Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

Hydrogen/Deuterium Exchange Mass Spectrometry reveals Mechanistic Details of Nucleoside Diphosphate Kinases Activation by Oligomerization

Alain Dautant^{*,†} Philippe Meyer,[‡] and Florian Georgescauld^{*,‡}

Université de Bordeaux, CNRS, Institut de Biochimie et Génétique Cellulaires, UMR5095, Bordeaux, France and Sorbonne Universités, UPMC Univ. Paris 06, CNRS, Laboratoire de Biologie Moléculaire et Cellulaire des Eucaryotes, UMR8226, Institut de Biologie Physico-Chimique, 13 rue Pierre et Marie Curie, 75005 Paris, France

Abstract: Most oligomeric proteins become active only after assembly, but why oligomerization is required to support function is not well understood. Here, we address this question using the WT and a destabilized mutant (D93N) of the hexameric nucleoside diphosphate kinase from the pathogen *Mycobacterium tuberculosis* (*Mt*-NDPK). The conformational dynamics and oligomeric states of each were analyzed during unfolding/folding by Hydrogen/Deuterium exchange mass spectrometry (HDX-MS) at peptide resolution and by additional biochemical techniques. We found that WT and D93N native hexamers present a stable core and a flexible periphery, the latter being more flexible for the destabilized mutant. Stable but inactive species formed during unfolding of D93N and folding of WT were characterized. For the first time, we show that both of these species are native-like dimers, each of its monomers having a major subdomain folded, while a minor subdomain (Kpn/α_0) remains unfolded. The Kpn/α_0 subdomain, which belongs to the catalytic site, becomes structured only upon hexamerization, explaining why oligomerization is required for NDPK activity. Further HDX-MS studies are necessary to establish the general activation mechanism for other homo-oligomers.

INTRODUCTION

Depending on the organism, 40 to 60% of proteins assemble and become functional after forming oligomeric complexes.^(1, 2) These proteins must, within a well determined tridimensional complex structure, subtly balance thermodynamic stability with conformational flexibility.^(3, 4) Thermodynamic stability is required to maintain a protein's activity throughout its lifetime while preventing proteolysis or aggregation. In parallel, flexibility is necessary for newly synthesized chains to acquire the native conformation, to assemble and afterwards for the protein to perform its function. How oligomerization induces a protein's "functionality" and how a protein's function, thermodynamic stability and conformational flexibility relate to each other are poorly understood, essentially due to lack of experimental information on the dynamic aspects. Since a single analytical method cannot provide information on a large panel of the physico-chemical properties of proteins, multi-technique approaches and development of new time and space resolved techniques appear essential in this understanding.⁽⁵⁻⁸⁾

Hydrogen/Deuterium exchange detected by mass spectrometry (HDX-MS) is a methodology applied to proteins in recent years for investigating their properties, at peptide resolution, such as dynamics, conformational changes, post-translational modifications, viral capsid assembly, spontaneous and assisted folding, and interactions with partners or ligands.⁽⁹⁻¹³⁾ The method is applied to proteins in solutions mimicking their physiological environment and relies on the natural property that proteins rapidly exchange their solvent accessible backbone amide hydrogens that are not involved in stable H-bonds. Exposure of the protein of interest into a D₂O-containing solvent environment induces the replacement of labile accessible backbone hydrogen (¹H, H) atoms with deuterium (²H, D). The exchange is measured by MS after protein digestion and interpreted in the view of the structure. The advantages of HDX-MS are that it requires only a small amount of material (in the pmol range), that it has great resolution and sensitivity, that it allows for an accessible mass range of up to 10⁶ Da, that it allows high speed analysis and that it is a non-ensemble technique; each single spectrum contains extractible information about all discrete co-existing states of the protein of interest. By massively increasing its interest in protein therapeutics within these last years, the biopharmaceutical industry became particularly interested in improving and developing spatially resolved analytical techniques like HDX-MS for its needs in both research and quality control.^(14, 15) Since so far HDX-MS was mostly implemented on monomeric proteins⁽¹⁶⁻

1
2
3 ²²⁾ and only a few studies have been conducted on homo-oligomeric proteins⁽²³⁻²⁷⁾ or protein
4 complexes,⁽²⁸⁻³¹⁾ efforts have to be continued for extracting the dynamic determinants of complexes.
5
6

7 Nucleoside diphosphate kinase (NDPK) is a multifunctional protein which catalyzes the gamma-
8 phosphate transfer from nucleoside triphosphate to nucleoside diphosphate⁽³²⁾ in order to maintain
9 equilibrium between the pools of nucleoside triphosphates (NDP/NTP). Several isoforms are found
10 in eukaryotes,⁽³³⁾ isoform 1 (called nm23A) being the first metastasis suppressor described in
11 humans.⁽³⁴⁻³⁶⁾ Additionally, NDPK also acts as a protein histidine kinase,⁽³⁷⁻³⁹⁾ and recent studies
12 have shown that by interacting with and providing GTP to dynamins, NDPK is involved in
13 membrane-remodeling events.^(40, 41) Like many enzymes, NDPKs are non-allosteric oligomers, but
14 *in vitro* and *in vivo* studies suggest that their assembly is required for kinase activity or metastasis
15 suppression function.⁽⁴²⁻⁴⁴⁾ Many aspects of the kinase activity mechanism are now understood from
16 a structural point of view,⁽³²⁾ namely, the role of amino acids involved in the catalysis, but the
17 requirement for assembly to become functional is still unclear and remains to be elucidated.^(42, 43)
18
19

20 NDPKs contain ferredoxin-like folds⁽⁴⁵⁾ which assemble first as dimers and then as tetramers or
21 hexamers.⁽⁴⁶⁻⁴⁸⁾ Tetramers are present in gram-negative bacteria and archaea, while hexamers are
22 present in gram-positive bacteria and eukaryotes. Hexamers represent the most abundant type of
23 oligomerization, which specifically relies on the well conserved surface loop that carries the site of
24 the natural “*Killer of prune*” mutation (*Kpn*-loop) (Figures 1, S1). In addition, the stabilization of
25 hexamers by subunit interactions has been studied.⁽⁴⁹⁻⁵³⁾ Crystallographic structures of several-
26 NDPK mutants provide detailed understanding of the WT stabilization mechanism,^(53, 54) but
27 provide little understanding as to why oligomerization is necessary for function. So, we realized that
28 by combining stability aspects with the study of their dynamic properties, we would improve this
29 understanding.

