggesting a common cause (Supplementary Table x).

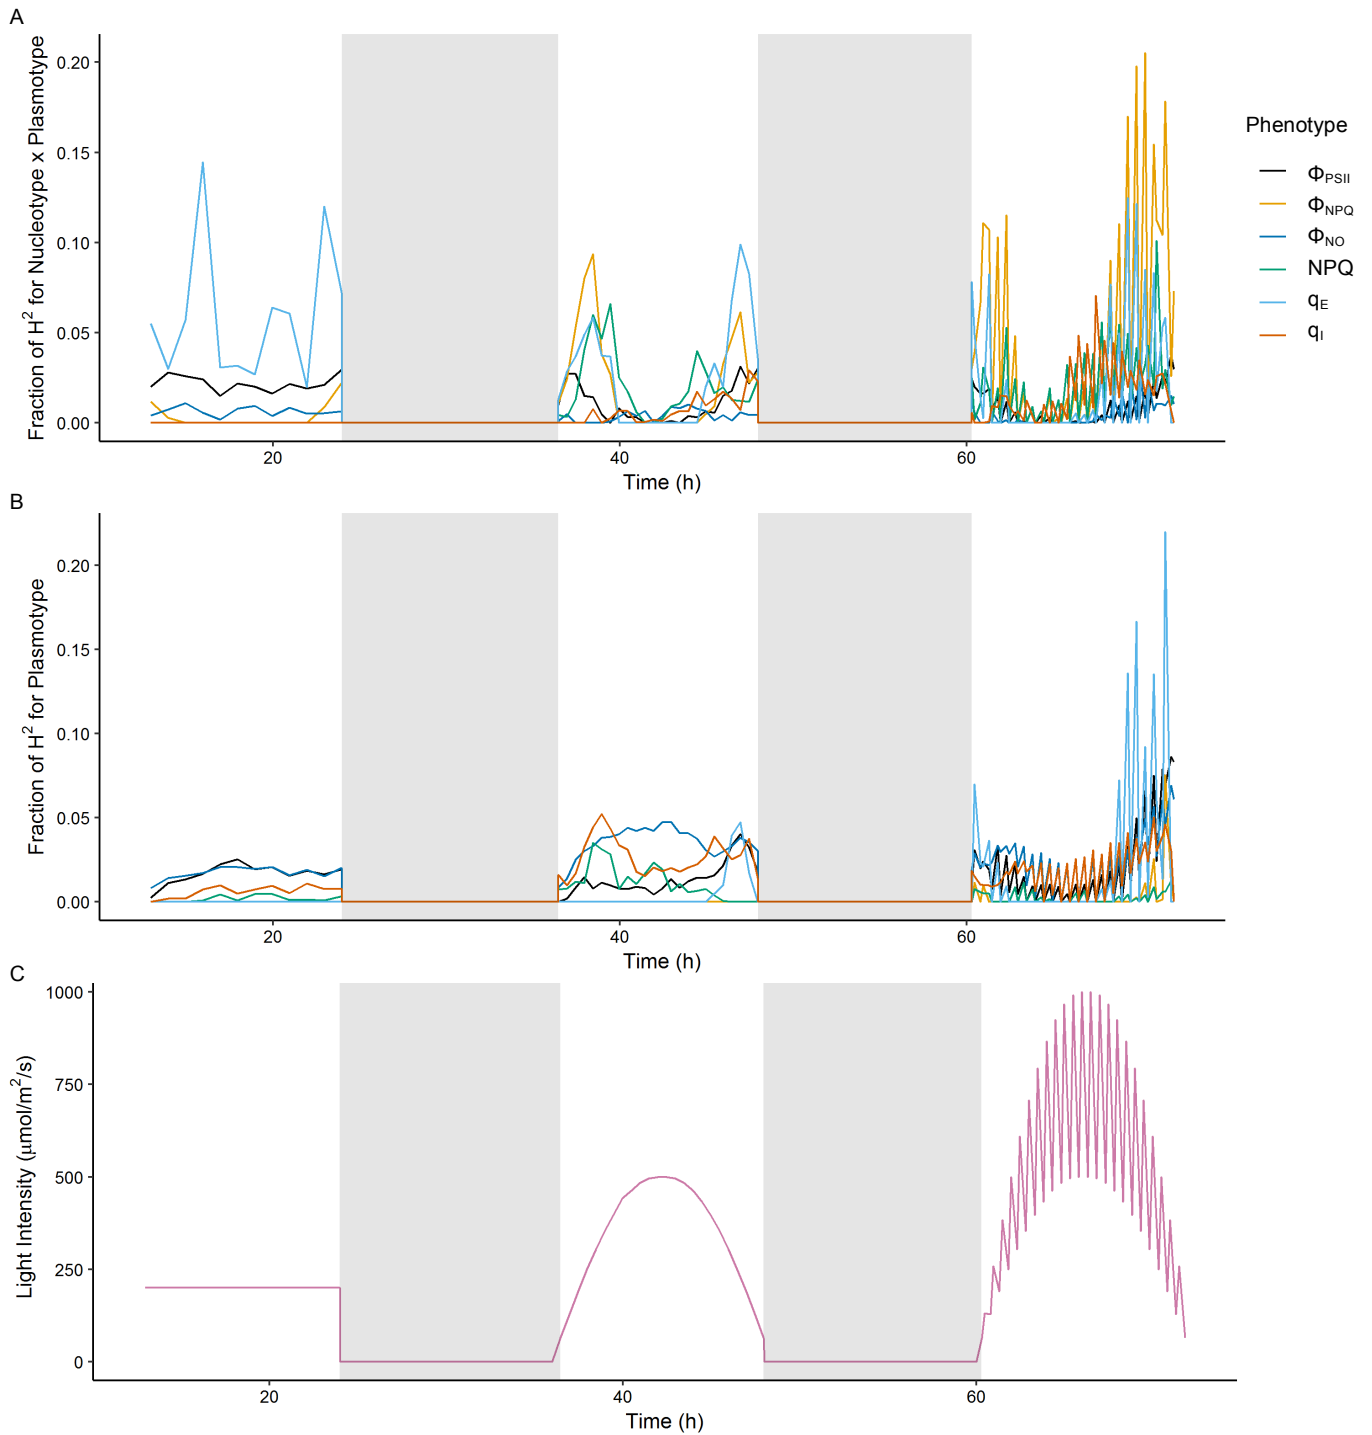

148

149 **Table 1. Plasmotype changes cause significant changes in 92 phenotypes.** A) Number of
 150 observed significant plasmotype additive effects when a specific plasmotype is changed for another
 151 plasmotype. Note that the replacement of Bur (top row) and Ely plasmotypes (last column) result in
 152 most plasmotype additive effects. For underlying p-values and phenotypes see Supplementary data 2.
 153 B) Number of observed significant epistatic effects in phenotypes between wild-type nucleotype-
 154 plasmotype combinations and cybrids with different plasmotypes. Rows indicate the number of
 155 significant effects when comparing self-cybrids to cybrids with identical nucleotype but non-native
 156 plasmotype. Columns indicate specific plasmotype changes. Note that changing the Ely plasmotype
 157 for another plasmotype (bottom row and last column) results in many epistatic effects due to the large-
 158 effect mutation in the chloroplast-encoded *PsbA* gene of the Ely plasmotype. Similar effects, but of
 159 smaller magnitude, result from changing the Bur plasmotype (top row and first column). Posthoc tests
 160 for A done with Hochberg's test and for B with Dunnet test, $\alpha = 0.05$. nd = not determined. For
 161 underlying p-values and phenotypes see Supplementary data 2. Yellow cells indicate low number of
 162 significant epistatic effects; blue cells show higher number of significant effects.

164 **Figure 2. The fraction of explained genetic variation (H^2) for photosynthesis phenotypes differs**
 165 **depending on light conditions.** A) shows the fraction of H^2 for plasmotype epistatic effects. B) shows
 166 the fraction of H^2 for plasmotype additive effects. C) shows the light intensity for three consecutive
 167 days with growth under steady light (day 1), sinusoidal light intensity (day 2) and fluctuating light
