Abstract

Mesoscale eddies, having a characteristic radius equal or larger than the local deformation radius, are generally considered to be geostrophic. Even if this is true for most of them, there are few cases where the ageostrophic velocity components induced by the local curvature of the streamlines are not negligible. In order to account for this ageostrophic part, we investigate the performance of an optimized iterative method which computes the cyclostrophic corrections starting from the geostrophic surface velocity of the AVISO/DUACS. We optimized the convergence of the iterative method using an intermediate cubic interpolation. The performance and the accuracy of the optimized iterative method is first evaluated on idealized eddies for which we can obtain their exact cyclogeostrophic solution. Mesoscale eddies of various shapes, intensities and different ellipticity are investigated. The iterative method is then applied to fifteen years (2000-2015) of AVISO/DUACS geostrophic velocity fields, gridded at $1/8^\circ$ for the Mediterranean Sea. We found that these ageostrophic corrections are needed for most of the mesoscale anticyclones that have a geostrophic vortex Rossby number larger than $Ro > 0.1$. Both the Alboran and the Ierapetra eddies are frequently affected by the cyclostrophic corrections that may exceed 50 cm s^{-1} . Lastly, the corrected velocity fields are compared with available in-situ observations of velocity measurements (VMADCP) performed within the Ierapetra eddy confirming the benefit of the proposed method.

1 Introduction

The increase of the spatial resolution of remote sensing observations has revealed the prevalence of mesoscale eddies throughout the oceans. These coherent structures can survive several months and sometimes several years [Puillat *et al.*, 2002; Ioannou *et al.*, 2017; Laxenaire *et al.*, 2018]. They are able to trap and transport heat, mass, and momentum from their regions of formation to remote areas. However, a correct assessment of eddy properties and how they vary temporally is still a challenge. The existing estimations are derived by analyzing satellite altimetry gridded fields which provide daily global 2D maps of sea surface height and surface geostrophic velocity that are not affected by cloud coverage.

In the last 10 years, eddy detection algorithms have been developed and used to identify automatically ocean mesoscale eddies [Doglioli *et al.*, 2007; Chelton *et al.*, 2007; Chaigneau *et al.*, 2009; Chelton *et al.*, 2011; Nencioli *et al.*, 2010; Mason *et al.*, 2014;

44 *Le Vu et al.*, 2018]. These methods locate the eddy center and estimate the eddy size.
 45 The eddy intensity is then usually defined as the difference of sea surface height (i.e. hy-
 46 drostatic pressure gradient) between the eddy center and its periphery [*Chaigneau et al.*,
 47 2009; *Chelton et al.*, 2011; *Souza et al.*, 2011; *Mason et al.*, 2014] or from some dimen-
 48 sionless parameters derived from the eddy surface velocity field: the relative eddy-core
 49 vorticity (*Doglioli et al.* [2007]), the Okubo-Weiss parameter [*Isern-Fontanet et al.*, 2006]
 50 or the vortex Rossby number [*Mkhinini et al.*, 2014; *Le Vu et al.*, 2018; *Laxenaire et al.*,
 51 2018]. The main advantage in using the latter is that it is easily comparable with direct
 52 in-situ measurements such as VMADCP, LADCP [*Ioannou et al.*, 2017], high frequency
 53 radar (HFR) current measurements [*Chavanne et al.*, 2010] or trajectories inferred from
 54 surface drifters [*Sutyryn et al.*, 2009; *Mkhinini et al.*, 2014; *Ioannou et al.*, 2017]. How-
 55 ever, the derivation of ocean surface velocity from remote sensing altimetry is based on
 56 the strong assumption that oceanic currents and, in particular, mesoscale eddies satisfy
 57 the geostrophic balance. This approximation is inaccurate for submesoscale structures
 58 whose ageostrophy is large [*Chang et al.*, 2013], but it could also induce significant bias
 59 for mesoscale eddies.

60 The dynamical characteristics of small-scale surface eddies (5 – 20 km) that were
 61 not accessible before with traditional oceanographic campaigns, can now be obtained from
 62 high frequency radar (HFR) current measurements [*Paduan and Washburn*, 2013; *Scha-*
 63 *effner et al.*, 2017] or from an intensive scanning of a small oceanic area with shipboard
 64 ADCP [*Hasegawa et al.*, 2004; *Chang et al.*, 2013]. These recent observations of subme-
 65 soscale eddies, having a radius smaller than the first baroclinic deformation radius, have
 66 shown that their relative vorticity ζ_0/f , where ζ_0 is the surface vorticity measured in the
 67 eddy core and f the Coriolis parameter, could exceed unity and could reach values up to
 68 $|\zeta_0/f| = 5 - 10$ [*Chang et al.*, 2013]. Such strongly ageostrophic structures which evolve
 69 rapidly cannot be detected by the current spatio-temporal resolution of altimetry products
 70 and are therefore, out of the scope of this paper.

71 On the other hand, mesoscale eddies, having a characteristic radius equal or larger
 72 than the local deformation radius, are generally considered to be geostrophic. Even if this
 73 is true for most of them, there are nevertheless few cases where the ageostrophic velocity
 74 components induced by the local curvature of the streamlines are not negligible [*Penven*
 75 *et al.*, 2014; *Douglass and Richman*, 2015; *Ioannou et al.*, 2017]. To make the distinction
 76 with the ageostrophic velocities induced by the surface wind-stress, we use here and in

77 what follows, the term cyclostrophic velocity correction for these ageostrophic velocity
78 components which take into account the centrifugal acceleration. The pioneering work
79 of *Uchida et al.* [1998], has shown that adding small ageostrophic velocity components,
80 induced by the curvature of the Kuroshio, improves the comparison of surface velocities
81 calculated from satellite altimetry (TOPEX/POSEIDON at that time) with the drifting
82 buoys velocities. More recent studies have shown that cyclostrophic corrections should
83 be applied to the geostrophic velocity, derived from altimetry maps, to assess correctly the
84 azimuthal velocity of some intense mesoscale eddies in the Mozambique channel [*Penven*
85 *et al.*, 2014], or for the intense Gulf stream rings [*Douglass and Richman*, 2015]. Simi-
86 larly, in the Mediterranean Sea strong ageostrophic components have been reported for
87 anticyclonic eddies in two specific areas. The Western Alboran Gyre, located between the
88 Strait of Gibraltar and Cape Tres Forcas, constitutes one of the strongest anticyclonic fea-
89 tures of the western Mediterranean Sea, with surface currents which exceed 1 m/s [*Viudez*
90 *et al.*, 1996a,b; *Gomis et al.*, 2001; *Flexas et al.*, 2006]. Moreover, in the eastern Mediter-
91 ranean Sea, the Ierapetra anticyclones (IEs), that recurrently form at the south-east cor-
92 ner of Crete, could also reach finite vorticity values [*Matteoda and Glenn*, 1996]. The IEs
93 can remain close to the area of their formation but also drift long distances in the Levan-
94 tine basin ([*Hamad et al.*, 2006; *Ioannou et al.*, 2017]). Strong ageostrophic components
95 were observed along their dynamical evolution. For these two specific areas, in-situ mea-
96 surements revealed the inadequacy of the geostrophic approximation to describe the eddy
97 dynamics. The standard AVISO/DUACS products, may often underestimate the eddy in-
98 tensity. However, in the Mediterranean Sea, ageostrophic corrections may not be limited to
99 these two eddies.

100 Two approaches were used to compute the cyclostrophic velocity corrections on
101 AVISO/DUACS products so far. The first one is to solve the quadratic cyclogeostrophic
102 equation (i.e. Eqn. (7) in subsection 4.1) for circular eddies which were detected in the
103 geostrophic velocity field. It was applied by *Ioannou et al.* [2017] for a few quasi-circular
104 configurations of the Ierapetra anticyclone and by *Douglass and Richman* [2015] who
105 assumed a Gaussian shape for all the quasi-circular eddies of the Atlantic ocean. This
106 method is quite simple but it requires to know precisely the velocity profile of the geostrophic
107 eddy and it is valid only for circular eddies. The second one, is based on an iterative
108 method which adds at each step small corrections to the surface velocity field in order
109 to account for the centrifugal acceleration induced by the local curvature [*Arnason et al.*,

110 1962; *Penven et al.*, 2014]. The main advantage of this global approach is that it provides
111 a cyclostrophic correction for all eddies regardless their initial shapes. The main drawback
112 is that the iteration may not converge to the exact cyclogeostrophic balance and so careful
113 accuracy tests should be done.