FIGURE 1

Mycobacterium tuberculosis (*Mt*), the pathogenic bacteria responsible of tuberculosis, possesses only one NDPK isoform (*Mt*-NDPK), which is hexameric (Figures 1, S1).⁽⁴⁹⁾ In addition to its kinase function, *Mt*-NDPK binds DNA⁽⁵⁵⁾ and also blocks phagosome maturation in murine macrophages leading to evasion of innate immunity.⁽⁵⁶⁾ The escape mechanism is unknown, but efficient intracellular survival of *Mt* requires a strong thermodynamic stability of proteins.⁽⁵⁷⁾ We recently showed *in vitro* that isolated sub-hexameric assemblies of *Mt*-NDPK are inactive, complete assembly being essential for function.⁽⁵³⁾ By combining crystallography and biochemistry, we also demonstrated that hexamer's high thermostability (76°C) is dependent on six inter-subunit R80-D93 salt bridges.⁽⁵⁴⁾ The point mutation D93N reduces the melting point by 28°C, without significant alteration of the hexameric 3D structure or enzymatic properties.⁽⁵³⁾ The link between the protein's function, stability and oligomerization is still an open question.

1
2
3 Here, we show why the full oligomeric state is required for and affects protein function, as
4 demonstrated by the study of WT and D93N *Mt*-NDPK. In addition to the classical biochemistry
5 methods (fluorescence, enzymology, size exclusion chromatography), we use the HDX-MS
6 technique to reveal the overall and local structure and dynamics of NDPK by monitoring amide
7 hydrogen atoms in polypeptides. We show that both native hexamers are stable, without in/out
8 subunit exchange, but that the D93N destabilizing mutation increases the flexibility at the hexamer
9 surface. Inactive dimers which accumulate during folding of WT and D93N, as well as during
10 D93N unfolding were analyzed. Strikingly, differences in conformational flexibility between
11 hexamers and dimers explain why hexamerization is required for kinase activity.

19 MATERIALS AND METHODS

20
21 **Reagents.** Chemicals were of the highest purity grade from Sigma. Solutions of urea were
22 freshly prepared for each experiment.
23

24
25 **Proteins and enzymatic assays.** WT and D93N *Mt*-NDPK were expressed without tag, using
26 a pET24 vector (Novagen) in BL21-CodonPlus[®](DE3)-RIL (Stratagene) strain. Transformed cells
27 were induced at 37°C with 1 mM IPTG for 6 h in the presence of 80 µg/mL kanamycin and the
28 purification steps were carried out at 4°C as previously described.⁽⁵³⁾ After sonication and
29 centrifugation, the soluble fraction containing *Mt*-NDPK was DNase-treated, and the extract was
30 applied to a Q-Sepharose column equilibrated with 100 mM Tris-HCl, pH 7.4. The enzyme was
31 eluted with a linear gradient of 0 to 0.8 M NaCl in the same buffer. Active fractions were
32 precipitated into 80% saturated ammonium sulfate (AS) and further purified by salting-out
33 chromatography on a Sepharose 6B column equilibrated with 80% AS, 100 mM Tris-HCl, pH 7.4.
34 The protein was eluted by decreasing AS concentration from 80% to 20% in the same buffer. The
35 active fractions were dialyzed against 100 mM Tris-HCl, pH 7.4, and further purified on a Source
36 15Q column, under the conditions described for the Q-Sepharose chromatography. The enzymes
37 were precipitated by dialysis against a saturated solution of AS, recovered by centrifugation and
38 further purified by size-exclusion chromatography on a Sephacryl S-200 column equilibrated with
39 0.2 M sodium phosphate buffer, pH 7.0. The final hexameric preparations were kept frozen in 50
40 mM Tris-HCl, pH 7.4 at -80°C.

5 ovalbumin, 44 000 Da; BSA, 68 000 Da; aldolase, 158 000 Da) from GE Healthcare Life Sciences
6 were used. The P105G *Dd*-NDPK, monomeric version from *Dictyostelium discoideum*, was a gift
7 from Pr. Ioan Lascu and has an elution volume of 12.6 mL (data not shown).
8
9

10
11 NDPK enzymatic activity was measured using a coupled assay.^(52, 53) The reactions of the test
12 are shown below and the enzymes catalyzing each reaction are indicated in parentheses. In this
13 assay, NDPK catalyzes phosphate transfer from ATP to 8-bromoinosine-5'-diphosphate (8-BrIDP).
14 The enzyme mix contained in a final volume of 0.8 mL: 20 mM Tris-HCl (pH 7.5), 5 mM MgCl₂,
15 100 mM KCl, 1 mg/mL BSA, 1 mM de phosphoenol pyruvate, 0.1 mM NADH, 1 mM ATP, 0.2
16 mM 8-BrIDP, 2U/mL of pyruvate kinase and lactate dehydrogenase. We measured NADH
17 disappearance at 340 nm and 25°C, using a Perkin-Elmer spectrophotometer. For such assay, the
18 errors associated with the kinetic parameters are under 20%.^(32, 53)

32 **Unfolding and refolding.** The unfolding/refolding experiments were performed as previously
33 described.⁽⁵³⁾ 10 µg/mL final concentration of native or unfolded *Mt*-NDPK were incubated for 16 h
34 in 0–8 M urea or 0–5 M GuHCl, and 20 mM phosphate buffer, pH 7.0 at 25°C. Fluorescence
35 intensities of the single tryptophan residue Trp132 were measured at 335 nm with an excitation at
36 295 nm.
37
38
39

40
41 **Continuous HDX.** Experiments were performed at full length and peptide resolution, by
42 following the schemes (Figures 2A and S2A). Stock solutions of 2.0 µM native *Mt*-NDPKs (WT
43 and D93N) were prepared in 20 mM Tris-HCl pH 7.5, 100 mM KCl, H₂O. Deuterium exchange was
44 initiated by dilution of the *Mt*-NDPK stock solution 10-fold into 20 mM Tris-HCl, 20 mM KCl, pD
45 7.5, 99.9% D₂O, 10°C. The KCl salt concentration was reduced from 100 mM to 20 mM in order to
46 obtain better MS spectra quality. At different times of incubation, a 200 µL aliquot from the
47 exchange reaction was removed (from 10 s to 90 min) and labeling was quenched by adjusting the
48 pH to 2.5 with formic acid, at 0°C.