 168 intensity (day 3). Days are separated by nights (shaded areas). Note that the fraction of H^2 for different
 169 phenotypes changes markedly during days 2 and 3. Some phenotypes are explained largely by
 170 additive effects (i.e. q_E) while others by interaction (i.e. Φ_{NPQ}).

171
 172 **Figure 3. Plasmotype changes result in cytonuclear epistasis, and in the case of cybrids with**
 173 **the Ely and Bur plasmotype also in additive effects.** A) Pollen abortion, percentage of dead pollen
 174 out of 250. B) PSII efficiency (Φ_{PSII}) 71.46 hours after start of experiment, after a full day of fluctuating
 175 light with a maximum difference between 500 and 100 $\mu\text{mol}/\text{m}^2/\text{s}$ irradiance (see Fig. 2C for light
 176 treatment). C) NPQ at 38.46 hours after start of experiment, which is at 300 $\mu\text{mol}/\text{m}^2/\text{s}$ on a sigmoidal
 177 light curve starting at 65 $\mu\text{mol}/\text{m}^2/\text{s}$. D) The rapidly reversible component of NPQ, q_E , at 259 $\mu\text{mol}/\text{m}^2/\text{s}$
 178 after a full day of fluctuating light with a maximum difference between 500 and 100 $\mu\text{mol}/\text{m}^2/\text{s}$. X-axis
 179 are labelled with the plasmotype, and the colours represent the nucleotypes. Any deviation from a
 180 horizontal line represents a potential additive or epistatic effect. Error bars represent the standard error
 181 of the mean. The * in panel A indicates a unique significant difference between the Sha^{Sha} cybrid and
 182 other nucleotypes with Sha nucleotype (epistasis) (Hochberg's test, $n=4-10$). The letters above panels
 183 B, C and D represent significant differences between plasmotypes regardless of the nucleotype

184 (additivity) (Hochberg's test, $n=4*7$). For panels B, C and D plants were grown at $200 \mu\text{mol/m}^2/\text{s}$ for 21
185 days prior to starting the experiment.