114 In the present study, we optimized the convergence of the iterative method using
115 an intermediate cubic interpolation. Besides, we tested thoroughly the accuracy of the
116 method on idealized eddies for which we can obtain a direct solution of the cyclogeostrophic
117 balance. We explore a wide distribution of sizes and intensities but also various shapes
118 that correspond to the statistical distribution of mesoscale eddies in the Mediterranean
119 Sea. Then, we applied this cyclostrophic correction to fifteen years (2000-2015) of daily
120 geostrophic velocity fields provided by AVISO/DUACS for the Mediterranean Sea at the
121 high grid resolution of $1/8^\circ$. We found that it may significantly impact the estimated in-
122 tensities of mesoscale anticyclones, especially the Alboran and the Ierapetra eddies but
123 not only. Finally, the corrected surface velocity fields were compared with direct in-situ
124 measurements performed within the Ierapetra anticyclone during the PROTEVS-PERLE
125 campaign of October-November 2018.

126 **2 Data**

127 **2.1 AVISO data set**

128 We used in the present study the geostrophic velocity fields, for the years 2000–2015,
129 produced by SSALTO/ Data Unification and Altimeter Combination System (DUACS) and
130 distributed by AVISO and derived from the absolute dynamical topography (ADT). Un-
131 like the sea level anomaly (SLA), which represents the variable part of sea surface height,
132 the ADT is the sum of this variable part and the constant part averaged over a 20-year
133 reference period. The “all sat merged” series distributed regional product for the Mediter-
134 ranean Sea combines, up-to-date datasets with up to four satellites at a given time, using
135 all the missions available at a given time [TOPEX/Poseidon, ERS-1 and ERS-2, Jason-1
136 and Jason-2, the Ka-band Altimeter (AltiKa) on the Satellite with the Argos Data Collec-
137 tion System (Argos) and AltiKa (SARAL), Cryosat-2 and Envisat missions]. This merged
138 satellite product, for the Mediterranean Sea, is projected on a $1/8^\circ$ Mercator grid, with a
139 time interval of 24h.

140 The spatial resolution of this regional dataset is 2 times higher than the global alti-
141 metric products at $1/4^\circ$. Nevertheless, it remains a coarse-resolution product, because the
142 horizontal resolution of the $1/8^\circ$ gridded velocity fields ($dX \approx 12 \text{ km}$) cannot fully resolve
143 the internal deformation radius that is around $Rd \approx 8 - 12 \text{ km}$ in the Mediterranean Sea
144 [Robinson *et al.*, 2001; Escudier *et al.*, 2016]. Moreover, the recent analysis of [Amores
145 *et al.*, 2018], which compares the eddies detected on a high-resolution numerical simu-
146 lation ($1/60^\circ$) with those detected on a synthetic AVISO field ($1/8^\circ$), showed that only
147 eddies, with a characteristic eddy radius smaller than $R_{max} \leq 25 \text{ km}$ (i.e. $R_{end} \leq 35 \text{ km}$)
148 couldn't be correctly detected with the regional AVISO/DUACS dataset. It will be there-
149 fore useless to apply any cyclostrophic correction on inaccurate submesoscale structures
150 that may appear on the AVISO field.

151 2.2 Shipboard ADCP measurements during the PROTEVS-PERLE campaign

152 The PROTEVS-PERLE campaign was held in October-November 2018 in the east-
153 ern Mediterranean Sea. Among the various measurements (CTD, LADCP, SEASOR etc.)
154 performed during the PERLE experiment we focus here on the vertical current profiles
155 that were acquired with Ocean Surveyors 150 kHz and 38 kHz (Teledyne RDI) when the
156 Ierapetra eddy was crossed between the 28th of October until the 2nd of November. These
157 systems are two Vessel-Mounted Acoustic Doppler Current Profilers (ADCP) on the R/V
158 L'Atalante. In order to obtain vertical profiles of current speed and direction in the up-
159 per layer, we use the 150 kHz Ocean Surveyors that provide velocity measurements every
160 8 m with maximum depth of about 220 m . The first bin sampled is located 26 m beneath
161 the surface in order to avoid any reflections and interactions with the vessel. The range
162 covered by the OS150 instrument varied between 150 m and 220 m over the diurnal cycle.
163 Despite it's short range it provides permanently an assessment of the horizontal compo-
164 nents of the current between 26 m and 100 m . The velocities obtained are averaged over
165 2 min . The ensemble and the bin size provide a precision of the horizontal velocity that
166 was assessed to be below 8 cm s^{-1} . Compared to the velocities observed in the vicinity of
167 the Ierapetra periphery, this corresponds to an error of a bit less than 10%.

3 Methods

3.1 AMEDA eddy detection algorithm

In order to quantify the eddy size and their intensity, we apply the Angular Momentum Eddy Detection and tracking Algorithm (AMEDA) which is based on physical parameters and the geometrical properties of the velocity field [Le Vu *et al.*, 2018]. The eddy centers are first identified and correspond to an extremum of the local normalized angular momentum. The streamlines surrounding this center are then computed (Figure 1(b)). The mean radius $\langle R \rangle$ and the mean velocity $\langle V \rangle$ are evaluated for each closed streamline. This mean radius $\langle R \rangle$ is defined as the equivalent radius of a circular disc with the same area A as the one delimited by the closed streamline (Eqn. (1)), while the mean velocity amplitude $\langle V \rangle$ is derived from the circulation along the closed streamline C , where L_p is the streamline perimeter (Eqn. (2)).

$$\langle R \rangle = \sqrt{A/\pi} \quad (1)$$

$$\langle V \rangle = \frac{1}{L_p} \oint_C V dl \quad (2)$$

We plot in Figure 1(c) the pair of the mean eddy velocity $\langle V \rangle$ and the mean radius $\langle R \rangle$ for each closed streamline of the mesoscale anticyclone located at the east of Sardinia the 2nd of November 2004. We can see on this example that the mean velocity increases when the radius increases until a maximum velocity V_{max} is reached. The corresponding radius is named R_{max} , also called the speed radius [Chelton *et al.*, 2011; Le Vu *et al.*, 2018; Laxenaire *et al.*, 2018]. The *characteristic contour* of the detected eddy (blue contours in Figure 1) is associated with the closed streamline of maximal speed. After this maxima, the azimuthal speed of the eddy decreases until the last closed streamline is reached. The latter is plotted with a black dashed line in Figure 1.

From the characteristic eddy velocity V_{max} and the corresponding radius R_{max} , we compute the vortex Rossby number to quantify the eddy intensity:

$$Ro = \left| \frac{V_{max}}{f R_{max}} \right| \quad (3)$$

where f is the Coriolis parameter. The eddy shape is characterized by two geometrical parameters. The first one is the ellipticity ε of the closest ellipse that fits the characteristic contour. The second one is the steepness parameter α which is used to fit the mean velocity profile $\langle V \rangle = F(\langle R \rangle)$ of quasi-circular eddies ($\varepsilon < 0.2$). These mean velocity profiles

196 are fitted with the generic function:

$$V_{\theta}(r) = \frac{V_{max}}{R_{max}} r e^{(1-(r/R_{max})^{\alpha})/\alpha} \quad (4)$$

197 Such generic profiles were used by *Carton et al.* [1989]; *Stegner and Dritschel* [2000];
 198 *Lazar et al.* [2013] to study the stability of various isolated eddies. Moreover, *Ioannou*
 199 *et al.* [2017] found that such generic velocity profile Eqn. (4) provides a high correlation
 200 fit for the 22 year analysis of the Ierapetra anticyclones. Note that when $\alpha = 2$ the eddy
 201 has a Gaussian velocity profile.

202 We apply the AMEDA algorithm to fifteen years (2000-2015) of surface veloc-
 203 ity fields provided by AVISO/DUACS for the Mediterranean Sea. These velocity fields
 204 are derived from the absolute dynamical topography (ADT) according to the geostrophic
 205 balance. Hence, all the following results are valid for geostrophic structures. The global
 206 statistics of the dynamical and geometrical properties of these geostrophic mesoscale ed-
 207 dies, detected by the AMEDA algorithm and having a characteristic radius larger than
 208 18 km, are plotted separately for cyclones and anticyclones in Figure 2. The total num-
 209 ber of detected cyclones (~ 295000) is slightly larger than the detected anticyclones (\sim
 210 220000). However, if we consider intense eddies, the proportion is strongly reversed and
 211 we get 16600 anticyclones and 5000 cyclones having a geostrophic Rossby number larger
 212 than 0.1. For larger values, for instance $Ro \geq 0.15$, there is a large predominance of an-
 213 ticyclones as shown in Figure 2(a). A significant cyclone anticyclone asymmetry is also
 214 visible on the eddy shape. The mesoscale cyclones tend to be more elliptical than the
 215 mesoscale anticyclones. There is a clear predominance of cyclonic structures when the
 216 ellipticity ε exceeds 0.3 (Figure 2(b)). However, as far as quasi-circular eddies are con-
 217 cerned, there is no clear asymmetry for the azimuthal velocity profiles. Both cyclones and
 218 anticyclones exhibit a similar distribution of the steepness parameter α which varies be-
 219 tween $\alpha = 1.2$ and $\alpha = 2.7$ while the highest probability is close to the Gaussian shape
 220 ($\alpha = 2$). Hence, this statistical analysis of the AVISO/DUACS data set, suggests that
 221 there is no universal velocity profile for mesoscale eddies in the Mediterranean Sea. The
 222 geostrophic Rossby number could be quite large exceeding 0.2 while a quite large num-
 223 ber of eddies deviate from the circular symmetry with a mean ellipticity which exceeds
 224 $\varepsilon > 0.3$.