3 For full length experiments, protein samples were immediately injected into an Alltech analytical
4 guard column, packed with POROS 20-R1 reversed-phase media (PerSeptive Biosystems). Each
5 sample was washed within 20 s with 400 μL of 0.1% formic acid, ice cold. The guard column was
6 then switched in line with the HPLC inject port with a flow rate of 200 $\mu\text{L}/\text{min}$ of 15%
7 acetonitrile/0.1% formic acid, pH 2.5 for 2 min. The protein was eluted at 40 $\mu\text{L}/\text{min}$ using a 1.5
8 min gradient of 15%–75% acetonitrile directly into a Waters Synapt G1 mass spectrometer with a
9 standard electrospray interface. The injector, column and all associated tubings were kept at 0°C
10 using an ice bath to minimize back exchange.⁽⁵⁸⁾ All experiments were conducted under identical
11 conditions to allow comparison of relative deuterium levels.⁽⁹⁾ Mass accuracy of less than 20 ppm
12 was maintained by infusing horse heart myoglobin into the mass spectrometer at the end of each
13 chromatographic gradient. Intact mass spectra were deconvoluted using MassLynx (Waters) and
14 masses were corrected for back exchange (17%) and dilution effect (10%). As controls, unfolded
15 and native *Mt*-NDPKs were subjected to D₂O pulse labeling and LC-MS analysis. The back-
16 exchange of 17% was measured by diluting denatured *Mt*-NDPKs (6 M GuDCl, 1 mM DTT) into
17 20 mM Tris-HCl, 20 mM KCl buffer prepared with 99.9 D₂O. After 10 s of deuteration, the reaction
18 was quenched and immediately subjected to LC-MS at 0°C.

19
20 To obtain HDX data at peptide resolution, 200 μL of each acid-quenched sample were injected
21 into a loop of 100 μL inside an HDX Waters nanoACQUITY Ultra Performance Liquid
22 Chromatography (UPLC).⁽⁵⁸⁾ The sample passed through a Poroszyme-immobilized pepsin
23 cartridge (Applied Biosystems) accommodated within the HDX manager at a flow rate of 100 μL
24 min^{-1} and temperature of 20°C. Peptic peptides eluting from the pepsin column were trapped and
25 desalted for 3 min at 100 $\mu\text{L} \text{min}^{-1}$, and then separated in 7 min with 8% to 40% acetonitrile:water
26 gradient at 40 $\mu\text{L} \text{min}^{-1}$, all steps were carried out in 0.1% formic acid pH 2.5 before MS analysis.
27 The separation column was a 1.0×100.0 mm ACQUITY UPLC C18 BEH (Waters) containing 1.7
28 μm particles and the back pressure averaged 8000 psi. All chromatographic elements were held at
29 0°C for the entire time of the measurements. The average amount of back exchange was around
30 25% based on analysis of highly deuterated peptide standards.⁽⁵⁸⁾ Deuterium levels were corrected
31 for 25% back-exchange and 10% dilution, all comparison experiments being done under identical
32 experimental conditions. The UPLC steps were performed with protonated solvents, thereby
33 allowing deuterium to be replaced with hydrogen from side chains and the amino/carboxyl terminus
34 that exchange much faster than amide linkages.^(5, 9) The error in the determination of the deuterium
35 levels was ± 0.20 Da in this experimental setup consistent with previously obtained values.^(17, 23, 59)

1
2
3 Mass spectra were obtained with a Waters Synapt G1 using a standard ESI source (Waters Corp.,
4 Milford, MA, USA) over an m/z range of 50-1700. Mass accuracy was ensured by calibration with
5 Glu-fibrinogen peptide, and was less than 10 ppm throughout all experiments. Identification of the
6 peptic fragments was accomplished with at least 4 replicate MS^E analyses⁽²³⁾ using Identity
7 Software (Waters Corp., Milford, MA, USA). MS^E was performed by realizing series of low-high
8 collision energies ramping from 5–30 V, therefore ensuring proper fragmentation of all the peptic
9 peptides eluting from the LC system.
10
11
12
13

14
15 **Pulse HDX.** To characterize the unfolding pathway of D93N, the purified protein was first
16 pre-incubated at 2 μ M in 0-8 M urea, for 16 h at 10°C. After this step, the pulse labeling experiment
17 was performed following the scheme (Figure S3C). 20 μ L of each sample were deuterated for 12 s
18 by dilution of the protein stock solution 10-fold into 20 mM Tris-HCl, 20 mM KCl, pD 7.5, 99.9%
19 D₂O, at 10°C. Deuteration was stopped by quenching the reaction with formic acid, final pH at 2.5,
20 at 0°C. After the quenching step, samples were digested or not and analyzed as described in the
21 previous paragraph concerning the continuous labeling.
22
23
24
25
26

27 The unfolding pathway of the WT was characterized in the same way as for the D93N one,
28 except that we used a higher performance mass spectrometer (Synapt G2 Si, Waters) allowing a 9-
29 fold lower working protein concentration. Pre-incubation of WT was performed at about 220 nM
30 final and the pulse labeling experiment followed the scheme (Figure S3C), all the other
31 experimental aspects were identical to the ones explained for unfolding of D93N.
32
33
34

35 Spontaneous refolding of WT *Mt*-NDPK was initiated by 400-fold dilution from 7.2 M GuHCl
36 into refolding buffer (20 mM Tris-HCl, pH 7.5, 100 mM KCl) at 10°C and final protein
37 concentration of 220 nM. Residual GuHCl concentration was as low as 18 mM in order to not
38 disturb the refolding process. The reaction scheme shown in Figure S4A was followed. Aliquots of
39 refolded *Mt*-NDPK were deuterated for 12 seconds, quenched with formic acid at pH 2.5 and
40 analyzed as described above for the continuous labeling experiments. A Synapt G2 Si mass
41 spectrometer was used for these experiments. The unfolded references were arbitrarily given a
42 refolding time of 3 s in these graphs.
43
44
45
46
47
48
49

50 **Peptide Mass Analysis and Data Processing.** Mass spectra were processed using DynamX
51 2.0 software (Waters) by centroiding the isotopic distribution corresponding to all charge states of
52 each peptide. Automated selection of the isotope distribution was verified manually for all peptides
53
54
55

