Abstract: We propose a technique to modify a given discrete-time (nonlinear) observer so that the state estimate remains in a given convex set, without altering the observer performances in terms of convergence and robustness to external disturbances. The proposed approach can be used to remove the peaking phenomenon or to attenuate the effect of impulsive outliers in the measures. It assumes that it is possible to execute a certain number of computations between any two sampling times in order to refine the current estimate and bring it back into the prescribed set. The proposed technique can be applied to any class of nonlinear observers for which a quadratic Lyapunov function is used to prove stability.

1. INTRODUCTION

In the context of observer design, it is well known that a wrong initialization of the estimate may induce very large estimation errors during transient behaviors. This phenomenon, also named peaking, see Khalil and Praly (2014), can be observed in both continuous and discrete time observers. For instance, peaking may be induced by large gains selected to guarantee fast convergence of the estimation error, or by dynamics possessing large overshoots caused by unstable poles on the open loop system, or by underdamping oscillatory behaviors, see, e.g., (Seron et al., 2012, §1, §8, §9). Moreover, large estimation errors can also occur in presence of large measurement disturbances of impulsive nature, denoted also as outliers, see Alessandri and Zaccarian (2018). This phenomena may make the observer impractical or unsafe to use during transient if not properly handled, see, e.g. Khalil and Praly (2014), and renders implementation tricky from a numerical perspective, in particular if the computational power is limited as in embedded systems, see, e.g., Henriksson (2006), Kopetz (2011). A simple solution could be to keep the observer dynamics intact but saturate its estimate. However, this approach does not solve the numerical issues and does not attenuate the effect of impulsive disturbances inducing undesired peaking in steady-state behavior. Another natural idea would be to saturate the observer dynamics and force the observer to remain in the prescribed set, but this may destroy the observer convergence properties as we show on an example.

For continuous-time systems, some solutions have been proposed, such as reducing the peaking in high-gain observers in Andrieu et al. (2016), Astolfi et al. (2018), or ensuring the invariance of a convex set for the high-gain observers in Astolfi and Praly (2013); Maggiore and Passino (2003), and for linear Kalman filters with linear constraints in Berkane et al. (2018) and references therein.

For discrete-time systems, many techniques have been developed to address the problem of outliers, as in Alessandi and Awawdeh (2016), Alessandri and Zaccarian (2018), De Palma and Indiveri (2017), Gandhi and Mili (2010). Yet, these approaches do not guarantee the state of the observer to remain in some given prescribed set.

We propose a technique to modify a given discrete-time observer that guarantees the estimate to remain in a prescribed convex compact set, while preserving the observer convergence properties. This technique is inspired from the convex design method first proposed in Astolfi and Praly (2013) for continuous-time observers and can be applied to any class of discrete-time nonlinear observer provided that a quadratic Lyapunov function for the error dynamics is known, see, for instance, Califano et al. (2003), Ciccarella et al. (1993), Ibrir (2007), Kazantzis and Kravaris (2001), Xie et al. (1994), Zemouche and Boutayeb (2013). We assume for this purpose that each discrete time corresponds to a sampling time of the plant and that some computations can be carried out between each consecutive sampling times. More precisely, if the estimate – following the initially given observer’s dynamics – exits the prescribed set at a sample time, we propose a refining strategy that brings it back into that viable set before the next sampling event. We guarantee that the Lyapunov function does not increase at these intermediate computations. Hence, the convergence properties of the observer are not altered.
The rest of the paper is organized as follows. The problem formulation is stated in Section 2 and the redesign approach presented in Section 3. Then, our main result is given in Section 4 and a numerical simulation is shown in Section 5. Finally, conclusions and future perspectives are discussed in Section 6.

Notation: We denote by \( \mathbb{R} \) the set of real numbers, \( \mathbb{R}_{\geq 0} \) is the set of non-negative real numbers, \( \mathbb{N} \) is the set of non-negative integers, and \( \mathbb{N}_{>0} \) is the set of positive integers. We define \( \mathbb{R}^{n_{\times}} := \mathbb{R} \times \cdots \times \mathbb{R} \) with \( n \in \mathbb{N}_{>0} \). Given a set \( A \subset \mathbb{R}^{n_{\times}} \), \( \text{int}(A) \) stands for the interior of \( A \), namely the set of all points in \( A \) that do not belong to its boundary. Given a real number \( x \in \mathbb{R}_{>0} \), we denote by \( \text{ceil}(x) \) the ceiling function, namely \( \text{ceil}(x) = \min\{y \in \mathbb{N} : y \geq x\} \).