3.2 Iterative method to compute the cyclogeostrophic velocities

We consider in what follows large oceanic eddies that evolve and propagate slowly over time. For such mesoscale oceanic eddies, the flow acceleration is negligible in comparison with the centrifugal acceleration induced by the streamlines curvature and therefore the surface velocity field \mathbf{U} should satisfy the cyclogeostrophic balance:

$$\mathbf{U} \cdot \nabla \mathbf{U} + f \mathbf{k} \times \mathbf{U} = -g \nabla \eta = f \mathbf{k} \times \mathbf{U}_g \quad (5)$$

where \mathbf{U}_g is the geostrophic velocity which is directly proportional to the gradient of the sea surface deviation $\nabla \eta$.

For the case of a steady circular eddy, this balance relation is strictly identical to the Bolin-Charney balance on a f -plane [Charney, 1955]. Higher order balanced equations were proposed for synoptic-scale weather systems which evolve rapidly over a few days in order to account for the divergent components of the flows [Iversen and Nordeng, 1982, 1984; McIntyre, 2015]. However, most of the mesoscale oceanic eddies are, at the first order of approximation, non-divergent and they evolve slowly if we neglect rapid merging and splitting events.

For non-circular eddies there is no analytical solution for \mathbf{U} when \mathbf{U}_g is known. Besides, this non-linear balance may have no solution at all, for instance when the geostrophic Rossby number of a circular anticyclone exceeds the critical value $Ro = V_g / (fR) > Ro_c = 0.25$ [Knox and Ohmann, 2006; Penven et al., 2014]. However, according to the Figure 2(a) such intense anticyclones are extremely rare (less than 0.01%) in the Mediterranean Sea and we therefore expect that the wide majority of mesoscale eddies detected on the AVISO/DUACS database satisfy the cyclogeostrophic balance Eqn. (5).

In order to calculate the ageostrophic velocity components of intense eddies having various shapes and velocity profiles we use an iterative method that was first proposed in atmospheric science [Arnason et al., 1962] and used for intense oceanic eddies in Penven et al. [2014] to approximate the cyclogeostrophic balance Eqn. (5). This iterative scheme is given by:

$$\mathbf{U}^{n+1} = \mathbf{U}_g + \frac{1}{f} \mathbf{k} \times (\mathbf{U}^n \cdot \nabla \mathbf{U}^n) \quad (6)$$

251 where $\mathbf{U}^0 = \mathbf{U}_g$. We first project, with a cubic interpolation, the initial geostrophic
 252 velocity field gridded at $1/8^\circ$ on a finer grid at $1/24^\circ$ in order to improve the computation
 253 of the velocity derivatives in Eqn. (6).

254 There is no proof of convergence for this iterative scheme and for intense eddies
 255 it may even diverge after few iterations [Arnason *et al.*, 1962; Penven *et al.*, 2014]. An
 256 example of the divergence of the velocity profile, for an initial geostrophic anticyclone
 257 with $Ro = 0.23$, is given in Figure 3(a). Hence, to prevent such local divergence, we per-
 258 formed, as Penven *et al.* [2014], a constraint iteration which stops the iteration at a grid
 259 point when the local residual $\|\mathbf{U}^{n+1} - \mathbf{U}^n\|$ starts to increase. The local norm $\|\cdot\|$ is com-
 260 puted here on nine grid points: the central one and the eight closest neighbors. For the
 261 example shown in Figure 4, the iteration will stop in the core of the anticyclone after two
 262 steps. The Rossby number of the final cyclogeostrophic anticyclone (red curve) will reach
 263 $Ro = 0.48$ which is twice its initial value (Figure 3).

264 **4 Cyclogeostrophic balance of steady and isolated eddies**

265 In order to test the accuracy of the iterative method (Eqn. (6)) and to develop some
 266 algorithmic optimizations, it was needed to compare the results with several test cases. We
 267 first consider circular eddies for which we can get simple analytical solutions for both the
 268 geostrophic and the cyclogeostrophic balance (Eqn. (5)). Then, assuming a slow evolution
 269 of the velocity field, we also consider steady elliptical eddies for the test cases.

270 **4.1 Impact of the cyclogeostrophic corrections on circular eddies**

271 Circular eddies are steady solutions of the cyclogeostrophic equation (Eqn. (5))
 272 which simplifies for any azimuthal velocity profile $V_\theta(r)$ to the gradient-wind equation:

$$\frac{V_\theta^2}{fr} + V_\theta = V_g = \frac{g}{f} \frac{\partial \eta}{\partial r} \quad (7)$$

273 where $V_g(r)$ is the geostrophic velocity profile associated to the free surface deviation η .
 274 Cyclonic eddies correspond to $V_\theta > 0$ while for anticyclonic eddies $V_\theta < 0$. To study
 275 various velocity profiles, we use the generic function (Eqn. (4)) for the azimuthal veloc-
 276 ity. The relation between the geostrophic velocity and the cyclogeostrophic velocity will
 277 then depend both on the dimensionless Rossby number Ro and the steepness parameter
 278 α . For very small Rossby number, the eddy satisfies the geostrophic balance and therefore

279 $V_\theta \simeq V_g$. However, when the Rossby number starts to increase, the centrifugal accelera-
 280 tion should be taken into account and due to the non-linear term of Eqn. (7) it induces an
 281 asymmetry between cyclonic and anticyclonic eddies. Hence, if we compare geostrophic
 282 velocities of opposite sign but of the same intensity (i.e. same amplitude of the free sur-
 283 face deviation) the cyclogeostrophic velocity could differ significantly even if the Rossby
 284 number is moderate. We should make here the distinction between the geostrophic vor-
 285 tex Rossby number $Ro_g = \max(|V_g|)/fR_{maxg}$ computed from the maximum value of
 286 geostrophic velocity and the real Rossby number Ro associated to the complete velocity
 287 of the gradient-wind equation (Eqn. (7)). We illustrate in Figure 5 this asymmetry in the
 288 cyclogeostrophic correction for some examples of isolated mesoscale eddies the charac-
 289 teristics of which could be observed in the Mediterranean Sea. The comparison is made
 290 between eddies of distinct shape (i.e. steepness parameter $1 \leq \alpha \leq 3$ in agreement
 291 with Figure 2(c) but with the same size $R_{max} = 30 \text{ km}$ and the same geostrophic am-
 292 plitude $\max(|V_g|) = 42 \text{ cm s}^{-1}$. For these cases the geostrophic Rossby number is mod-
 293 erate $Ro_g = 0.14$ but nevertheless the cyclogeostrophic velocity profiles differ signif-
 294 icantly from the geostrophic solution. The amplitudes of anticyclonic (cyclonic) eddies
 295 are amplified (attenuated). The maximum velocity of the anticyclones increases up to
 296 $V_{max} = -52 \text{ cm s}^{-1}$ while, for cyclones, it decreases slightly down to $V_{max} = 36 \text{ cm s}^{-1}$.
 297 Moreover, depending on their specific shape, the characteristic radii R_{max} of the anticy-
 298 clones (cyclones) are reduced (increased) in comparison with their geostrophic signature.