1
2
3 and all charge states. The resulting relative deuterium levels (corrected for 25% back exchange and
4 10% dilution factor) were plotted versus the exchange-in time with respect to experimental
5 described conditions. All comparison experiments were done under identical experimental
6 conditions. NDPKs unfolded during 1 h in GuDCI 6 M were used as controls for 100% deuterated
7 protein. The error of determining the deuterium levels was ± 0.20 Da for the experimental setup
8 used.^(17, 23, 59) For the pulse labeling experiments, when the isotope distributions were bimodal, all
9 isotopes of the entire bimodal pattern were selected for processing.⁽²³⁾ The relative deuterium
10 incorporation was calculated by subtracting the centroid of the isotopic distribution for peptide ions
11 of the native reference from the centroid of the isotopic distribution for peptide ions from each
12 refolding sample (Figure S4B). All molecular structure figures were prepared using PyMol,⁽⁶⁰⁾ and
13 the alignment figure using ESPrpt (<http://esprpt.ibcp.fr>).⁽⁶¹⁾

22 RESULTS AND DISCUSSION

23 Impact of destabilizing D93N mutation on *Mt*-NDPK hexamer dynamics

24 Here we perform continuous labeling HDX coupled to liquid chromatography (LC) and mass
25 spectrometry (MS) to characterize the overall conformational dynamics of purified hexameric WT
26 and D93N *Mt*-NDPKs (Figure 2A). Samples kept at 10°C are incubated for 10 s to 90 min into 90%
27 D₂O final concentration and acid quenched on ice to stop the H/D exchange. On line injection of
28 full length protein to a LC-MS system allows immediate mass measurement. Deuterium
29 incorporation in WT and D93N hexamers follows apparent first-order exponential kinetics from 10
30 s to 40 and 60 min respectively, when two maximum values are reached (Figure 2B). These values
31 of 67 and 75 D's (after correction for back exchange (17%) and dilution effect (10%)), on 129
32 theoretically accessible H's, show that more than half of each chain is solvent accessible. At each
33 incubation time, WT incorporates between 5 and 11 D's less than D93N indicating a higher overall
34 rigidity for WT. The WT is thermodynamically more stable than the D93N mutant, clearly
35 supporting the view that increased stability reduces flexibility.⁽³⁾
36
37

41
42
43
44
45
46

47 To gain spatial information, we next performed continuous labeling HDX-MS at peptide level
48 resolution by adding a pepsin digestion step before LC-MS (Figure S2A). 27 identical polypeptides
49 covering 95.6% of the sequence were analyzed in both proteins (Figure S2B). 17 peptides had
50 identical or almost identical behavior while 10 overlapping peptides (gray shaded panels) covering
51 27% of the total sequence, start and end with different exchange levels of at least 0.50 Da,
52
53
54
55
56
57
58
59
60

1
2
3 representing more than 15% when normalized to the maximal incorporation value (Figure S2C).
4 The highest flexibility is noticed in both hexamers for surface regions 39-62 (hairpin α_A/α_2), 108-
5 113 (helix α_3'), and 132-136 (C-term end), which interestingly correspond to the most divergent
6 sequences in NDPKs (Figures 2C-D, S2D). For the C-terminal end, the deuteration is already
7 maximal at the first experimental time point after 10 s, as indicated by the corresponding flat plots.
8 Because of its biological relevance, original search for flexible regions in NDPKs started two
9 decades ago using ^1H NMR.⁽⁶²⁾ Here, our HDX-MS results show that as previously suggested,^(50, 62)
10 the hairpin α_A/α_2 which is a part of the nucleotide binding site, is highly flexible and could undergo
11 large movement in order to accommodate DNA, explaining the DNA binding function.⁽⁵⁵⁾ Both WT
12 and D93N hexamers present with full deuteration after 10 min, with three quarters of their sequence
13 being already deuterated at 10 s. The regions specifically affected by the D93N mutation are
14 contiguously located at the hexamer surface (9-15: helix α_0) and at the trimer interface (85-113:
15 *Kpn*-loop) (Figures 2C-D, left columns showing the surface). The region 108-113 is fully solvent
16 accessible in the mutant, while in WT it becomes fully deuterated after 3 min exposure to solvent.
17 The peptides covering region 114-130 present about 1 Da difference in deuterium incorporation,
18 which corresponds to less than 15% difference indicating that mutation did not substantially affect
19 this part of the structure. The strand β_2 (32-38) and the helix α_1 (18-27), which form the dimer
20 interface, remain inaccessible to solvent indicating high stability for dimers (Figure 2D, right
21 column showing the interface). In conclusion, differences in dynamics for D93N and WT Mt-
22 NDPK hexamers correlate only with their difference in stability, while their 3D structures are very
23 similar with an RMSD of 0.23 Å. Importantly, the decrease of thermostability of D93N is
24 accompanied by the increase of the conformational flexibility at the hexamer surface, without
25 affecting the stable core of the protein (Figure S2D).

42 **D93N and WT unfolding pathways comparison**

43
44 The next questions we addressed were whether the conformational flexibility of NDPK varies
45 with the oligomeric state and whether this potential variation is the reason why oligomerization is
46 required to support function. To find sub-hexameric species, unfolding and refolding pathways of
47 WT and D93N were analyzed in the presence of urea. First, enzyme activity was measured after
48 incubation of native and unfolded NDPK for 16 h in 0 to 7.2 M urea (Figure S3A). In both cases a
49 hysteresis phenomenon was observed, since unfolding and refolding curves did not overlap,
50 indicating that WT and D93N proteins were not at equilibrium. Second, the hydrodynamic radii of
51

60

1
2
3 NDPK were measured by SEC in 0 to 7.2 M urea, after the same unfolding/refolding procedure
4 (Figure S3B). Again, a hysteresis phenomenon was observed, since for the same urea concentration,
5 the elution volume of NDPK differed between folding and unfolding. Taken together, these results
6 show an absence of equilibrium for WT and D93N during unfolding/folding experiments. They are
7 in full agreement with our previous data on *Mt*-NDPK as well as with other similar studies on
8 NDPK which show hysteresis after about 1 day of unfolding/refolding in presence of denaturing
9 agents.^(42, 53)
10
11
12
13
14

15 Having established that unfolding and refolding pathways were different for both WT and D93N
16 NDPKs, we next characterized the potential sub-hexameric species formed during unfolding. WT
17 hexamers were incubated in 0 to 7.2 M urea during 16 hours and the oligomeric state was
18 established by SEC for the different urea concentrations (Figure S3B). Two elution volumes of 9.65
19 and 10.2 mL were noticed, indicating respectively a direct passage from native hexamers (0 to 4.0
20 M urea) to unfolded monomers (>4 M urea). The WT unfolding pathway was next characterized by
21 enzyme activity, which reflects integrality of quaternary structure and by the fluorescence of the
22 unique tryptophan (W132), which reflects integrity of tertiary structure. Both curves overlapped,
23 indicating again concomitant dissociation and unfolding (Figure 3B).