We suppose to know an observer of the form

\[
\mathbf{x}_{k+1} = F(\mathbf{x}_k, u_k, y_k),
\]

where \( \mathbf{x}_k \in \mathbb{R}^{n_{\times}} \) is the state, \( u_k \in \mathbb{R}^{n_u} \) a known input, \( y_k \in \mathbb{R}^{n_y} \) is the output, and \( d_k \in \mathbb{R}^{n_d} \) is a perturbation acting on the dynamics and/or the measurement, at time \( k \in \mathbb{N} \). The following assumption is stated.

**Assumption 1.** We are given compact subsets \( X_0 \subset \mathbb{R}^{n_{\times}}, \mathcal{U} \subset \mathbb{R}^{n_u}, \mathcal{D} \subset \mathbb{R}^{n_d}, \) and \( \mathcal{X} \subset \mathbb{R}^{n_{\times}}, \) such that any trajectory of (1) initialized in \( X_0 \), with input in \( \mathcal{U} \) and perturbation in \( \mathcal{D} \), remains in \( \mathcal{X} \) for all \( k \in \mathbb{N} \).

We suppose to know an observer of the form

\[
\hat{x}_{k+1} = F(\hat{x}_k, u_k, y_k)
\]

where \( \hat{x}_k \in \mathbb{R}^{n_{\times}} \) is the state estimate at time \( k \in \mathbb{N} \). By denoting the estimation error \( e := \hat{x} - x \) and the observer error dynamics as

\[
e_{k+1} = \Delta(x_k, e_k, u_k, d_k) := F(e_k + x_k, u_k, h(x_k, d_k)) - f(x_k, u_k, d_k),
\]

the performances of observer (2) are characterized in the following assumption.

**Assumption 2.** There exist a matrix \( P = P^T > 0 \) and a map \( \beta : \mathbb{R}_{\geq 0} \times \mathbb{R}^{n_{\times}} \to \mathbb{R}_{\geq 0} \), such that, by defining

\[
V(e) := e^T P e,
\]

\[
V(x, e, u, d) \leq \beta(V(e), d).
\]

**Remark 1.** At this point, no particular assumption is made on the map \( \beta \) which characterizes the performances of the observer. For an exponentially stable observer which is input-to-state stable (ISS) with respect to the perturbation, the function \( \beta \) is typically of the form

\[
\beta(v, d) = \rho v + \alpha(d)
\]

with \( \rho \in [0, 1) \) and \( \alpha \in \mathcal{K} \).

In the following, \( \lambda \) and \( \lambda \) are the minimum and maximum eigenvalue of \( P \), respectively, so that for all \( e \in \mathbb{R}^{n_{\times}} \),

\[
\lambda \leq V(e) \leq \lambda \|e\|^2.
\]

Although the plant state \( x_k \) is known to remain in \( \mathcal{X} \), the estimate \( \hat{x}_k \) may leave \( \mathcal{X} \), especially during transient behaviors. As a consequence, our goal is to modify the observer dynamics (2) to ensure the estimate \( \hat{x}_k \) remains in a given compact set \( \mathcal{X} \supset \mathcal{X} \), while preserving the original performances stated in Assumption 2.

In the following, we suppose that the discrete-time instances \( k \) correspond to sampling times \( t_k \) where a measurement \( y_k \) is available, and that between any two consecutive sampling events \( t_k \) and \( t_{k+1} \), we are able to carry out \( \theta \in \mathbb{N} \) - to be defined - computations in order to refine the estimates given by (2). This assumption is realistic when system (1) is the exact or approximate discrete-time model obtained by sampling a continuous-time system at instants \( t_k, t_{k+1}, \ldots \), if the digital controller has a computational frequency which is higher than the sampling frequency. In other words, we run the following algorithm depicted in Figure 1:

1. At instant \( t_k \), we compute

\[
\hat{x}_{k,1} = F(\hat{x}_k, u_k, y_k).
\]

2. If \( \hat{x}_{k,1} \notin \mathcal{X} \), we select \( \hat{x}_{k+1} = \hat{x}_{k,1} \). Otherwise, if \( \hat{x}_{k,1} \notin \mathcal{X} \), we carry out \( \theta \) refining computational steps leading to \( \hat{x}_{k,i} = \hat{x}_{k,1}, i = 2, \ldots, \theta + 1 \), such that at the end of these steps \( \hat{x}_{k,\theta+1} \in \mathcal{X} \).