299 To investigate a wider range of parameters and quantify more precisely the devia-
 300 tion between the cyclogeostrophic and the geostrophic velocity profiles we plot, for three
 301 distinct profiles, the percentage of the relative error on the vortex Rossby number:

$$\Sigma_{Ro} = \frac{Ro - Ro_g}{Ro_g} \quad (8)$$

302 and on the characteristic eddy radius:

$$\Sigma_R = \frac{R_{max} - R_{maxg}}{R_{maxg}} \quad (9)$$

303 as a function of the geostrophic Rossby number Ro_g which is the only dynamical
 304 parameter that can be initially deduced from the altimetry data-sets. The cyclostrophic
 305 corrections are more pronounced for anticyclonic eddies than for cyclonic ones (Figure 6).
 306 The standard geostrophic velocity provided by the AVISO/DUACS products underesti-

307 mate the intensity of mesoscale circular anticyclones especially when their geostrophic
 308 Rossby number exceeds 0.1. Besides, this analysis shows that the cyclostrophic correction
 309 is indeed profile dependent. The percentage of the cyclostrophic correction depends both
 310 on the vortex intensity (i.e. Ro_g) and the steepness parameter α of the velocity profile.
 311 Hence, the vortex intensity, is not the single parameter that controls the deviation from the
 312 geostrophic approximation.

313 **4.2 Accuracy of the iterative method on circular eddies**

314 The analytical solutions, obtained in the previous section for circular eddies, can
 315 then be used to test the accuracy of the iterative method Eqn. (6). We first project the
 316 geostrophic velocity components of the circular vortex on a regular $1/8^\circ$ grid which is
 317 identical to the standard AVISO/DUACS gridded products. In a second step, this geostrophic
 318 velocity field is interpolated on a higher resolution grid at $1/24^\circ$ to improve the com-
 319 putation of the velocity gradients in the non linear terms of the Eqn. (6). The iterative
 320 scheme is then applied to this new velocity field and the corrected circular velocity pro-
 321 file is then estimated at each step of the iteration. In order to prevent local divergence,
 322 the iteration process is stopped when the local residual $\|\mathbf{U}^{n+1} - \mathbf{U}^n\|$ starts to increase.
 323 As shown in Figure 7 this iterative scheme may, or may not, converge to the exact cy-
 324 clogeostrophic solution but due to the constrain on the decay of local residual it will not
 325 diverge. The iteration scheme applied on two Gaussian anticyclones ($\alpha = 2$) with the same
 326 radius ($R_{maxg} = 30\text{ km}$) but different intensities is depicted in Figure 7. When the initial
 327 geostrophic Rossby number is moderate ($Ro_g = 0.16$) the scheme converges rapidly, after
 328 4 iterations, to the cyclogeostrophic solution (Figure 7(a)). The latter has a smaller radius
 329 ($R_{max} = 26\text{ km}$) and a significantly higher Rossby number ($Ro = 0.24$) than the initial
 330 geostrophic velocity profile. However, when the anticyclone intensity ($Ro_g = 0.2$) gets
 331 closer to the critical value $Ro_c = 0.25$, the iteration scheme does not succeed to reach the
 332 cyclogeostrophic solution and a residual error of 17% on the Rossby number does persist
 333 after 5 iterations (Figure 7(b, c)). Cyclonic gaussian eddies were also tested and we did
 334 not find any convergence issue even for large Rossby number up to $Ro_g = 0.2$, which is
 335 the largest value found for Mediterranean cyclones. For these intense cyclonic eddies the
 336 residual errors of the iteration scheme were below 15%. Other iteration scheme using a
 337 relaxation parameter were tested on these few test cases. The convergence is slower with

338 this under-relaxation scheme but unfortunately it does not provide a better accuracy (Ap-
 339 pendix A:)

340 We also quantify how the initial interpolation on a finer grid, from $1/8^\circ$ to $1/24^\circ$,
 341 impacts the iteration scheme. The accuracy of the convergence is tested for three cases:
 342 no interpolation (open circle), in other words we stay on the initial AVISO/DUACS grid, a
 343 linear interpolation at $1/24^\circ$ and a cubic interpolation at $1/24^\circ$ (Figure 8). We have found
 344 that the cubic interpolation improves significantly the accuracy of the iterative scheme,
 345 both for the vortex intensity and its size. Higher order interpolation (quintic) and also
 346 higher resolution ($1/48^\circ$) were tested with no significant improvements on the iteration
 347 scheme.

348 The accuracy of this optimized iterative scheme was tested for the wide range of pa-
 349 rameters (Ro_g , R_{maxg} , α) that were found for mesoscale anticyclonic eddies (Figure 2).
 350 The percentage of the relative error on the vortex Rossby number between the geostrophic
 351 and the cyclogeostrophic anticyclones were plotted at the initial stage (Figure 9(a, c)) and
 352 at the final stage of the iteration process (Figure 9(b, d)). We arbitrary fix the separation
 353 between weak (in green) and strong (in red) errors at 30%. The relative errors are almost
 354 negligible ($< 15\%$) when the vortex Rossby number is below 0.08. However, when Ro_g
 355 exceeds 0.12 – 0.15 the deviations between the cyclogeostrophic and the geostrophic solu-
 356 tion becomes strong (i.e. $> 30\%$) and the use of the standard AVISO/DUACS geostrophic
 357 velocity field will lead to a systematic underestimation of the intensity of circular anticy-
 358 clones. This deviation tends to decrease when the steepness parameter α increases (Fig-
 359 ure 9(b)). For almost all the anticyclones we studied, the iterative scheme reduces this ini-
 360 tial deviation and the final result is much closer to the cyclogeostrophic solution than the
 361 initial one. Hence, we've shown here that the iterative scheme leads to a correct estima-
 362 tion of the ageostrophic terms, induced by the streamline curvature, for idealized circular
 363 eddies.

364 The (R_{max} , α) parameter space was not thoroughly investigated for cyclonic ed-
 365 dies because, their maximal amplitudes are generally weaker than the anticyclones in the
 366 AVISO/DUACS product (Figure 2). Besides, for the same geostrophic Rossby number the
 367 cyclostrophic correction is generally much weaker for cyclonic eddies than for anticyclonic
 368 ones (Figure 6(a)).

4.3 Accuracy of the iterative method on elliptical eddies

We have seen, in the previous section, that the iterative scheme provides a correct estimation of the full cyclogeostrophic profile for idealized circular anticyclones which are not too close to the divergent limit $Ro_g = 0.25$. However, according to the AVISO DU-ACS products, most of the detected eddies are elliptical (Figure 2(b)). Hence, the accuracy of the iterative scheme should also be tested on an elliptical eddy configuration. We first generate elliptical velocity fields which are non-divergent (i.e. $\nabla \cdot \mathbf{V} = \mathbf{0}$). To do so, we started from a circular Gaussian velocity profile ($\alpha = 2$) and we apply a deformation, that conserves the area inside each streamline:

$$x' = x\sqrt{1-\varepsilon} \quad (10)$$

$$y' = y/\sqrt{1-\varepsilon} \quad (11)$$

This deformation will transform a circle of radius R_{max} into an ellipse of ellipticity (i.e. flattening) ε having for the semi-major $R/\sqrt{1-\varepsilon}$ and the semi-minor axis $R\sqrt{1-\varepsilon}$. We should then also transform the velocity field according to

$$V'_x(x', y') = \sqrt{1-\varepsilon}V_x(x, y) \quad (12)$$

$$V'_y(x', y') = V_y(x, y)/\sqrt{1-\varepsilon} \quad (13)$$

in order to get a non-divergent velocity field and the conservation of angular momentum for each fluid parcel. Such type of deformation could be induced in the real ocean by the external strain exerted on a circular eddy by its close neighbors.

We compute from the elliptical velocity field the geostrophic velocity components according to cyclogeostrophic balance Eqn. (5). Then we apply the iterative scheme Eqn. (6) (with constrain on the local residual) to these geostrophic velocity components and check how close they are to the initial cyclogeostrophic solution. We compare in Figure 10 the vortex Rossby numbers associated to the initial elliptical vortex (black square), to the corresponding geostrophic vortex (open square) and the results of the iterative scheme after five steps (crosses). We study here the impact of the ellipticity ε while the vortex Rossby

391 number is kept fixed to $Ro_g = 0.18$. This initial value is quite large and the cyclostrophic
 392 corrections are therefore significant. Indeed, the vortex Rossby numbers of the cyclo-
 393 geostrophic eddies are almost the double ($0.28 < Ro < 0.3$) of the initial geostrophic
 394 ones. The differences between the cyclogeostrophic solutions and the results of the itera-
 395 tive scheme remain small (less than 15%) and weakly impacted by a moderate ellipticity.
 396 We can see that the intensity (i.e. the Rossby number) of the elliptical structure obtained
 397 with the iterative scheme, after five iterations, is relatively close to the cyclogeostrophic
 398 one unless the ellipticity exceeds large values (above $\varepsilon > 0.6$). The agreement is even
 399 better when the intensity of the elliptical structure is weaker (not shown here). Hence, the
 400 methodology used in this paper to approximate the cyclostrophic velocity components pro-
 401 vides accurate results for both circular and elliptical eddies.