186 Though the average total explained variance due to the cytonuclear epistasis is only 5.2%,
187 these interactions can have strong effects for specific phenotypes or in specific cybrids. Explained
188 variance for some phenotypes can be markedly higher, for example for projected leaf area this
189 amounts to 12.3%, for hyponastic leaf movement to 8.3% and for ΦNPQ to 17.8%. A strong epistatic
190 effect in pollen viability (43.5%) was due to relatively high pollen abortion in Sha^{Sha} (Fig. 3A) that we
191 also observed in Sha wildtype. The only cybrid for which we initially failed to obtain seed was Ely^{Sha} .
192 This haploid was regenerated and pollinated with wild-type Ely pollen to increase the chance of seed
193 set. The diploid offspring were male sterile, indicating that in combination with the Ely nucleotype the
194 Sha plasmotype results in cytoplasmic male sterility (Supplementary Fig. 7). In combination with the
195 Sha plasmotype pollen abortion across the seven nucleotypes can range from near zero, to 10% in
196 Sha^{Sha} and to full male sterility in Ely^{Sha} , highlighting the strong epistasis that can be present.

197 Cybrids with the Ely plasmotype exhibit clear additive effects: all have a lower PSII efficiency
198 (Φ_{PSII}) (Fig. 3A) and lower values for other photosynthesis related phenotypes i.e. NPQ, q_E and
199 chlorophyll content (Fig. 3C and Supplementary Fig. 5). This reduced Φ_{PSII} is likely to be responsible
200 for the concomitant reductions in biomass (Fig. 3B), growth rate and seed size and altered primary
201 metabolite content (Supplementary Data 2). To check whether this additivity could also be detected at
202 the level of gene expression we contrasted the transcriptome of Ely^{Ely} with those of cybrids with Ler
203 and Bur plasmotypes. We also studied the Ely, Ler and Bur plasmotypes in a Ler nuclear background
204 (Supplementary Data 3; for details see Supplementary Fig. 9 and Supplementary table 5). Exchanging
205 the Ely plasmotype with Ler or Bur, in either the Ler or Ely nuclear background resulted in a consistent
206 change in the expression of 40 genes (Supplementary Data 3). A GO-term analysis of the gene set
207 where the Ely plasmotype has an additive impact on expression is significantly enriched for genes
208 involved in photorespiration (GO:0009853) and in glycine- and serine family amino acid metabolism
209 (GO:0006544 and GO:0009069) (Supplementary data 3). This is in line with the low serine and glycine
210 content of cybrids with Ely plasmotypes suggesting reduced photorespiration (Somerville and Ogren,
211 1980), which can be linked to lower overall photosynthetic activity.

212 The Ely plasmotype was deliberately included in our panel for its strong additive effect. In
213 addition to Ely we also observed strong additive effects by the Bur plasmotype which were mainly

214 restricted to the photosynthetic parameters. Under normal conditions PSII efficiency is slightly
215 increased by the Bur plasmotype (1.6%), however when fluctuating the light intensity, this difference
216 becomes more apparent (3.5% increase) (Fig 3B). This increase in Φ_{PSII} , under fluctuating conditions
217 results in a corresponding reduction in Φ_{NO} and Φ_{NPQ} of 7.3% and 2.2% respectively. NPQ, q_E and q_i
218 are also influenced by the plasmotype, but the time points at which these differences occur differs per
219 phenotype (Fig. 2A and B). The Bur plasmotype shows an increase for NPQ, with the largest increase
220 of 5.9% at the beginning of day 2 (38.46h) (Fig. 3C), while the largest rapidly reversible component of
221 NPQ, q_E , has a maximum reduction of 26.6% at the end of day 3 (71.46h) (Fig. 3D). These
222 photosynthesis-related phenotypes are likely to be due to chloroplast-derived variation. In support of a
223 chloroplastic origin for this photosynthetic variation, measurements of mitochondrial respiration
224 suggest that Bur is not an outlier and shows standard respiration rates (Supplementary Fig 10). Based
225 on coverage plots there are no obvious duplications or deletions in the mitochondrial or chloroplast
226 sequences of Bur, thus we expect that altered expression or protein activity as opposed to gene gain
227 or loss is driving the Bur derived phenotypes (Supplementary Fig. 11). We annotated the sequence
228 variation of all plasmotypes using SNPeff (Cingolani et al., 2012). From this we found no large effect
229 mutations in the Bur mitochondria. There were, however, unique missense variants in the chloroplastic
230 genes MATURASE K (MATK), NAD(P)H-QUINONE OXIDOREDUCTASE SUBUNIT 6 (NDHG) and
231 hypothetical chloroplast open reading frame 1 (YCF1) as well as a frameshift mutation in tRNA-Lys
232 (TRNK) (Supplementary Data 4). The 7th amino acid of NDHG is changed from Isoleucine to Lysine,
233 NDHG is part of the NAD(P)H-dehydrogenase-like complex (NDH). NDH is located inside the thylakoid
234 membrane and acts as a proton pump in cyclic electron flow around photosystem I and
235 chlororespiration. NDH creates a pH differential that can be causative of the observed non-
236 photochemical quenching phenotypes (Strand et al., 2017; Laughlin et al., 2019). In contrast to Ely,
237 the plasmotype which evolved in response to the use of herbicides, an anthropogenic selective
238 pressure (Flood et al., 2016), the Bur plasmotype represents a naturally occurring plasmotype that has
239 an additive impact on key photosynthetic phenotype. Improving photosynthesis is a key plant breeding
240 goal, and by testing just seven plasmotypes we have found two that significantly impact
241 photosynthesis. Expanding our panel one is likely to find many more. Thus, future research aiming to
242 enhance crop photosynthesis should play close attention to the impact of variation in the plasmotype.