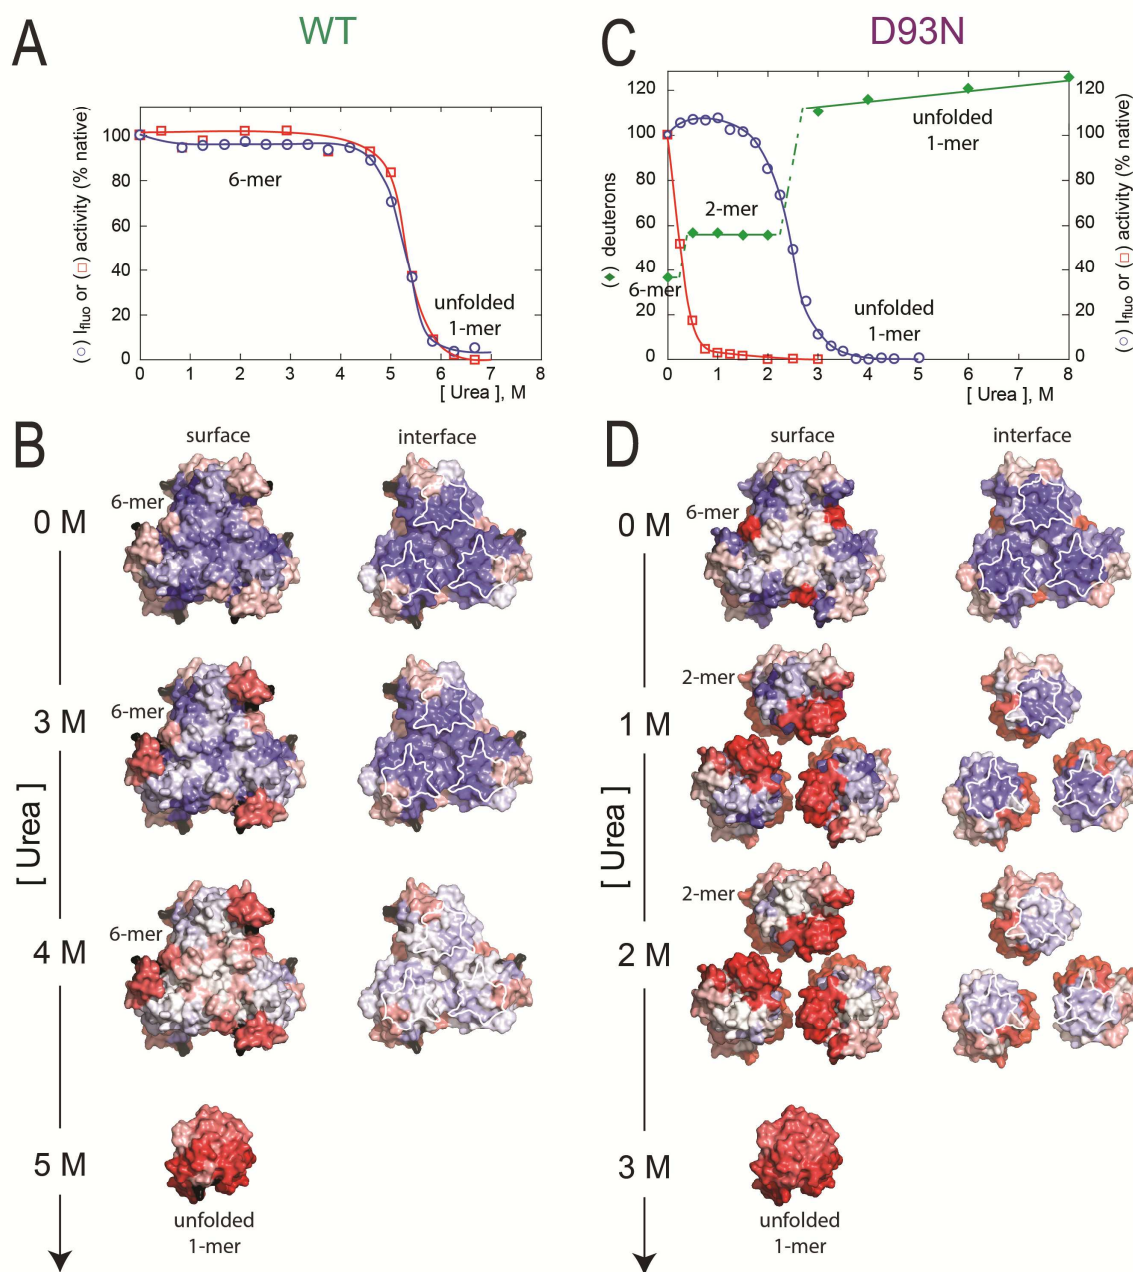

FIGURE 3

To obtain mechanistic details, pulse labeling HDX-MS at the peptide level was performed, following the scheme described in (Figure S3C). The level of deuterium which is detected in the peptides is a signature of the NDPK conformations during unfolding, providing a snapshot of the different coexisting populations. The 31 peptides analyzed, covering 98.5% of the sequence (Figure

S2B), all showed bimodal behavior with one transition between the folded/assembled hexamers and unfolded monomers around 4.5 M urea (Figure S3D). Two representative peptides are shown in Figure 4 (left panels). This result clearly shows concomitant dissociation and unfolding of WT hexamers (Figure 3B), in full agreement with SEC, tryptophan fluorescence and activity data.