3. We finally define

\[
\hat{x}_{k+1} = \hat{x}_{k,\theta+1}.
\]

We thus address the following problem.

**Problem 1.** For a given convex compact set \( \mathcal{X} \supset \mathcal{X} \), design a refining strategy, i.e. a map \( \Delta : \mathbb{R}^{n_{\times}} \to \mathbb{R}^{n_{\times}} \) and a number \( \theta \in \mathbb{N} \) so that, by combining (8)-(9) with

\[
\hat{x}_{k+1} = \Delta(\hat{x}_{k,\theta+1}), \quad i = 1, \ldots, \theta, \quad k \in \mathbb{N},
\]

the resulting new observer dynamics

\[
\hat{x}_{k+1} = F_m(\hat{x}_k, u_k, y_k)
\]

with \( F_m : \mathbb{R}^{n_{\times}} \times \mathbb{R}^{n_u} \times (\mathbb{R}^{n_{\times}} \times \mathbb{R}^{n_{\times}}) \to \mathbb{R}^{n_{\times}} \), verify

1. (1) the Lyapunov function (4) still satisfies (5) with \( \Delta \) replaced by

\[
\Delta_m(x_k, e_k, u_k, d_k) := F_m(e_k + x_k, u_k, h(x_k, d_k)) - f(x_k, u_k, d_k),
\]

2. i.e. the performances of the observer are preserved,

3. for any initial conditions pair \( (x_0, \hat{x}_0) \in X_0 \times \mathcal{X} \), any input in \( \mathcal{U} \) and perturbation in \( \mathcal{D} \), the corresponding solution to (11) lies in \( \mathcal{X} \) for all \( k \in \mathbb{N} \).

3. REDISEIGN APPROACH

3.1 Convexity assumption

The method we propose requires convexity properties of the set \( \mathcal{X} \) in which we want to keep the estimate trajectories. For this, let us define \( v_{\text{max}} \) as

\[1\text{ See for instance Nešić et al. (1999) and references therein.} \]
with \( \beta \) given by Assumption 2, and the compact sets \( \Omega_{\text{max}} \) and \( \hat{\Omega}_{\text{max}} \) as

\[
\Omega_{\text{max}} := \{ e \in \mathbb{R}^{n_x} : V(e) \leq v_{\text{max}} \},
\]
\[
\hat{\Omega}_{\text{max}} := \{ \bar{e} \in \mathbb{R}^{n_x} : \exists \bar{\epsilon} \in \mathcal{X}, \bar{x} - \bar{\epsilon} \in \Omega_{\text{max}} \}. \tag{15}
\]
According to Assumption 1, and in view of (5), \( v_{\text{max}} \) defines the size of the largest Lyapunov level sets of \( V \) after a jump from \( x_k \in \mathcal{X}, \hat{x}_k \in \hat{\mathcal{X}}, \) with \( u_k \in \mathcal{U} \) and \( d_k \in \mathcal{D}. \) In other words, \( \hat{x}_{k+1} \) is in \( \hat{\Omega}_{\text{max}} \) and \( e_{k+1} \) is in \( \Omega_{\text{max}} \) when \( (x_k, \hat{x}_k, u_k, d_k) \) is in \( \mathcal{X} \times \hat{\mathcal{X}} \times \mathcal{U} \times \mathcal{D} \) along the dynamics (2). We make the following assumption.

**Assumption 3.** There exist \( \eta \in \mathbb{N}, \) a \( C^1 \) function \( c : \mathbb{R}^{n_x} \to \mathbb{R}_{\geq 0} \) and real numbers \( \epsilon_{\text{max}} > \epsilon_{\text{min}} > 0 \) such that, by letting \( c_i \), the \( i \)-th component of \( c \) and

\[
\begin{align*}
C_0 &= \{ x \in \mathbb{R}^{n_x} : c(x) = 0 \}, \\
C_{\text{min}} &= \{ x \in \mathbb{R}^{n_x} : |c(x)| \leq \epsilon_{\text{min}} \}, \\
C_{\text{max}} &= \{ x \in \mathbb{R}^{n_x} : |c(x)| \leq \epsilon_{\text{max}} \},
\end{align*} \tag{16}
\]
the following properties hold.