243 Our experiments have shown that a clean, systematic exploration of plasmotypic variation in a
244 plant species is feasible. The development of inducer lines for crop species would allow elite
245 nucleotypes to be brought into new plasmotypic backgrounds to explore novel plasmotype-nucleotype
246 combinations (REF). Exploring the potential of plasmotypic variation via the use of inducer lines is
247 promising both for plant breeding and for understanding the ecological role such variation plays in
248 plant adaptation (Bock et al., 2014; Dobler et al., 2014). Our data indicate that there is substantial
249 variation for phenotypes such as NPQ and Φ_{PSII} which are important for plant productivity (Flood et al.,
250 2011; Kromdijk et al., 2016). Finally, the increased impact of plasmotypic variation under fluctuating
251 and stressful conditions is of interest as it suggests that much of the variation present will only be
252 captured under specific environmental settings which is in line with studies of mitonuclear interactions
253 in animals (Dowling et al., 2007; Hoekstra et al., 2013; Mossman et al., 2016; Hill et al., 2019). Thus to
254 fully understand the impact and functional relevance of plasmotypic variation future studies should
255 include additional environmental variables.

256

257 **Online Methods**

258 *Plant materials:* Seven *Arabidopsis* accessions were chosen for the construction of a full nucleotype-
259 plasmotype diallel. Ely (CS28631) is atrazine resistant due to a chloroplast-encoded mutation in *PsbA*
260 which leads to a modified D2 protein that greatly reduces PSII efficiency (El-Lithy et al., 2005). Ws-4
261 (CS5390) was included for its unusual photosystem II phosphorylation dynamics (Yin et al., 2012). Bur
262 (CS76105) is commonly used in diversity panels and is a standard reference accession. Sha
263 (CS76227) was selected based on its capacity to induce cytoplasmic male sterility in some crosses
264 (Gobron et al., 2013). The set was completed by adding *Ler* (CS76164), *Col* (CS76113) and C24
265 (CS76106) which are three widely used genotypes in *Arabidopsis* research. *Col* is the reference
266 genome for nuclear and chloroplast sequences and C24 for the mitochondrial sequence. The *GFP-*
267 *tailswap* haploid-inducer that expresses a GFP-tagged CENTROMERE HISTONE 3 protein in a
268 *cenh3/htr12* mutant background, is in a *Col* background (Ravi and Chan, 2010).

269

270 *Generation of a nucleotype-plasmotype diallel:* To generate new nucleotype-plasmotype
271 combinations, plants of all seven accessions (*Bur*, C24, *Col*, *Ely*, *Ler*, *Sha* and *Ws-4*) were crossed as
272 males to *GFP-tailswap* resulting in all cybrids with the *Col* plasmotype. New HI lines were created by
273 crossing the original *GFP-tailswap* line as a male to the six additional plasmotype mothers (*Bur*, C24,
274 *Ely*, *Ler*, *Sha* and *Ws-4*). Genome elimination does not always occur and some of the offspring were
275 diploid F1 lines. These were selfed and F2 lines homozygous for the *cenh3/htr12* mutation and
276 carrying the *GFP-tailswap* were selected as new HI lines in different plasmotypic backgrounds (Fig.
277 1B). Plants of all seven accessions were then crossed as males to these new HI lines and the haploids
278 arising from these 49 crosses were identified based on their phenotype (as described in Wijnker et al.
279 (2014)). These haploid lines self-fertilized, either following somatic genome duplication or after
280 restititional meiosis (Ravi and Chan, 2010), and gave rise to doubled haploid offspring (Fig. 1A). The
281 resulting 49 lines comprise a full diallel of 21 pairs of reciprocal nucleotype-plasmotype combinations
282 (cybrids) as well as seven nucleotype-plasmotype combinations that have, in principle, the same
283 nucleotype-plasmotype combinations as their wild-type progenitors (self-cybrids; Fig. 1C, diagonal). All
284 cybrids and the wild-type accessions were propagated for one generation before use in further
285 experiments, with the exception of *Ely*^{Sha} of which the original haploid died without setting seed and

286 was recreated at a later stage by generating haploids that were pollinated with Ely wild-type plants to
287 ensure seed set.