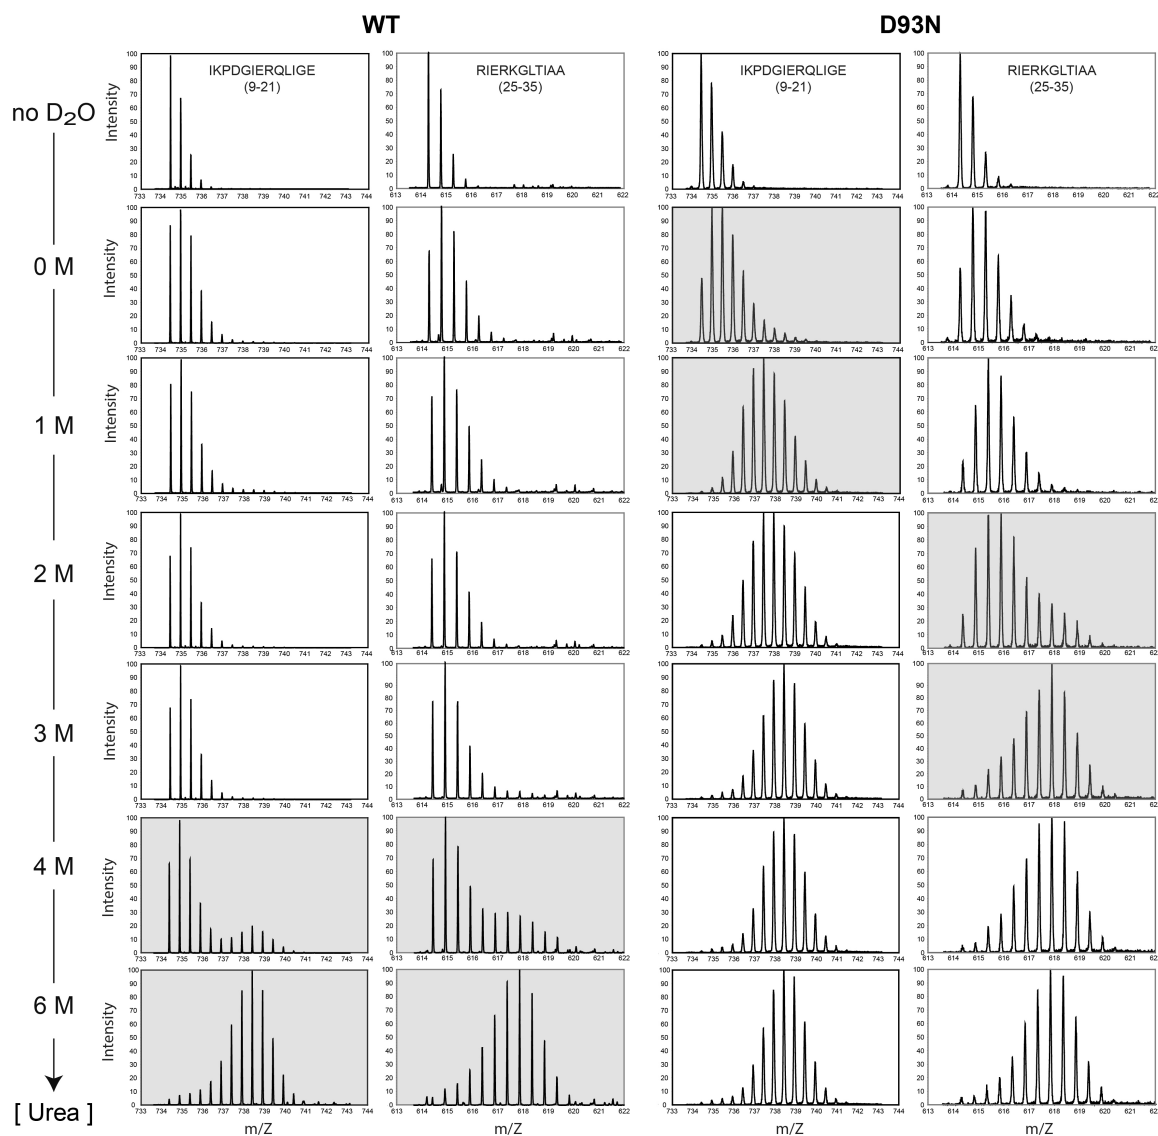

FIGURE 4

When the same strategy of characterization by SEC, enzyme activity and tryptophan fluorescence, followed by HDX-MS analysis was applied to the D93N mutant, a different unfolding

1
2
3 pathway was highlighted. By SEC, in addition to hexamers and unfolded monomers, a new species
4 was detected at low denaturant concentrations (1 and 2 M urea). The column calibration indicates
5 that the elution volume of 11.7 mL corresponds to native dimers (Figure S3B). At 4 M or higher
6 urea concentrations, this species disappears and only one new peak corresponding to unfolded
7 monomers appears (10.2 mL), indicating that dimers dissociate and unfold concomitantly.
8 Confirmation of this unfolding pathway was obtained using two additional methods: enzyme
9 activity is lost for urea concentrations higher than 0.5 M (Figure 3C, empty red squares), while from
10 Trp fluorescence, only one transition between native and unfolded species was observed around 2.7
11 M urea (Figure 3C, empty blue circles). Taken together, these results indicate that D93N hexamers
12 disassemble into dimers before further concomitant dissociation and unfolding into monomers.
13 Pulse labeling HDX-MS at full-length protein level was performed to further characterization. In
14 the absence of urea, hexameric full length D93N incorporates 36 D, while between 0.5 and 2.0 M
15 urea, dimers incorporate additional 19 D (Figure 3C, green diamonds). From 3 to 8 M urea,
16 progressive incorporation from 111 to 125 D over the 129 available amide protons reveals
17 monomers with a slightly different level of unfolding, in agreement with SEC, fluorescence and
18 activity data (Figure 3C).