402 **5 Cyclostrophic corrections of mesoscale eddies in the Mediterranean Sea**

403 **5.1 Statistical analysis**

404 We now apply the iterative scheme to fifteen years (2000-2015) of surface geostrophic
 405 velocity fields provided by AVISO/DUACS for the Mediterranean Sea. Then we use the
 406 AMEDA algorithm to detect and track eddies on the corrected velocity field in order to
 407 quantify the impact of cyclogeostrophy on the Mediterranean eddies. The statistical prop-
 408 erties of the mesoscale eddies (i.e. $R_{maxg} > 18 km$) of the initial geostrophic eddy field
 409 are compared to the mesoscale eddies detected on the new cyclogeostrophic velocity field.
 410 As expected the cyclostrophic correction mainly impacts the mesoscale anticyclones (Fig-
 411 ure 11). We should note that ageostrophic submesoscale eddies cannot be detected on the
 412 AVISO/DUACS altimetry products and therefore only large mesoscale eddies ($R_{max} > R_d$)
 413 are considered in this analysis.

414 The probability distribution functions of the vortex Rossby numbers, for both cy-
 415 clones and anticyclones, are impacted by the cyclostrophic correction when $Ro_g > 0.1$.
 416 However, the impact is much stronger for anticyclonic eddies for which the maximum in-
 417 tensities of the probability distribution function almost double (Figure 11(a)) and reach
 418 values up to $Ro = 0.4$. While for cyclonic structures, the maximum intensities of cyclo-
 419 geostrophic eddies are slightly attenuated in comparison with the geostrophic ones (Fig-
 420 ure 11(c)).

421 Besides, as we have seen on idealized circular eddies (Figure 7) the cyclostrophic
 422 corrections also modify the velocity profile, especially in the core of anticyclones, where
 423 it may significantly amplify the core vorticity [Ioannou *et al.*, 2017]. This change on the
 424 velocity profiles is also visible on the distribution of the steepness parameter α . The prob-
 425 ability distribution of mesoscale anticyclones is shifted toward lower value of α (Fig-
 426 ure 11(b)) while it remains unchanged for cyclones (Figure 11(d)). Lower values of the
 427 steepness parameter correspond to a steeper velocity gradient in the eddy core (i.e. stronger
 428 core vorticity) and a lower velocity decay at the eddy periphery.

429 5.2 Areas where cyclostrophic corrections are significant

430 The statistical analysis provides an overall view of the impact of the cyclostrophic
 431 corrections but does not allow to identify the areas in the Mediterranean sea where this
 432 correction is the most needed. Therefore, we plot in the Figure 12(a), at each grid point,
 433 the maximal amplitude of the cyclostrophic correction $\|\mathbf{V} - \mathbf{V}_g\|$ during the 2000 - 2015
 434 period. We plot here the amplitude of this correction (i.e. the difference between cyclo-
 435 geostrophic and geostrophic velocities) only if it exceeds 10 cm s^{-1} . This graph allows us
 436 to immediately identify two “hot spots” where the cyclostrophic correction may exceed
 437 50 cm s^{-1} . These two places correspond to the usual locations of the Alboran and the Ier-
 438 apetra anticyclones.

439 The Alboran eddy is generated by the recirculation of the incoming jet of Atlantic
 440 Water (AW) flowing continuously through the Strait of Gibraltar due to the differential
 441 pressure gradient that exists between the Mediterranean Sea and the Atlantic Ocean across
 442 the Gibraltar Strait. This intense anticyclone constitutes the strongest dynamical feature of
 443 the Western Mediterranean mean circulation, with surface currents of up to 1.5 m s^{-1} [Viudez
 444 *et al.*, 1996a,b; Gomis *et al.*, 2001; Flexas *et al.*, 2006]. It is therefore normal to observe a
 445 strong ageostrophic component in the velocity or the vorticity field [Viudez, 1997]. The
 446 analysis of Gomis *et al.* [2001] has already showed the existence of large ageostrophic ve-
 447 locities up to 40 cm s^{-1} , induced by the cyclostrophic acceleration of this intense mesoscale
 448 anticyclone. Our analysis shows that these ageostrophic components of the velocity field
 449 can be even stronger (Figure 12(a)).

450 The Ierapetra Eddy (IE), which is generally formed during the summer months at
 451 the south-east corner of Crete, is one of the strongest anticyclones of the Eastern Mediter-

452 reanean Sea. This first estimation of the core vorticity of the Ierapetra anticyclones, per-
453 formed by *Matteoda and Glenn* [1996], was relatively large in comparison with the local
454 Coriolis parameter f . More recently, *Mkhinini et al.* [2014] and especially *Ioannou et al.*
455 [2017] performed a thorough study of the IEs intensities based on the AVISO/DUACS
456 surface velocity fields. Assuming a circular eddy shape, *Ioannou et al.* [2017] computed
457 the cyclogeostrophic velocity profiles of the IEs during their formations or intensification
458 stages and found that the core vorticity ζ_0 could sometimes exceed the standard threshold
459 of inertial instability $\zeta_0 < -f$. Hence, it is not surprising that the cyclogeostrophic correc-
460 tions, computed by the iterative scheme, are very strong in the formation or intensification
461 area of the IEs.

462 We quantify in Figure 12(a) the amplitude of the cyclostrophic corrections on the
463 velocity magnitude but we could also consider how these corrections impact the intensity
464 of the detected eddies. We plot in Figure 12(b) the location of all the anticyclones having
465 a Rossby number higher than 0.2 after the cyclostrophic correction. This simple criterion
466 selects intense anticyclones which satisfy the cyclogeostrophic balance with finite core vor-
467 ticity (i.e. $\zeta/f < -0.6$ for circular Gaussian eddies). About 5000 eddy detections satisfy
468 this criterion during the 15 year period. Since we consider here daily detections, several
469 points could correspond to the same eddy. The large majority of these cyclogeostrophic
470 eddies correspond to the Alboran gyres (60%) or the Ierapetra anticyclones (30%). How-
471 ever, apart from these two “hot spots” it appears that few other anticyclones may also
472 show strong deviations from the standard geostrophic balance in the Mediterranean Sea.
473 Two other areas are concerned: the Algerian basin and a fraction of the Levantine basin,
474 off the Libyo-Egyptian coast.

475 The first area concerned in the Algerian basin corresponds to the detachment and
476 the recirculation area of long-lived anticyclones named Algerian Eddies (AE) [*Escudier*
477 *et al.*, 2016; *Pessini et al.*, 2018; *Garreau et al.*, 2018]. These large mesoscale anticyclones,
478 that are formed by the meanders of the Algerian Current, are generally considered to have
479 small Rossby numbers and satisfy the geostrophic balance.

480 We show in Figure 13(a) the temporal evolution of the Rossby number Ro and the
481 relative core vorticity for an AE detected in 2005. This anticyclone was studied by [*Pessini*,
482 2019] and exhibit a significant intensification when it interacts with the Balearic front six
483 months after its formation. During this event, the geostrophic Rossby number reaches

484 large value up to 0.2 which indicates that the cyclogeostrophic balance should be taken
485 into account. Then, when the cyclostrophic correction is applied the vortex Rossby num-
486 ber exceeds 0.3 and the core vorticity could reach intense negative values below $-f$ for
487 several days or weeks.

488 The second area is located in the Levantine basin ($31^{\circ} - 34^{\circ}\text{N}$, $27^{\circ}-30^{\circ}\text{E}$), and over-
489 lays the Herodotus Trough. It has been poorly studied and has very few in-situ observa-
490 tions. Nevertheless, *Mkhinini et al.* [2014] have shown that the Herodotus Trough is a for-
491 mation area of long-lived anticyclones. These mesoscale anticyclones, often called Mersa-
492 Matruh Eddies, have been mentioned in several studies [*Horton et al.*, 1994; *Hamad et al.*,
493 2006; *Amitai et al.*, 2010; *Menna et al.*, 2012] but never identified as intense eddies. The
494 instabilities of the Libyo Egyptian Current or the local changes of the mean shelf slope
495 could explain the formation of intense meanders or coastal anticyclones in this area.

496 This analysis confirms that the Alboran and the IE anticyclones are the most intense
497 mesoscale eddies in the Mediterranean Sea. However, the cyclostrophic correction applied
498 to the whole Mediterranean Sea revealed that few other mesoscale eddies that were not
499 identified before as ageostrophic could also exhibit a strong negative core vorticity during
500 their lifetime.