288

289 *Genotype confirmation:* To confirm that all cybrids in our panel are authentic, all 49 cybrids and 7 wild-
290 type progenitors were whole-genome sequenced at the Max Planck Genome Centre Cologne
291 (Germany) using Illumina HiSeq 2500 150-bp paired-end sequencing. The cybrids were sequenced at
292 8.5X coverage and the wild-type progenitors at 40X coverage. To remove erroneous bases, we
293 performed adapter and quality trimming using Cutadapt (version 1.18) (Martin, 2011). Sequences were
294 clipped if they matched at least 90% of the total length of one of the adapter sequences provided in
295 the NEBNext Multiplex Oligos for Illumina® (Index Primers Set 1) instruction manual. In addition, we
296 trimmed bases from the 5' and 3' ends of reads if they had a phred score of 20 or lower. Reads that
297 were shorter than 70 bp after trimming were discarded. Trimmed reads were aligned to a modified
298 version of the *A. thaliana* Col-0 reference genome (TAIR10, European Nucleotide Accession number:
299 GCA_000001735.2) which contains an improved assembly of the mitochondrial sequence (Genbank
300 accession number: BK010421) (Sloan et al., 2018) using bwa mem (version 0.7.10-r789) (Li, 2013)
301 with default parameters. The resulting alignment files were sorted and indexed using samtools
302 (version 1.3.1) (Li et al., 2009). Duplicate read pairs were marked using the MarkDuplicates tool of the
303 GATK suite (version 4.0.2.1), using an optical duplicate pixel distance of 100, as recommended in the
304 documentation of GATK when working with data from unpatterned Illumina flowcells. Variants were
305 called using a workflow based on GATK Best Practices. Base quality scores of aligned reads were
306 recalibrated using GATK BaseRecalibrator with default parameters, using a set of variants of a world-
307 wide panel of 1135 *A. thaliana* accessions (The 1001 Genomes Consortium, 2016) (obtained from
308 ftp://ftp.ensemblgenomes.org/pub/plants/release-37/vcf/arabidopsis_thaliana/) as known sites.
309 Following base recalibration, variants were called in each sample using GATK HaplotypeCaller,
310 allowing for a maximum of three alternate alleles at each site. Samples were then jointly genotyped
311 using GATK GenomicsDBImport and GATK GenotypeGVCFs with default parameters. This last step
312 generated three different VCF files: one containing the calls of the nuclear genome, one containing
313 calls of the mitochondrial genome and one containing calls of the chloroplast genome.

314 To remove likely false positive calls, we filtered the callsets using two complementary
315 approaches. First, we filtered the nuclear callset using GATK VariantRecalibrator and GATK

316 ApplyVQSR (--truth-sensitivity-filter-level set at 99.9), using the set of variants called in the world-wide
317 panel of 1135 *A. thaliana* accessions as a training and truth set (prior=10.0). This step could not be
318 performed for the mitochondrial and chloroplast calls, as these lack a golden truth set that can be used
319 for recalibration. Second, we filtered variants based on their quality by depth score (QD). For the
320 nuclear callset, we used a QD score of 40, leaving 3.7 million SNPs, for the chloroplast callset a QD of
321 25, leaving 356 SNPs and for the mitochondrial callset a QD of 20, leaving 135 SNPs.

322 46 cybrids were found to have the correct genotypes. With one line, Bur^{Ws-4}, there was a
323 sample mix-up during library preparation with Sha^{Sha}. To confirm sequences we therefore used the
324 Sha genotype (CS76382) from the 1001 genomes project (The 1001 Genomes Consortium, 2016).
325 Two other lines, C24^{C24} and Ws-4^{Col}, had a high number of heterozygous calls, which we attributed to
326 sample contamination. To ensure that the sample mix-up and the putative event of cross-
327 contamination had occurred in the laboratory, we designed KASPTM makers (LGC,
328 <https://www.lgcgroup.com>) and genotyped all lines. These KASPTM markers are designed to be
329 chloroplast specific, based on the obtained sequence data of the wildtypes (Supplementary Table 7).
330 All lines showed the correct genotypes, and no heterozygosity was observed in any of the lines,
331 including C24^{C24} and Ws-4^{Col} (Supplementary Table x). Unfortunately, the Ely^{Sha} used for sequencing
332 died before setting seed and although it has since been recreated, it could not be included in our
333 phenotypic analyses. We have used the KASPTM marker for the Sha chloroplast, and confirmed it to
334 be correct (Supplementary Table x).

335 To check for any incomplete chromosome elimination, we calculated the read coverage for all
336 cybrids, normalized per chromosome. We did not observe any remaining chromosomes, although we
337 found a 200kb duplication in Bur^{Bur} and Bur^{C24}. In Bur^{C24} and the self-cybrid Bur^{Bur} we discovered the
338 presence of a duplicated segment on chromosome 2. Because this duplicated segment is present
339 (and identical) in two independent cybrid lines and this segment is of a Bur nuclear origin (i.e. there
340 are only Bur SNPs in this region), we conclude this segment results from a *de-novo* duplication in one
341 of the wild-type Bur lines used to generate these cybrids. Following the exclusion of phenotyping data
342 for Bur^{Bur} and Bur^{C24} we limited our analyses to 46 rather than 49 cybrids. The parental lines were
343 included in the screens to test for possible unforeseen effects of cybrid production (which involves a
344 haploid growth stage). This brings the number of phenotyped lines in this study to a total of 53 (40
345 cybrids, 6 self-cybrids and 7 wild types).

346 The functional effects of the chloroplast and mitochondrial SNPs and INDELS were predicted
347 using SnpEff (ref). A SnpEff database was built using the genome, transcriptome and proteome as
348 released in TAIR10.1. SNPs and INDELS were predicted on the filtered VCF, as mentioned above. In
349 the analysis we only considered variants with a "HIGH" or "MODERATE" impact.

350

351 *Phenotyping:* Cybrids were phenotypically assessed using different platforms. For details on the
352 number of phenotypes per experiment see Supplementary Table 4.