23
24
25
26
27
28
29

30 To structurally determine why such dimers are enzymatically inactive, the D93N unfolding
31 pathway was characterized by pulse labeling HDX-MS at peptide level, as described in the scheme
32 of Figure S3C. 30 peptides covering 100% of the sequence (Figure S2C) were analyzed (Figures
33 3D, S3E-F). All spectra show bimodal isotope distribution, which corresponds to native or fully
34 unfolded peptide, except peptides 108-113 and 132-136, which are permanently unfolded. Bimodal
35 peptides had transitions between their folded and unfolded states at the same urea concentrations as
36 the ones noticed for the loss of activity (0.5 M) or tertiary structure (2.7 M). The specific behavior
37 of these two categories of peptide is illustrated by their mass spectra of peptides 9-21 and 25-35,
38 respectively (Figure 4, right panels). Remarkably, at 0.5 M urea, the loss of enzyme activity is due
39 to unfolding of the regions 85-107 (*Kpn*-loop) at the trimer interface and 9-16 (helix α_0). These
40 regions are far in the sequence but close in the structure and constitute a separate subdomain of the
41 rest of the monomer, further called *Kpn*/ α_0 subdomain. The rest of the sequence including the dimer
42 interface (region 17-40: helix α_1 , and strand β_2) is not altered up to urea concentrations higher than
43 2.7 M, when the dimers simultaneously dissociate and unfold. Taken together, these data show that
44 the D93N inactive intermediate species correspond to native-like folded dimers, instead of
45
46

1
2
3 monomers, as previously proposed.⁽⁵³⁾ These dimers are well folded except for the *Kpn/α₀*
4 subdomain which is fully solvent accessible and by consequence lacks stable structure.
5
6

7 WT and D93N hexamers exhibit similar enzyme properties but different thermodynamic
8 stabilities, which are responsible for their different unfolding pathways (Figure S3G). WT hexamers
9 dissociate and unfold concomitantly indicating high cooperativity between all six subunits. D93N
10 hexamers first dissociate into dimers before further concomitant dissociation and unfolding,
11 indicating a partial loss of cooperativity between subunits, and so demonstrate the important role
12 played by ionic bonds for cooperativity inside complexes. D93N dimers are inactive and much less
13 stable compared to WT-hexamers (Figures 3A and 3C, blue curves). Importantly, the lack of
14 activity is only due to the lack of stable structure of the *Kpn/α₀* subdomain, indicating that even a
15 single-domain protein can have its dynamics uncoupled between its structural subdomains.
16

22 **Characterization of refolding and assembly pathway of WT *Mt*-NDPK**

23

24 Stable but inactive species accumulate for WT *Mt*-NDPK only during refolding at low protein
25 concentration (Figure 5A, blue circles),⁽⁵³⁾ and their characterization by size exclusion
26 chromatography indicates they are dimers (Figure S3B).

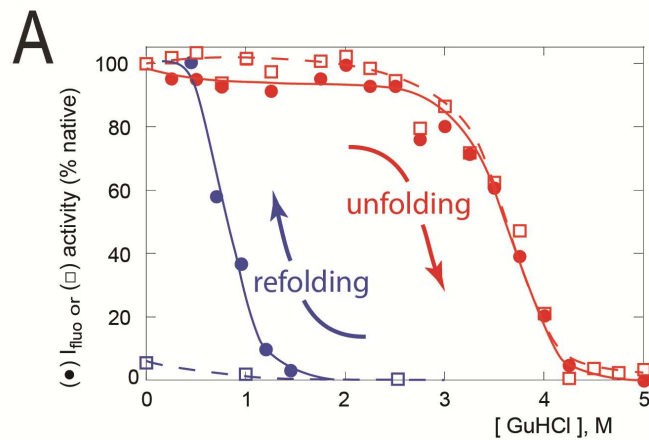

FIGURE 5

1
2
3 Next, we took advantage of the HDX-MS sensitivity to analyze the WT refolding and assembly
4 pathway at peptide resolution. Unfolded WT protein in 7.2 M GuHCl final concentration was
5 diluted 400-fold into refolding buffer to a final concentration of 220 nM for 0-3 h. Aliquots were
6 deuterated, quenched and digested, and the peptide masses were immediately measured (Figure
7 S4A). It is important to note that the residual 18 mM GuHCl in the refolding buffer is insufficient to
8 unfold any peptide and did not affect the folding/assembly pathway. Strikingly, after 10-30 seconds
9 refolding, all peptides became native, except for the previously described *Kpn/α₀* subdomain (84-
10 107 and 9-21), which stays fully unfolded during at least 3 h (Figure S4B). The weak
11 hydrophobicity of the *Kpn/α₀* subdomain, when compared to the rest of the NDPK sequence, is
12 probably not sufficient to allow its burying/folding by hydrophobic collapse. We conclude that, in
13 agreement with stopped-flow data,⁽⁵³⁾ WT monomers are rapidly folded and assembled into inactive
14 dimers (Figures 5B, S4C) similar to the ones described for D93N unfolding. WT and D93N dimers
15 are native-like except for the *Kpn/α₀* subdomain, which gets buried and structured only during
16 assembly into hexamers, inducing enzyme activation.
17

18
19 During two decades and based on spectroscopic methods, it has been proposed that structurally
20 single-domain proteins - like NDPKs - present only two conformations (folded or unfolded), the
21 interconversion between them being performed within one single step, without formation of stable
22 intermediates.⁽⁶³⁾ Here we show that such methods are insufficient to fully characterize properties of
23 folding/unfolding intermediates, mostly when such intermediates present many but not all physical
24 properties the native protein possess. We propose that as for a few proteins,⁽⁶⁴⁾ *Mt*-NDPK
25 folding/unfolding appears by blocks or subdomains, which are called foldons in the literature.⁽⁶³⁾
26 Clearly in our study the *Kpn/α₀* subdomain is indeed such a foldon. We could demonstrate that the
27 *Kpn/α₀* foldon is unstructured in monomers/dimers and acquires stable conformation only upon full
28 hexameric assembly. Since the *Kpn/α₀* foldon is part of the catalytic site, this explains why full
29 hexamerisation is required for enzyme function acquisition. Finally, our study demonstrates that
30 during the phenomena of folding/unfolding of NDPK, the *Kpn/α₀* foldon is stabilized/destabilized in
31 a cooperative sequential order.