501 **5.3 Comparison with in-situ measurements**

502 This study would not be complete without a comparison with in-situ data, to ver-
503 ify that the proposed method effectively corrects the AVISO/DUACS fields so that they
504 are closer to the observations. This requires two conditions that are not easy to obtain
505 during oceanographic surveys. The first one is to find an intense eddy for which the cy-
506 clogeostrophic correction will be significant and the second one is to locate accurately the
507 eddy center in order to perform enough velocity measurements within the eddy core. One
508 of the goals of the Atalante cruise during the last PROTEVS/PERLE campaign, held in
509 October-November 2018, was to survey thoroughly the Ierapetra anticyclone in autumn,
510 when its intensity is usually strong. Among the large amount of measurements performed
511 during this campaign, we focus our analysis on two VMADCP transects, which were per-
512 formed close to the eddy center on October 29th (Figure 14) and on November 1 (Fig-
513 ure 15). First, the geostrophic surface velocities, provided by AVISO/DUACS, were inter-
514 polated along the boat trajectory and compared to the VMADCP averaged between 30 m

515 and 70 m. For these two transects (Figure 14(a) and Figure 15(a)), the magnitude of the
 516 geostrophic velocity vectors (black arrows) are significantly weaker than the measured
 517 ones (blue arrows) while their directions are almost similar. Indeed, the magnitude of the
 518 strongest geostrophic velocity component does not exceed 42 cm s^{-1} while the maximum
 519 surface velocity measured by the VMADCP reaches 62 cm s^{-1} . Thanks to the AMEDA al-
 520 gorithm, the characteristic contours of the geostrophic anticyclone were computed (black
 521 contour) and the characteristic speed radius was estimated around $R_{max} \simeq 34 \text{ km}$. Hence,
 522 we can estimate the geostrophic vortex Rossby number $Ro_g \simeq 0.13$ for this Ierapetra an-
 523 ticyclone. According to our analysis (Figure 9) for such values of the geostrophic Rossby
 524 number, the cyclostrophic corrections will be significant. Therefore, in a second step we
 525 apply the iterative corrections Eqn. (6) to the surface velocity field and we compare these
 526 new velocity fields (in red) to the in-situ measurements (in blue). We observe in the Fig-
 527 ure 14(b) and Figure 15(b) better agreements with the observations despite a clear differ-
 528 ence in the position of the eddy center. We should mention here that the accuracy of the
 529 AVISO/DUACS products is affected by the spatio-temporal distribution of the altimetry
 530 tracks and the correlation lengths used in the interpolation scheme [LeTraon *et al.*, 1998]
 531 to build the gridded maps from multiple satellites. It is thus, not surprising to find a shift
 532 of the order of 10 km ($\sim 1/8^\circ$) in the positioning of the eddy center. Nevertheless, the
 533 maximal amplitude of the cyclogeostrophic velocity field reaches 59 cm s^{-1} which is in
 534 better agreement with the observation. The speed radius of the corrected anticyclone is
 535 reduced ($R_{max} \simeq 30 \text{ km}$) which leads to a strong increase of the vortex Rossby number
 536 up to $Ro \simeq 0.2$. Besides, according to the fine comparison of the meridional and latitu-
 537 dinal velocity profiles, plotted in the panels (c, d) of the Figure 14 and Figure 15, we do
 538 see that the iterative method improves significantly the velocity gradients in the eddy core.
 539 In order to perform relevant comparisons between the VMADCP measurements and the
 540 velocities profiles from the geostrophic and cyclogeostrophic fields, any misalignments of
 541 the velocity profiles were first minimized. The Root Mean Square Error (RMSE) between
 542 the VMADCP measurements and the velocity profiles (geostrophic and cyclogeostrophic)
 543 were then estimated. The RMSE of the velocity norm based on the cyclogeostrophic pro-
 544 files was estimated of the order 9 cm/s and 8 cm/s for each transect respectively. The cy-
 545 clogeostrophic RMSE remained 30 – 40% lower than the geostrophic one (13 cm/s and
 546 14 cm/s).

547 This example shows that the cyclostrophic corrections of the AVISO/DUACS surface
 548 velocities, that we used, are relevant for intense mesoscale anticyclones. Thanks to the
 549 optimized iterative method we obtained corrected velocity fields that were much closer to
 550 the in-situ observations.

551 6 Conclusions

552 This study investigates the cyclogeostrophic balance of intense mesoscale eddies in
 553 the Mediterranean Sea. To do so, we optimized an iterative scheme, that was initially de-
 554 veloped for atmospheric flows [Endlich, 1961; Arnason *et al.*, 1962] and recently used for
 555 oceanic eddies in the Mozambique Channel [Penven *et al.*, 2014]. This iterative method
 556 computes with the best accuracy the cyclostrophic terms from the geostrophic surface ve-
 557 locity of the AVISO/DUACS products. We have tested the performance of this method on
 558 a wide range of idealized mesoscale eddies of different sizes, intensities and shapes that
 559 can be detected in the Mediterranean Sea. Since, we can obtain exact cyclogeostrophic so-
 560 lutions for these analytical eddies, we were able to compare the results obtained at the end
 561 of the iterations with the exact solutions and therefore validate the accuracy of the whole
 562 methodology. The thorough analysis of the various eddy parameters show that the ampli-
 563 tude of the cyclostrophic corrections depend not only on the vortex intensity but also on
 564 the vortex shape: the steepness parameter α or the vortex ellipticity ε for instance. The
 565 main advantage of this type of iterative method is that cyclostrophic corrections can be
 566 calculated for a very wide range of vortices of different shapes, be they circular or moder-
 567 ately elliptical.

568 We found that the cyclostrophic correction is needed for most of the mesoscale anti-
 569 cyclones that have a geostrophic vortex Rossby number larger than $Ro_g = \max(|V_g|)/f R_{maxg} >$
 570 0.1. This threshold is below the one chosen by *Douglass and Richman* [2015]. Indeed,
 571 these authors used the value of the mean relative vorticity $\bar{\zeta}/f$ inside the eddy contour to
 572 quantify the vortex intensity instead of the vortex Rossby number. For Gaussian eddies,
 573 we get the simple relation $Ro_g = \bar{\zeta}/2f$ and therefore the threshold $\bar{\zeta}/f = 0.3$ proposed
 574 by *Douglass and Richman* [2015] to classify strong cyclogeostrophic eddies correspond to
 575 $Ro_g = 0.15$. The lower value, that we propose, for this correction threshold, is also justi-
 576 fied by the intensive survey of the Ierapetra eddy performed during the 2018 PROTEVS-
 577 PERLE campaign. Even if the initial vortex Rossby number of this mesoscale anticyclone
 578 seems weak $Ro_g \simeq 0.13$, below the threshold proposed by *Douglass and Richman* [2015],

579 the corrections that we applied to the AVISO/DUACS geostrophic velocities were signifi-
580 cant (54%) and the corrected velocities were much closer to the VMADCP measurements.

581 We apply this cyclostrophic correction to fifteen years (2000-2015) of AVISO/DUACS
582 geostrophic velocity fields, gridded at $1/8^\circ$ for the Mediterranean Sea. We found that ve-
583 locity errors up to 50 cm s^{-1} could occur for large and intense anticyclones, due to the
584 initial geostrophic approximation. The two most intense anticyclones of the Mediterranean
585 Sea, the Alboran and the Ierapetra eddies, should be corrected but not only. Our analysis
586 suggest that other anticyclones in the Algerian basin or the Levantine basin may also ben-
587 efit from this ageostrophic correction. The statistical analysis shows that this cyclostrophic
588 correction have a strong impact on the most intense mesoscale anticyclones while it is
589 quite weak for cyclonic eddies. This may seem surprising because in high resolution nu-
590 merical simulations the most intense and ageostrophic eddies are generally cyclonic [*Klein*
591 *et al.*, 2008; *Roullet and P.*, 2010; *Qiu et al.*, 2014]. But, we must not forget, that these
592 very intense cyclones correspond to submesoscale eddies, whose radii are less than the
593 local deformation radius, which is around $R_d = 8 - 12 \text{ km}$ in the Mediterranean Sea.
594 Since, the effective resolution of altimetric products is coarse, such intense submesoscale
595 cyclones cannot be resolved by the standard AVISO/DUACS regional products gridded
596 at $1/8^\circ$ [*Amores et al.*, 2018]. Therefore, only large mesoscale cyclones can be detected
597 on altimetry products and they are generally less stable and coherent than their anticy-
598 clonic counterpart *Stegner and Dritschel* [2000]. Several stability analysis have shown that
599 ageostrophic effects, finite Rossby numbers or finite isopycnal deviations, tend to increase
600 the baroclinic instability for cyclones and weaken it for anticyclones [*Dewar and Killworth*,
601 1995; *Baey and Carton*, 2002; *Benilov and Flanagan*, 2008; *Lahaye and Zeitlin*, 2015;
602 *Mahdinia et al.*, 2017]. On the other hand, surface intensified anticyclones could remain
603 stable to baroclinic or centrifugal instabilities, even if they reach finite Rossby numbers up
604 to $Ro = 0.4$ [*Lazar et al.*, 2013].