1. \( \mathcal{X} \subset C_0 \subset C_{\text{min}} \subset \hat{\mathcal{X}} \subset C_{\text{max}}. \)
2. \( \hat{\Omega}_{\text{max}} \subseteq C_{\text{max}}. \)
3. Each function \( c_i : \mathbb{R}^{n_x} \to \mathbb{R}_{\geq 0} \) is convex on \( C_{\text{max}} \), i.e.

\[
c_i(\hat{x}) \leq c_i(x) + \frac{dc}{dx}(\bar{x}) (\hat{x} - \bar{x}) \quad \forall x, \hat{x} \in C_{\text{max}}. \tag{17}
\]
4. \( \sup_{x \in C_{\text{max}}} \left| \frac{dc}{dx} (x) \right| \leq \delta. \)

If the set \( \mathcal{X} \) can be arbitrarily chosen, we have the following result.

**Lemma 1.** Consider \( Q = Q^T > 0 \) and \( r > 0 \), such that \( \mathcal{X} \subset \{ x \in \mathbb{R}^{n_x} : x^T Q x \leq r \}. \) Then, Assumption 3 is verified with \( \hat{\mathcal{X}} = \{ x \in \mathbb{R}^{n_x} : x^T Q x \leq \bar{r} \}, \)

\[
e(\hat{x}) := \max \left\{ \frac{x^T Q x}{r} - 1, 0 \right\}^2,
\]
for some \( \bar{r} > r > 0 \) and \( \epsilon_{\text{max}} > \epsilon_{\text{min}} > 0. \)

If \( \mathcal{X}, \hat{\mathcal{X}} \) are imposed but a compact convex intersection of half-planes and quadratics fits between \( \mathcal{X} \) and \( \hat{\mathcal{X}}, \) \( c \) can be taken multi-dimensional with each \( c_i \) built as in (18) from linear or quadratic maps, as showed in the next lemma.

**Lemma 2.** Suppose there exist real numbers \( \tau_i \) and \( \tau_i \) \( i = 1, \ldots, n_x \) such that \( \mathcal{X} \subset \prod_{i=1}^{n_x} \tau_i, \tau_i \subset \hat{\mathcal{X}}. \) Then, Assumption 3 is verified with

\[
e(c) = (\tau_1(x), \tau_1(x), \ldots, \tau_1(x), \tau_1(x), \ldots, \tau_{n_x}(x), \tau_{n_x}(x)), \]
\[
(\hat{e}(x)) = \max \left\{ \tau_i - x_i, 0 \right\}^2, \quad \tau_i(x) = \max \left\{ x_i - \tau_i, 0 \right\}^2, \tag{19}
\]
for some \( \epsilon_{\text{max}} > \epsilon_{\text{min}} > 0. \)

The proofs of Lemma 1 and 2 are omitted for space reasons.

### 3.2 Refining strategy

We introduce the map \( M : C_{\text{max}} \to \mathbb{R}^{n_x} \) defined as

\[
M(\hat{x}) = -\gamma P^{-1} \frac{dc}{dx}(\hat{x})^T c(\hat{x}), \tag{20}
\]
with a positive scalar \( \gamma \), and \( P \) coming from Assumption 2. As proved in Lemma 3 of Appendix A, if \( \gamma \) is sufficiently small, modifying the estimate \( \hat{x} \) as \( \hat{x} + M(\hat{x}) \) makes \( V(\hat{x} - x) \) decrease no matter where the plant state \( x \) actually is, with \( V \) the quadratic Lyapunov function defined in (4). Besides, \( V \) decreases strictly (by \( \gamma \epsilon_{\text{min}}^2 \)) when \( \hat{x} \) is outside int(\( C_{\text{min}} \)), with \( C_{\text{min}} \) defined in (16).

Since \( C_{\text{min}} \subseteq \hat{\mathcal{X}}, \) a possible strategy is therefore to repetitively use \( M \) to bring the estimate back in \( \hat{\mathcal{X}} \) at each iteration \( k \). For that, consider \( v_{\text{min}} > 0 \) as \( v_{\text{min}} := \max \{ v \in \mathbb{R}_{>0} : v \in \mathcal{X}, \{ \hat{x} \in \mathbb{R}^{n_x} : V(\hat{x} - x) \leq v \} \subseteq C_{\text{min}} \}. \)

In other words, \( v_{\text{min}} \) is the largest positive number such that the following property holds

\[
x \in \mathcal{X} \text{ and } V(\hat{x} - x) \leq v_{\text{min}} \implies \hat{x} \in \mathcal{X} \subset \hat{\mathcal{X}}. \tag{21}
\]
Since the true state \( x \) is known to be in \( \mathcal{X}, \) a way to bring \( \hat{x} \) back into \( \hat{\mathcal{X}} \) is thus to bring \( V \) below the threshold \( v_{\text{min}}. \)