49 CONCLUSIONS

50
51 In this study we have applied a combination of biochemical and biophysical methods to *Mt*-
52 NDPK including the emerging technique of structural mass spectrometry to investigate the link
53 between a protein's function and several of its physical parameters: conformational dynamics,
54
55
56
57
58
59
60

1
2
3 stability and oligomerization. Even though NDPK research today comprises more than 2500
4 publications, the HDX-MS methodology has only marginally been applied to study this important
5 class of proteins.⁽⁶⁵⁾ Here, for the first time, its application provides an explanation of why
6 oligomerization is required for the kinase function. We show that in order to be active, hexameric
7 NDPK requires a structured *Kpn/α₀* foldon, while to be structured the foldon requires the assembly
8 of the NDPK. NDPKs are oligomeric enzymes devoid of allosteric regulation. Many structures of
9 NDPKs have been solved in the presence of different ligands (ADP, non hydrolysable ATP
10 analogues, small molecules, ...), but the apo and in complex structures are identical and do not
11 show conformational changes. Here, we show that the *Kpn/α₀* foldon is an activation region and a
12 critical control switch, through its shifting between the structured or unstructured conformation.
13
14
15
16
17
18
19

20 Since not all NDPKs are hexameric, the question arises as to how bacterial tetrameric and
21 dimeric ones are active. The analysis of crystal structures shows that in the type 2 tetramer,⁽⁴⁶⁾ the
22 *Kpn/α₀* foldon is located at the dimer-dimer interface and has the same control switch role. On the
23 contrary, in type 1 tetramer⁽⁶⁶⁾ and dimer,^(47, 67, 68) the *Kpn/α₀* foldon is fully exposed and could not
24 have such a regulatory role. High eukaryotes have several isoforms of NDPK with additional
25 functions: metastasis suppression in humans^(35, 36, 69, 70) and involvement in animal development.⁽⁷¹⁻

73) Interestingly, natural mutants for these two hexameric NDPKs present folding or assembly
defects.⁽⁷²⁾ Since our present study on *Mt*-NDPK shows that flexibility is increased by the
hexamer's destabilization, we suggest these mutants are inactive because of aberrant conformational
dynamics. Potentially, their stabilization could be enhanced by rational design of their most
dynamic parts, a promising but actually unexplored strategy in cancer or developmental research. In
conclusion, our results illustrate the power of MS-based technologies to uncover new concepts in
studying structure-activity relationships, in complement to biochemical techniques, X-ray
crystallography and NMR.

LEGENDS OF FIGURES

Figure 1. Structure of *Mt*-NDPK (A) View of a *Mt*-NDPK monomer with labelled secondary structural elements. (B) Side view of a dimer showing the dimer interface (residues 17, 19-21, 23-24, 27, 33-38, and 72) and the active site pocket (K10, Y50, R104, N114, H117, S119, E128). (C) Top view of a trimer. At the trimer interface (residues 16, 25, 28-31, 79-80, 83-84, 87-88, 93-96, 98-102, and 105-110) the *Kpn*/ α_0 foldon (the *Kpn*-loop and the α_0 helix are colored in magenta and pink, respectively), and the R80-D93 salt bridge (sticks) are involved in hexamer assembly. The trimers stack ‘head-to-head’ and not ‘head-to-tail’ such that the *Kpn*/ α_0 is exposed on either side of the hexamer. (D) Side view of the surface of the 6-color hexamer *Mt*-NDPK. The active site is colored in yellow. In (B) and (C), the chains are colored as in (D).

Figure 2. Overall and local dynamics of WT and D93N *Mt*-NDPK. (A) Scheme of full length continuous labeling HDX-MS experiment. (B) Plot of deuterium incorporation over time, after correction for back-exchange and dilution. On top, arrows refer to analysis at peptide level on panels C and D. (C, D) Relative percent of deuterium incorporation into each peptide (Figure S2C-D) mapped onto the protein surface using a blue (0%) to red (100%) scale. For WT (C) and D93N (D), a top view along the 3-fold axis of the 6-mer (first column) and the dimer interface after splitting the two trimers (second column) are shown. The white contour outlines the fingerprint of the dimer interface. Residues with no data are coloured in black.

Figure 3. Unfolding pathway at full length and peptide level of D93N (A-B) and WT (C-D) *Mt*-NDPK. Each sample was pre-incubated during 16 hours at different concentrations of urea. Unfolding was monitored by intrinsic fluorescence (blue circles), residual enzymatic activity (red squares)⁽⁵³⁾ (A, C). The values are normalized to the experiment in the absence of urea. D93N unfolding was also monitored by a 12 sec pulse labeling deuterium incorporation at full-length level (green diamond) (C). The relative percentage of deuterium incorporation measured at peptide level with a 12 sec D₂O pulse for WT in 0, 3, 4, and 5 M urea (B) and D93N in 0, 1, 2 and 3 M urea (D) was mapped onto the crystal structure of *Mt*-NDPK using a blue (0%) to red (100%) scale (Figure S3). A top view (left) and a split dimer interface (right) were shown. When the hexamer was dissociated or unfolded, it was split into three dimers or six randomly oriented monomers, respectively. The white contour on columns two and four outlines the fingerprint of the dimer interface.

Figure 4. Representative HD-XMS spectra, obtained during peptic peptide analysis for WT and D93N *Mt*-NDPK after a 12 second pulse at different urea concentrations. The detailed experimental scheme is shown in the figure S3B. Mass spectra of the +2 charge state of peptides 9-21 and 25-35

1
2
3 for the unlabeled sample and six HDX experiments in 0 to 6 M urea are shown. WT: both peptides
4 9-21 (left) and 25-35 at the dimer interface (right) unfold at the same urea concentration 4-6 M
5 (grey frames). D93N: Residues 9-21 (left) and 25-35 at the dimer interface (right) unfold at 0-1 M
6 and 2-3 M urea, respectively (grey frames).
7
8
9

10 **Figure 5.** Unfolding and refolding pathways of WT *Mt*-NDPK. (A) Refolding (blue lines) versus
11 unfolding (red lines) pathways measured by intrinsic fluorescence (full circles) and enzyme activity
12 (empty squares) after 16 hours pre-incubation in GuHCl.⁽⁵³⁾ The lines do not represent theoretical
13 models but were drawn to help the reader. (B) Refolding and assembly pathway of WT *Mt*-NDPK.
14 The percentage of deuterium incorporation after 12 seconds D₂O pulse at different refolding time is
15 plotted onto the structure (Figure S4B). Six monomers in random orientation are drawn when
16 unfolded. For each time point, a top view (left) and a split dimer interface of three split dimers
17 (right) are shown. Residues with no data are colored in black. Note for refolding experiments that at
18 this low protein concentration, only dimers are formed. Hexamers are formed at ten time higher
19 concentrations.⁽⁵³⁾