605 Such methodology could be easily applied to other sub-basins or marginal seas at
606 mid-latitude in order to improve substantially the estimation of surface velocities. The ac-
607 curacy of these cyclostrophic corrections depends on the initial resolution of the AVISO/DUACS
608 products and is therefore more relevant on altimetry products gridded at $1/8^\circ$. These re-
609 gional products will be more numerous in the years to come, thanks to the growing num-
610 ber of conventional nadir altimeter satellites that will be deployed in the next two years
611 (Jason-C, HY-2C, HY-2D, HY-2E). We could then expect “all sat merged” series at higher

612 resolution that will combines up to 5 or 7 altimeters, for several years, with a significant
 613 reduction of the inter-track distance. Besides, the operational development of SWOT mis-
 614 sion (launched in 2021) will provide wide-swath altimetric measurements of the ocean
 615 surface topography leading to an unprecedented increase of the sea surface signature of
 616 oceanic mesoscale and submesoscale eddies.

693 **A: Appendix**

694 We quantify in this section how another iterative scheme that uses an under-relaxation
 695 factor λ [Iversen and Nordeng, 1982, 1984] may improves on the accuracy of convergence
 696 to the cyclogeostrophic solution. In accordance with Figure 7, the accuracy of conver-
 697 gence was tested for two Gaussian anticyclones ($\alpha = 2$) of the same radius ($R_{maxg} =$
 698 30 km) but different initial geostrophic intensities ($Ro_g = 0.16$ and $Ro_g = 0.2$). Based
 699 on the iterative method with under-relaxation, only a fraction λ of the previous correction
 700 is applied at each iteration step (Eqn.(A.1)-Eqn.(A.2)). The iterative scheme with under-
 701 relaxation writes as follows:

$$\mathbf{U}^{n+1} = \mathbf{U}_g + \frac{1}{f} \mathbf{k} \times (\mathbf{U}^n \cdot \nabla \mathbf{U}^n) \quad (\text{A.1})$$

702

$$\begin{aligned} \mathbf{U}_{\text{under-relaxation}}^{n+1} &= \mathbf{U}^n + \lambda (\mathbf{U}^{n+1} - \mathbf{U}^n) \\ &= (1 - \lambda) \mathbf{U}^n + \lambda \mathbf{U}^{n+1} \end{aligned} \quad (\text{A.2})$$

703 When $\lambda = 1$, there is no under-relaxation and we recover the classical iterative method
 704 that was used in this study (full correction at each iteration step). High λ parameters pro-
 705 vide lower weight to the solution of step \mathbf{U}^n . We compare in Figure A.1 the accuracy of
 706 the under-relaxation scheme to converge at the corresponding analytical cyclogeostrophic
 707 solution for the two anticyclones. Two under-relaxation factors were tested ($\lambda = 0.4$ and
 708 $\lambda = 0.6$). The relative error Σ_{Ro} is computed at each iteration step for the free (Fig-
 709 ure A.1(a,d)) and the constrained iterative method (Figure A.1(c,f)). The normalized resid-
 710 ual drop $\|\mathbf{U}^{n+1} - \mathbf{U}^n\|$ of the velocity norm illustrates the convergence of the geostrophic

711 field to the cyclogeostrophic solution at each iteration step (Figure A.1(b,e)). As men-
712 tioned in section 4.2, in order to prevent local divergence, the iteration process is con-
713 strained when the local residual $\|\mathbf{U}^{n+1} - \mathbf{U}^n\|$ starts to increase. For the eddy example
714 with moderate initial geostrophic Rossby intensity ($Ro_g = 0.16$) in Figure A.1(a-c), all
715 iterative schemes converge with high accuracy to the same cyclogeostrophic solution. The
716 relative error Σ_{Ro} remains below 5%. The under-relaxation delays the iterative method
717 convergence requiring more iterations to reach the same final solution. Yet it does not pre-
718 vent the local divergence (Figure A.1(b)). The performance of the iterative method is also
719 shown for the eddy example with the strong intensity ($Ro_g = 0.2$) in Figure A.1(d-f).
720 Similarly, in this case the convergence is slower but the iterative scheme does not succeed
721 to reach the cyclogeostrophic solution. The residual errors for the constrained iterative
722 method with under-relaxation are estimated 23% and 29% for $\lambda = 0.6$ and $\lambda = 0.4$ respec-
723 tively. The under-relaxation iterative scheme does not provide for a better accuracy while
724 the residual errors are estimated slightly higher than the standard iteration scheme (17%
725 when $\lambda = 1$).

734 Acknowledgments

735 This work was funded by the ANR-Astrid Project DYNED-Atlas (ANR-15-ASMA-0003-
736 01). The gridded altimeter products were produced by SSALTO/DUACS and distributed
737 by the Copernicus Marine Environment Monitoring Service (marine.copernicus.eu). The
738 authors gratefully acknowledge the Délégation Générale de l'Armement which funded
739 the program Protevs II into which the Protevs-Perle campaign was scheduled, the French
740 Naval Hydrologic and Oceanographic Service (SHOM) and the crew of the R/V L'Atalante
741 for their contribution to the PROTEVS-PERLE campaign providing us with the in-situ
742 data. Thanks to the two reviewers for their constructive comments and helpful sugges-
743 tions on an earlier version of the manuscript. The cyclostrophic data used in this work are
744 stored online (doi:10.5281/zenodo.3452045). The DYNED-Atlas data base for the Mediter-
745 ranean Sea is available at doi:10.14768/2019130201.2.

617 **Figure 1.** Principle of the automatic eddy detection algorithm AMEDA. The characteristic contour (solid
 618 blue line) and the last contour (black dashed line) are calculated from the surface velocity field (a) for an
 619 large anticyclone located at the east of Sardinia. The background colors correspond to the ADT map while
 620 the black vectors to the surface geostrophic velocities. The streamlines associated with the velocity field are
 621 plotted in (b) and also the correspondence with the *characteristic contour* (solid blue line) and the last closed
 622 contour (black dashed line). The mean velocity profile $\langle V \rangle = F(R)$ deduced from the streamlines analysis
 623 and the characteristic eddy radii R_{max} and R_{end} are plotted in (c).

624 **Figure 2.** Probability distributions of the vortex Rossby number (a), the ellipticity ϵ (b) and the steepness
 625 parameter α (c) for cyclones (solid line) and anticyclones (dashed line) in the Mediterranean sea for the 2000-
 626 2015 period. We consider here only geostrophic mesoscale eddies having a characteristic radius larger than
 627 $R_{max} \geq 18$ km. The steepness parameter α was computed here only for quasi circular eddies ($\epsilon < 0.2$).

628 **Figure 3.** Modifications of the meridional velocity profile of the Alboran eddy (depicted Figure 4) along
 629 the longitude axis at each step of the iterative process Eqn. (6) for the free iteration (a) and for the constrained
 630 iteration (b). The vortex Rossby number, of the initial geostrophic eddy (bold profile in (b)), is 0.24 while at
 631 the end of the constrain iteration (red profile in (b)) it reaches $Ro = 0.48$.

632 **Figure 4.** Example of the cyclogeostrophic corrections (red) applied to the AVISO/DUACS surface
 633 geostrophic velocity field (black) on the Alboran anticyclone in December 2000 (a). The characteristic eddy
 634 contour computed by the AMEDA algorithm (b) is also modified by the cyclogeostrophic correction (red) in
 635 comparison with the initial contour computed from the geostrophic field (black) as shown in Figure 3.

636 **Figure 5.** Comparison of geostrophic vs. cyclogeostrophic velocity profiles of both cyclonic and anticy-
 637 clonic eddies having the same geostrophic Rossby number ($Ro_g = 0.14$) but distinct steepness parameters:
 638 $\alpha = 1$ (black solid line), a Gaussian eddy $\alpha = 2$ (red line) and $\alpha = 3$ (black dashed line).

639 **Figure 6.** Percentages of the relative errors, between the cyclogeostrophic and the geostrophic vortex so-
 640 lution, are plotted for the vortex Rossby number (a) and the characteristic eddy radius R_{max} (b). Negative
 641 (positive) Rossby numbers correspond here to anticyclonic (cyclonic) eddies. Various circular eddies having
 642 distinct shape ($\alpha = 1$ dotted line, $\alpha = 2$ solid line and 3 dashed line) and intensity ($-0.25 < Ro_g \leq 0.25$) are
 643 considered.