353 Growth, PSII efficiency (Φ_{PSII}), chlorophyll reflectance and leaf movement (all parameters at
354 $n=24$) was screened in the Phenovator platform, a high-throughput phenotyping facility located in a
355 climate-controlled growth chamber (Flood et al., 2016). This phenotyping platform measured the plants
356 for: Φ_{PSII} using chlorophyll fluorescence, reflectance at 480 nm, 532 nm, 550 nm, 570 nm, 660 nm,
357 700 nm, 750 nm and 790 nm, and projected leaf area (PLA) based on pixel counts of near infra-red
358 (NIR) images (Flood et al., 2016). The growth chamber was set to a 10 h day/14 h night regime, at
359 20°C day and 18°C night temperature, 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ irradiance, and 70% relative humidity. The
360 plants were grown on a rockwool substrate and irrigated daily with a nutrient solution as described in
361 Flood et al. (2016).

362 Growth ($n=24$) and subsequently above ground biomass ($n=12$) was measured in another
363 high-throughput phenotyping facility (Kokorian et al., 2010), where projected leaf area was measured
364 three times per day with 14 fixed cameras (uEye Camera, IDS Imaging Development Systems GmbH,
365 Obersulm, Germany). This growth chamber was set to a 10 h day/14 h night regime, at 20°C day and
366 14°C night temperature, 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light and 70% relative humidity. Plants were grown on
367 rockwool and irrigated weekly with a nutrient solution as described before.

368 Non-fluctuating and fluctuating light treatments were performed in the DEPI phenotyping
369 facility of Michigan State University ($n=4$) (Cruz et al., 2016). This facility is able to measure the
370 chlorophyll fluorescence derived photosynthetic parameters, Φ_{PSII} , Φ_{NO} , Φ_{NPQ} , NPQ, q_E , q_I . Three
371 week old plants were moved into the facility, where they were left to acclimatize for 24 hours after
372 which three days of phenotyping was performed under different light regimes. On the first day the
373 plants were illuminated with a constant light intensity of 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$. On the second day the plants
374 received a sinusoidal light treatment where the light intensity began low and gradually increased to a
375 maximum of 500 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light from which it decreased back down to 0. On the third day the plants

376 received a fluctuating light treatment ranging between 0 and 1000 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light in short intervals
377 (Figure 2C). For the second experiment in the DEPI phenotyping facility the experiment was extent
378 with 2 days, in which day 4 replicated day 2 and day 5 replicated day 2 (Supplementary Data 1 and
379 Supplementary Figure 7C). For further details see Cruz et al. (2016).

380 Bolting time and flowering time were measured on all cybrids (n=10) in a greenhouse
381 experiment in April 2017, with the exception of Ely nucleotype cybrids which needed vernalisation and
382 were not included in this experiment. Additional lighting was turned on when the natural light intensity
383 fell below 685.5 $\mu\text{mol m}^{-2} \text{s}^{-1}$, and turned off when the light intensity reached 1142.5 $\mu\text{mol m}^{-2} \text{s}^{-1}$, with a
384 maximum of 16 h per day.

385 Seeds for the germination experiments were generated from two rounds of propagation. In the
386 first-round seeds were first sown in a growth chamber set to a 10 h day/14 h night regime, at 20°C day
387 and 18°C night temperature. 200 $\mu\text{mol m}^{-2} \text{s}^{-1}$ light intensity, and 70% relative humidity. After three
388 weeks they were moved to an illuminated cold room at 4°C for six weeks of vernalization. After
389 vernalization all plants (n=8) were moved to a temperature-controlled greenhouse (20°C) for flowering
390 and seed ripening. Exceptions to this were LerEly, LerWs-4, and ElyWs-4 for which no doubled
391 haploid seed was available at the beginning of the first propagation round. LerEly and LerWs-4 were
392 sown later, during the vernalization stage and flowered at the same time as the vernalized plants.
393 ElyWs-4 produced haploid seed at a later stage and could not be included in the first propagation
394 round. Plants were grown in a temperature-controlled greenhouse set at 20°C. In this round only lines
395 with the Ely nucleotype were vernalized. For the germination experiments seeds were stratified on wet
396 filter paper for four days at 4°C before being assayed in the Germinator platform (Joosen et al., 2010)
397 for seed size, germination rate and total germination percentage. Germination under osmotic stress
398 was performed on filter paper with 125 mM NaCl. For the controlled deterioration treatment, seeds
399 were incubated for 2.5, 5 or 7 days at 40°C and 82% RH and subsequently assayed in the Germinator
400 platform without stratification.

401 To assess pollen abortion all cybrid lines and wild-type progenitors (except those with the Ely
402 nucleotype) were grown simultaneously in a growth chamber (Percival) under controlled conditions
403 (16H/ 8H light cycle, 21°/18° °C and 50%-60% relative humidity). Pollen abortion was manually
404 assessed for all the ecotypes by using a differential staining of aborted and non-aborted pollen grains
405 (Peterson et al., 2010). A total of three plants and three flowers per plant of each cybrid were collected

406 on the same day and submerged in a drop of 13 μ l of phenol-free Alexander staining solution placed
407 on a glass slide with a glass cover slip of 18x18 mm. For each flower 250 pollen grains were counted
408 and the number of aborted pollen therein.