This can be done by applying \( M \) at most \( \theta \in \mathbb{N} \) times, with \( \theta \) defined as

\[
\theta := \text{ceil} \left( \frac{\max \{ v_{\text{max}} - v_{\text{min}}, 0 \} \gamma_{\text{max}}}{\epsilon_{\text{min}}^2} \right). \tag{22}
\]

**Remark 2.** By definition of \( \hat{\Omega}_{\text{max}} \), it may occur that \( \hat{\Omega}_{\text{max}} \subset C_{\text{min}} \) and that \( v_{\text{max}} < v_{\text{min}}. \) This means that after every jump of the original observer (2), the estimate remains in the desired set \( \hat{\mathcal{X}}. \) In such a case, no modification is needed, namely \( \theta = 0 \) and all the analysis is trivially satisfied since no refining is needed.

The redesign we propose consists in correcting the state estimate with the map \( M \) as long as the estimate is outside \( C_{\text{min}}, \) namely the function (10) is selected as

\[
G(\hat{x}_{k,i}) = \begin{cases} \\
\hat{x}_{k,i} + M(\hat{x}_{k,i}) & \text{if } \hat{x}_{k,i} \notin C_{\text{max}} \setminus C_{\text{min}} \\text{ or otherwise} \\
\hat{x}_{k,i} & \text{for } i = 1, \ldots, \theta.
\end{cases} \tag{23}
\]
For \( i = 1, \ldots, \theta, \) as it can be noted by the expression of \( M, \) the correction (23) uses the gradient of the convex map \( c, \) namely \( -dc/dx, \) to bring \( \hat{x}_{k,i+1} \) closer to \( \hat{\mathcal{X}} \) along level sets of \( V. \) The recursive algorithm steps when we cross \( C_{\text{min}} \) this strategy is depicted in Figure 2. Note that this could not be achieved in one iteration because \( \gamma \) needs to be sufficiently small to ensure that \( V \) decreases, as shown in Lemma 3 in the Appendix, which justifies the \( \theta \) steps.

**Remark 3.** This redesign generates new observer dynamics (11) with a function \( F_m \) recursively defined through (23). If an explicit expression of \( F_m \) is available known, as in Berkane et al. (2018) for the particular case of linear dy-
The corresponding solution to (27) is constant, namely $x_k = (-1, -1)$ for all $k \in \mathbb{N}$, and lives therefore in the set $X = [-1,1] \times [-1,1]$. Consider the observer

$$\dot{x}_{k+1} = Ax_k + L(y_k - Cx_k), \quad (28)$$

with $L$ chosen such that the matrix $A - LC$ is Schur, namely its eigenvalues lie in the open unit disk. The result of a simulation of observer (28) with $\dot{x}_0 = (1,1)$, $L = [-1.87, 1.874]$ (eig($A - LC$) = $\{0.95, 0.92\}$), and a disturbance $d_k$ selected as

$$d_k = \begin{cases} 0, & 0 \leq k \leq 150 \text{ or } k \geq 154, \\ 3, & 150 < k < 154 \end{cases}$$

is given in Figure 3a). Two large peaking phenomena are present, caused by the wrong initial conditions and by the effect of the disturbance $d$.

We would like to preserve the convergence of observer (28) while keeping $\dot{x}$ in the set $\hat{X} = [-r, r] \times [-r, r]$, for some scalar $r > 1$. Note that we cannot implement the saturated observer

$$\dot{\hat{x}}_{k+1} = \text{sat}_r (F(\hat{x}_k, u_k, y_k)), \quad (29)$$

where the function sat is taken component-wise, because the convergence is not preserved in absence of disturbances if $r$ is taken too small. For instance, by selecting $\dot{x}_0 = (1,1)$ and $r = 2$, solutions to (29) remain stuck in $\hat{x}_k = (-2, -2)$ for all $k > 0$.

We thus apply the method presented in this paper. We know that for all $\lambda > \max |\text{eig}(A - LC)|$, there exists$^2$ a $P$ solution to

$$(A - LC)^T P (A - LC) \leq \lambda^2 P, \quad P > 0.$$  

We choose for instance $\lambda = 0.955$, $P = 10^3 \cdot \begin{pmatrix} 1.259 & 1.319 \\ 1.319 & 1.381 \end{pmatrix}$, $P^{-1} = \begin{pmatrix} 0.039 & -0.037 \\ -0.037 & 0.036 \end{pmatrix}$.