644 **Figure 7.** Accuracy of the iteration scheme Eqn. (6) applied to two geostrophic gaussian anticyclones
 645 ($\alpha = 2$) having the same radius, $R_{max} = 30$ km, but distinct Rossby number: $Ro_g = 0.16$ (a) and $Ro_g = 0.2$
 646 (b). The initial geostrophic profiles $V_g(r)$ are plotted with thin dashed lines, while the targeted velocity pro-
 647 files $V_\theta(r)$, solution of the cyclogeostrophic equation Eqn. (7), are plotted with a thick black line. (c) Relative
 648 error ($\Sigma Ro = (Ro - Ro_i)/Ro_i$) between the Rossby number reached at every iterative step (Ro_i) and the
 649 corresponding exact cyclogeostrophic solution (Ro) for the two gaussian anticyclones.

650 **Figure 8.** Impact of the initial interpolation on the evolution of the characteristic radius R_{max} and the
 651 speed radius V_{max} at each step of the iteration scheme Eqn. (6) for an initial geostrophic gaussian eddy
 652 ($\alpha = 2$). The horizontal dashed lines correspond to the initial geostrophic solution. The horizontal solid lines
 653 correspond to the targeted values of the cyclogeostrophic solution. Three cases are plotted: no initial inter-
 654 polation (open circle), a linear interpolation at $1/24^\circ$ (open square) and a cubic interpolation (filled circle) at
 655 $1/24^\circ$.

656 **Figure 9.** Initial relative error on the vortex Rossby number between geostrophic and cyclogeostrophic
 657 circular anticyclones of various intensity (Ro_g), sizes (a), or profiles (b) when there is no correction on the
 658 initial geostrophic velocity field. Relative error ($\Sigma_{Ro} = (Ro - Ro_i)/Ro_i$) between the Rossby number reached
 659 at the end of the iterative scheme (Ro_i) and the one corresponding to the exact cyclogeostrophic solution (Ro)
 660 for the same range of initial parameters (b,d).

661 **Figure 10.** Evolution of the vortex Rossby numbers for geostrophic (open square) and cyclogeostrophic
 662 (filled square) elliptical anticyclones as a function of their ellipticity $\epsilon = 1 - b/a$, where a and b are respec-
 663 tively the semi-major and semi-minor axis. The elliptical velocity fields were obtained from the deformation
 664 (Eqn. (10-13)) of a circular Gaussian velocity profile having a characteristic radius $R_{max} = 30 \text{ km}$ and a
 665 maximum azimuthal speed $V_{max} = 0.9 \text{ m s}^{-1}$. The vortex Rossby numbers of the elliptical eddies obtained by
 666 the iterative scheme Eqn. (6) applied to the geostrophic solutions are plotted with crosses.

667 **Figure 11.** Probability distribution function of the vortex Rossby numbers Ro_g and Ro (a,c) and the steep-
 668 ness parameters α (b,d) of the mesoscale eddies detected by the AMEDA algorithm on the AVISO/DUACS
 669 geostrophic velocity field (dashed line) and on the corrected velocity field where cyclogeostrophic compo-
 670 nents are estimated (black solid line).

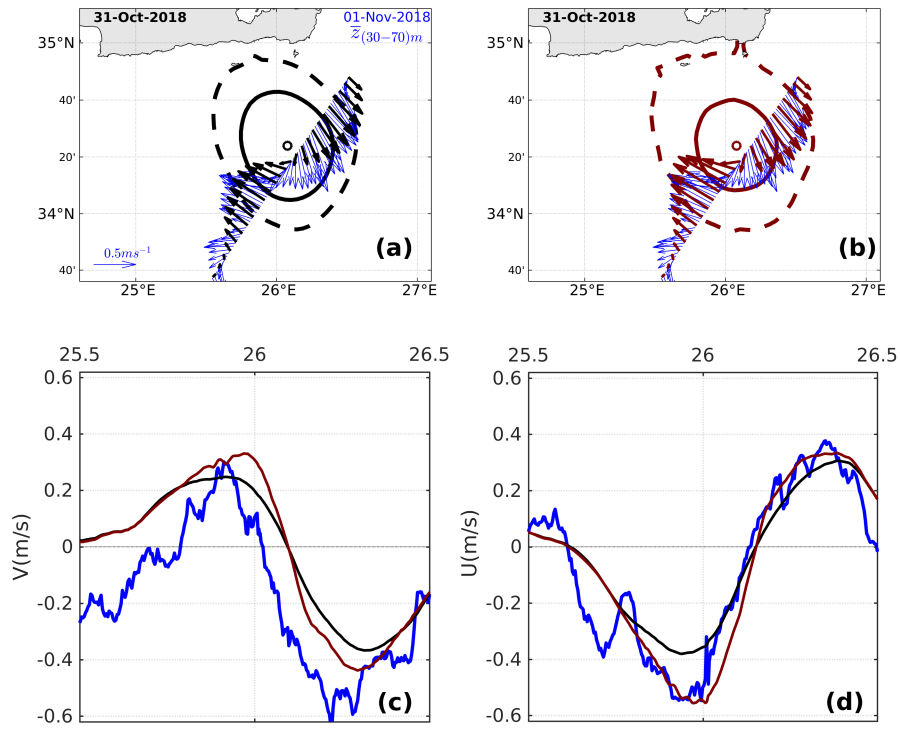

671 **Figure 12.** The localization of the maximal velocity correction, averaged for 5 days at each grid point, dur-
 672 ing the 15 year period (2000-2015) is plotted in the upper panel (a). Velocity corrections having an amplitude
 673 $\|V - V_g\|$ below 10 cm s^{-1} are not plotted. The location of eddies detected by the AMEDA algorithm (once
 674 the cyclostrophic correction is applied) having a vortex Rossby number higher than 0.2 are plotted in the
 675 lower panel (b).

676 **Figure 13.** Temporal evolution of the vortex Rossby number Ro and the relative core vorticity $\zeta(0)/f$ for
 677 a) an Algerian Eddy (AE) detected in 2005 b) a Libyo-Egyptian eddy detected in 2003 and c) for an Ierapetra
 678 Eddy (IE) detected in 2010. The characteristics of the mesoscale eddies are illustrated with the black filled
 679 circles as detected by the AMEDA algorithm applied on the AVISO/DUACS geostrophic velocity fields and
 680 with the filled red circles when applied on the corrected cyclogeostrophic velocity fields.

681 **Figure 14.** Comparison between the geostrophic surface velocities provided by the AVISO/DUACS product
 682 (black lines or arrows) and the VMADCP in-situ measurements (blue lines or arrows) performed the October
 683 29, 2018. The cyclogeostrophic velocity field obtained by the iterative method Eqn. (6) is plotted in red. The
 684 upper panels show the surface geostrophic (a) or the cyclogeostrophic (b) velocity vectors along the boat
 685 trajectory in comparison with the VMADCP measurements. The characteristic contours (solid lines) and the
 686 last closed streamlines (dashed lines) computed by the AMEDA algorithm are both plotted for the geostrophic
 687 (in black, panel (a)) and the cyclogeostrophic (in red, panel (b)) surface velocity fields. The meridional and
 688 the latitudinal velocity profiles, of the geostrophic (black), the cyclogeostrophic (red) and the in-situ measure-
 689 ments (blue), are plotted respectively in the lower panels (c) and (d).

690 **Figure 15.** Comparison between the geostrophic surface velocity provided by the AVISO/DUACS prod-
 691 uct (black lines or arrows) and the VMADCP in-situ measurements (blue lines or arrows) performed on
 692 November 1, 2018. The panels are in the form identical to Figure 14.

726 **Figure A.1.** Accuracy of the different iterative schemes (Eqn.(A.1) - Eqn(A.2)) applied on two geostrophic
 727 anticyclones with $Ro_g = 0.16$ in the upper panels and $Ro_g = 0.2$ in the lower panels as described in Fig-
 728 ure 7. The classical iterative method (crosses) and the iterative method with the under-relaxation parameter
 729 $\lambda = 0.4$ (diamonds) and $\lambda = 0.6$ (squares) are illustrated with the different markers. The Relative error
 730 ($\Sigma_{Ro} = (Ro - Ro_i)/Ro_i$) between the Rossby number reached at every iteration step (Ro_i) and the correspond-
 731 ing exact cyclogeostrophic solution (Ro) is illustrated in panels a) and b). The normalized residual drop of the
 732 velocity norm is shown in panels b) and e) at every iteration step. The relative error Σ_{Ro} of the constrained
 733 iterative schemes is shown in panels c) and f).