409 Oxygen consumption of seedlings was measured in 2 mL of deionized water with a liquid-
410 phase Oxytherm oxygen electrode system (Hansatech Instruments) calibrated at the measurement
411 temperature. Three-day-old seedlings (about 50 mg) were directly imbibed in the electrode chamber.
412 The rates of oxygen consumption were measured after tissue addition and subtracted from the rates
413 after addition of 500 μ M KCN. The remaining oxygen consumption resulting from the alternative
414 pathway was assessed after addition of salicylhydroxamic acid (SHAM) to block alternative
415 oxidase. Results are the mean of at least five measurements. Measurements for different ecotypes
416 were performed on consecutive days, and to correct for daily variation normalized to Col-0 samples
417 that were run daily.

418

419 *Metabolomics*: Plant material for primary metabolite analysis was obtained from the 'Phenovator'
420 photosynthetic phenotyping experiment. Plants were harvested 26 days after sowing, which due to the
421 10-hr photoperiod was prior to bolting for all lines. Samples were frozen in liquid nitrogen, and samples
422 of each genotype were subsequently combined into four pools each made up of material of
423 approximately six replicates. Each pool was ground and homogenized before an aliquot was taken for
424 further analysis. Reference samples for the metabolite analysis were composed of material from all
425 seven parents in equal amounts and then homogenized. The method used for the extraction of polar
426 metabolites from *Arabidopsis* leaves was adapted from Lisec et al. (2006) as described by Carreno-
427 Quintero et al. (2012). Specific adjustments for *Arabidopsis* samples were made as follows; the polar
428 metabolite fractions were extracted from 100 mg of *Arabidopsis* leaf material (fresh weight, with max.
429 5% deviation). After the extraction procedure, 100 μ L aliquots of the polar phase were dried by
430 vacuum centrifugation for 16 hours. The derivatization was performed on-line similar as described by
431 Lisec et al. (2006) and the derivatized samples were analyzed by a GC-ToF-MS system composed of
432 an Optic 3 high-performance injector (ATASTM, GL Sciences, Eindhoven, The Netherlands) and an
433 Agilent 6890 gas chromatograph (Agilent Technologies, Santa Clara, California, United States)
434 coupled to a Pegasus III time-of-flight mass spectrometer (Leco Instruments, St. Joseph, Michigan,
435 United States). Two microliters of each sample were introduced in the injector at 70°C using 5% of the

436 sample (split 20). The detector voltage was set to 1750 Volts. All samples were analyzed in random
437 order in four separate batches. The systematic variation that inadvertently is introduced by working in
438 batches, was removed upon analysis of covariance. In this model the batch number was used as a
439 factor (four levels) and “run number within a batch” as a covariate since it is also expected that (some)
440 variation will be introduced by the sample run order within each batch. For this the S2 method
441 described by (Wehrens et al., 2016) was used to perform the least-squares regression. After quality
442 control and removing metabolites with more than 20% missing data and a broad sense heritability (H^2)
443 of less than 5%, we were left with data on 41 primary metabolites. Metabolites were identified based
444 on the Level of Identification Standard of the Metabolomics Standards Initiative (Sumner et al., 2007).

445

446 *Transcriptome analysis:* Using the same material as described in the metabolome analysis, total RNA
447 was extracted from six cybrids, three in a Ler and three in an Ely nuclear background: $Ler^{Ler} Ler^{Ely}$,
448 Ler^{Bur} and $Ely^{Ler} Ely^{Ely}$, Ely^{Bur} with three replicates per genotype, totaling 18 plants. Library preparation
449 was done with a selection on 3' polyadenylated tails to preferentially include nuclear mRNA. Read
450 alignment was done using TopHat (Trapnell et al., 2009). Any chloroplast and mitochondrial genes
451 remaining were excluded from further analysis. The raw counts were normalized and analyzed using
452 the DeSeq2 package in R (Love et al., 2014). Genes for which the expression levels were significantly
453 different between two cybrids were determined by comparing two genotypes using the contrast
454 function of DeSeq2. P-values were determined using the Wald test, and p-values were adjusted using
455 the Benjamini-Hochberg correction ($\alpha=0.05$). GO enrichment analysis was done using default setting
456 in g:profiler (g:GOST). The complete set of detected genes in each cybrid was used as a statistical
457 background in the analysis (Reimand et al., 2016).

458

459 *Phenotypic data analysis:* We used the self-cybrids as our baseline in phenotypic comparisons to
460 control for any possible effects of cybrid creation, with the exception of Bur^{Bur} which was replaced in all
461 analysis with Bur-WT. Raw data was directly analyzed except for time series data of growth and
462 chlorophyll reflectance which was preprocessed as follows. Time series data were fitted with a smooth
463 spline using the gam function from the mgcv package in R (Wood et al., 2016). The fitted B-spline was
464 subsequently used to derive several curve parameters. In addition, we calculated relative growth rate
465 per time point by dividing the growth rate, relative to the plant size (Flood et al., 2016). All raw

466 parameters and derived parameters were analyzed by fitting either a linear mixed model or a linear
467 model. The linear mixed model was used when a random correction parameter was present, when
468 such random correction parameters were absent a linear model was used. The models were analyzed
469 using the Restricted Maximum Likelihood (REML) procedure for each relevant phenotype using the
470 lme4 package in R (Bates et al., 2015). As each experiment had a different design, several models
471 were employed (Supplementary Table 4). The following model was generally used, in some instances
472 random terms (underlined below) were added:

$$\underline{Y} = \underline{Nucleotype} + \underline{Plasmotype} + (\underline{Nucleotype} * \underline{Plasmotype}) + \underline{Block} + \underline{\varepsilon} \quad (1)$$