Then, Assumption 2 holds along the lines of Remark 1, so that we can follow Section 4 to modify the observer (28). By following Lemma 2, we choose the function $c$ satisfying Assumption 3 as in (19) with

$$\ell_1 = -1.1, \quad \ell_2 = 1.1, \quad \ell_3 = -1.1, \quad \ell_4 = 1.1,$$

and $\varepsilon_{\text{min}} = 0.01$ which defines the set $\mathcal{C}_{\text{min}}$ that will be made invariant for the observer. As for $\varepsilon_{\text{max}}$ and $\mathcal{C}_{\text{max}}$, notice that they are not used in the design apart from providing an upper bound on $\gamma$ in (24) through $\delta$ defined in Assumption 3. Here we take $\gamma = 17$. Instead of computing the theoretical number of steps $\theta$ by using (22), we suppose that, due to computation limit constraints, we cannot carry out more than $\theta_m$ computations in-between

$^2$ Because $\frac{1}{\lambda}(A - LC)$ is Schur.

6. CONCLUSION

We proposed a technique that guarantees the estimate to remain in a prescribed convex set for a given observer’s dynamics, without modifying its convergences properties. For this, we need to know a quadratic Lyapunov function for the error dynamics and we assume that, between any two samples, we are able to make a certain number of computations in order to refine the estimate of the observer. The proposed methodology allows one to attenuate the peaking phenomenon caused by wrong initial conditions and/or by measurement outliers, as illustrated by the numerical example. Future works aim at extending the proposed technique to observers with a state-dimension different from the plant’s, as in e.g. Astolfi et al. (2018), observers with time-varying dynamics to handle Kalman-like designs as in Besançon (1999) or Boutayeb et al. (1997), and finally observers whose convergence is proved in other coordinates (Astolfi and Praly (2013), Bernard and Marconi (2018) Ciccarella et al. (1993)).
Lemma 3. Suppose Assumptions 1 to 3 hold. If $\gamma$ verifies (24), the functions $V$ and $M$ defined in (4) and (20) satisfy
\[
V(e + M(\hat{x})) \leq V(e) \quad \forall x, \hat{x} \in X \times C_{max}\]
\[
(A.1a)
\]
\[
V(e + M(\hat{x})) \leq V(e) - \gamma_\min^2 \quad \forall x, \hat{x} \in X \times (C_{max} \setminus \text{int}(C_{min}))\]
\[
(A.1b)
\]
where $e = \hat{x} - x$.

Proof. Take $x$ in $X$ and $\hat{x}$ in $C_{max}$. In view of (20),
\[
V(e + M(\hat{x})) \leq V(e) - 2\gamma c(\hat{x})^T \frac{dc}{d\hat{x}}(\hat{x}) (\hat{x} - x)\]
\[
+ \gamma^2 c(\hat{x})^T P^{-1} \frac{dc}{d\hat{x}}(\hat{x}) c(\hat{x}).\]
\[
(A.2)
\]
By using the convexity properties in (17), we compute
\[
-c(\hat{x})^T \frac{dc}{d\hat{x}}(\hat{x}) (\hat{x} - x) = -\sum_{i=1}^{m} c_i(\hat{x}) \frac{dc}{d\hat{x}}(\hat{x}) (\hat{x} - x)
\]
\[
\leq -c(\hat{x})^T (c(\hat{x}) - c(x))
\]
\[
\leq -c(\hat{x})^T c(\hat{x}) \leq 0\]
\[
(A.3)
\]
where we used the fact that $c_i$ takes nonnegative values and $c(x) = 0$ for all $x \in X$ by Assumption 3. By combining (A.2), (A.3), and by using (20), we obtain
\[
V(e + M(\hat{x})) \leq V(e) - \gamma c(\hat{x})^T (2I - \gamma \frac{dc}{d\hat{x}} P^{-1} \frac{dc}{d\hat{x}} c(\hat{x}) \leq V(e) - \gamma |c(\hat{x})|^2 \leq V(e)
\]
in which we used $|P^{-1}| \leq \lambda^{-1}$. Hence (A.1a) holds. Moreover, when $x \in C_{max} \setminus \text{int}(C_{min})$, we have $|c(\hat{x})| \geq \varepsilon_{\min}$ and hence (A.1b) holds. $\square$