474
475 For every model, normality and equal variances were checked. Next for every phenotypic parameter it
476 was determined whether an interaction model or a plasmotype additive model would suit best. This
477 was done by ANOVA in which Kenward-Roger approximation for degrees of freedom was used. As
478 posthoc tests we used a two sided Dunnett's test, where we tested whether a given cybrid was
479 different from the self-cybrid control, within one nucleotype. Two side Hochberg's posthoc tests were
480 used when all pairwise comparisons were tested within one nucleotype (to test for epistasis) and
481 across all nucleotypes (to test for additivity). The significance threshold for all posthoc tests was set at
482 $\alpha=0.05$. The contribution of the nucleotype, plasmotype and the interaction between the two, was
483 determined by estimating the variance components in mixed models containing the same terms as in
484 model (1). However, the fixed terms were taken as random:

$$\underline{Y} = \underline{Nucleotype} + \underline{Plasmotype} + (\underline{Nucleotype} * \underline{Plasmotype}) + \underline{Block} + \underline{\varepsilon},$$

486
487 Where the variance components were estimated by the VarCorr function from the lme4 package. Total
488 variance was calculated by summing all the variance components, after which the fraction explained
489 variance for every term in the model was calculated. The broad sense heritability, in our case equal to
490 repeatability (Falconer and Mackay, 1996), is determined by the three genetic components, i.e.
491 nucleotype, plasmotype and the interaction, together. The fraction of broad sense heritability explained
492 by the separate genetic components was calculated subsequently.

493 In total we measured 1859 phenotypes. After data processing, further analysis was only
494 conducted on phenotypes with a broad sense heritability higher than 5%, removing phenotypes that
495 were non-informative, leaving with 1782 phenotypes. Furthermore, to avoid biases in the results due
496 to overly correlated data when stating summary statistics, we further subset the remaining 1782
497 phenotypes (Supplementary Data 2). Using a threshold based purely on correlation would favor the
498 inclusion of variation largely driven by the nucleotype. Because the population is balanced, we
499 therefore subtracted the averages of the nucleotype values from the cybrid phenotype values, to reveal
500 the plasmotype effect per cybrid. From these we calculated the correlations for all phenotypes
501 (Supplementary Figure x). As a result, some phenotypic categories were not represented in a subset
502 between 50 and 100 phenotypes, as they correlated highly with another phenotype. To be able to give
503 a good overview of all phenotypes we score, but not to have a bias of one phenotype category, we
504 decided to manually choose a subset. We therefore selected the following phenotypes. For time series
505 in which we scored for up to 25 days after germination, we selected mornings of day 8, 13, 18 and 23.
506 The time series analysis of fluctuating light were only measured for three days in a row, with each day
507 a different treatment. As these treatments reached their extremes in the middle of the day, both at
508 these time points and at the end of the day were selected. For the different seed treatments we used
509 the germination time until 50% of the seeds germinated. In addition, we included biomass, leaf
510 movement, seed size, flowering time as single phenotypes and all 36 primary metabolites. This
511 resulted in 92 phenotypes, that are used when giving summary and test statistics (for correlation plot
512 of the plasmotype effect see Supplementary Figure x). All data on the 1859 phenotypes, with
513 summary and test statistics, are available in Supplementary Data 1 and Supplementary Table x.

650

651

652 **Acknowledgements:** Hetty Blankestijn, Jose van de Belt, Daniel Oberste-Lehn, Elio Schijlen, Corrie
653 Hanhart, and Joris ter Riele (all Wageningen University & Research) are acknowledged for help with
654 experiments, Jonas Klasen (Max Planck Institute for Plant Breeding Research) for statistical advice,
655 and Duur Aanen (Wageningen University & Research) for helpful discussions.

656

657 **Author contributions:** P.J.F. and E.W. conceived and designed the study. T.P.J.M.T. designed and
658 performed the statistical analysis with help from P.J.F., W.K. and F.v.E.. P.J.F., T.P.J.M.T., E.K.,
659 F.F.M.B., L.W., V.C.B., J.v.A., J.M.G., and L.S. performed experiments. P.J.F., T.P.J.M.T., K.S., P.K.,
660 E.S., J.A.H., S.K.S., R.W., W.L., R.M., F.v.E. and E.W. analysed data. D.M.K., J.J.B.K., M.K., J.H. and
661 M.G.M.A. contributed to the interpretation of results. P.J.F., T.P.J.M.T. and E.W. wrote the paper with
662 significant contributions from M.K., J.H. and M.G.M.A. All authors read and approved the final
663 manuscript.

664

665 **Competing interests statement:**

666 T.B.D.

667

668 **Data availability:** Sequencing and transcriptome data will be available in the European Nucleotide
669 Archive with the primary accession code PRJEB29654. The raw datasets will be made available
670 through Dryad, a reporting summary will be provided. The analysed datasets that support our findings
671 are available as supplementary datasets. The associated raw data for Figures 2 and 3 are provided in
672 Supplementary data 1, the raw data for Table 1 are provided in Supplementary data 2. The
673 germplasm generated in this project will be available via NASC.
