23 and its genericity allowing crop rotation simulation and robustness for a wide range of
24 pedoclimatic conditions. However, there is so far for *STICS* no parameterization for faba
25 bean. We calibrated 38 crop related parameters based on literature, direct measurements and
26 sequential estimation using the optimisation tool *OptimiSTICS* and a dataset of winter faba
27 bean grown in two sites in France with contrasting soil conditions over several growing
28 seasons (2002-2015). Data from 22 experimental plots were used for calibration and the
29 remaining independent 13 plots were used for model evaluation. After calibration, the *STICS*
30 model reproduced well phenology, Leaf Area Index and dynamic growth of above ground
31 biomass, uptake of mineral N, N₂ fixation and grain yield, with satisfactory model efficiency
32 (0.56 to 0.81) and low relative bias (-7% to 2%). The model adequately reproduced the large
33 observed variation in faba bean grain yield (0.42 – 4.70 t ha⁻¹) and total N₂ fixed at harvest
34 (62 – 172 kg N ha⁻¹) in the contrasted years and soil conditions of this study. Simulations
35 indicated that water stress was the overriding factor driving yield and N₂ fixation variability.
36 Simulation of temporal crop growth and water stresses during grain onset and grain filling
37 allowed a robust and credible agronomic diagnosis of the causes of this variability for faba
38 bean crops not significantly damaged by pests and diseases. Water supply/demand ratio
39 averaged over a period of six days preceding beginning of grain filling explained 78% of the
40 observed grain yield variability while water deficit factor for N₂ fixation averaged over a
41 period of 20 days following the beginning of grain filling explained 83% of the variability of
42 fixed N₂ at harvest. Our work provides a first calibration and evaluation of the *STICS* model
43 for faba bean. It offers the opportunity to quantify the ecosystem services associated with crop
44 rotations including faba bean and the effect of climate change on the performance of such
45 rotations.

46

47 **Keywords:** *parameter estimation, yield variability, abiotic stresses, grain legume*

48 **1. Introduction**

49 Current cropping systems in Europe are characterized by high productivity but rely on
50 simplification of crop rotations and high level of synthetic inputs which has led to soil, water
51 and air pollution and loss of biodiversity (*e.g.* Stoate et al. 2009). Diversification of current
52 cropping systems with grain legumes can improve agronomic, economic and environmental
53 performance and provide supporting and regulating ecosystem services. In particular, relying
54 on biological N₂ fixation decreases the dependence on synthetic nitrogen fertilizer and reduces
55 the associated direct and indirect greenhouse gases emissions and risks of nitrate leaching
56 (Plaza-Bonilla et al., 2017; Reckling et al., 2016). However, legumes often suffer from water
57 and temperature stress: i) drought during reproductive phase can cause severe yield reduction
58 (Daryanto et al., 2017) and ii) heat can impact negatively seed set and grain filling (Prasad et
59 al., 2017). Even though not always well appreciated, N₂ fixation can also be severely
60 restricted by stresses due to drought, heat, anoxia and soil mineral N content in the root zone
61 (Liu et al., 2011). Furthermore, legumes are exposed to damages from pests, diseases and
62 weeds at different time in their growth cycle (Rubiales et al., 2015). Strong yield variability
63 and lack of reliable agronomic diagnosis are the main reasons mentioned by farmers for non-
64 adoption of legumes in cropping systems (Meynard et al., 2017; Watson et al., 2017).
65 Dynamic process based soil crop models can assist the understanding of current yield
66 variability by simulating patterns of seasonal water and temperature stress (Affholder et al.,
67 2003; Hayman et al., 2010). They are useful tools to diagnose agronomic constraints to crop
68 production and to explore the impact of current and future climate variability. Therefore, they
69 can assist the design of more resilient cropping systems by analysing model outputs.
70 Furthermore, these models allow to estimate indicators that are crucial for the assessment of
71 crop rotations but tedious or expensive to quantify in experimental plots, *e.g.* biological N₂

72 fixation (Liu et al., 2011), water drainage (Bruelle et al., 2017), N₂O emissions or nitrate
73 leaching (Plaza-Bonilla et al., 2015).

74 The *STICS* model is a generic dynamic soil-crop model that has been used to assess the
75 agronomic and environmental performances of crop rotations and to support the design of
76 innovative cropping systems in a wide range of agro-pedo-climatic conditions (Coucheney et
77 al., 2015). For example, Bécél et al. (2015) assessed the impact of various integrated weed
78 management strategies on nitrate leaching. Constantin et al. (2015) determined the optimal
79 date of emergence and destruction of cover crops to reduce nitrate leaching. Jégo et al. (2010)
80 analyzed the effect of fertilization, irrigation strategies and climate variability on nitrate
81 leaching in sugar beet/potato cropping systems. So far, spring pea (*Pisum Sativum* L.) and
82 soybean (*Glycine max* (L.) Merr.) are the only grain legume calibrated for *STICS* (Corre-
83 Hellou et al., 2009; Jégo et al., 2010). *STICS* can simulate N sharing between companion
84 crops and N carry over effects on following crops, but all the involved crops must be
85 calibrated for *STICS*. Given the potential of grain legume to improve cropping system
86 sustainability in Europe (Watson et al., 2017) and the potential of crop models to help with
87 the design of innovative and resilient cropping systems including legumes, there is a need to
88 broaden the number of grain legume crops calibrated and evaluated with the *STICS* cropping
89 system model.

90 Faba bean (*Vicia Faba* L.) is the second most widely grown European grain legumes (Watson
91 et al., 2017). Its proportion of crop N derived from atmospheric N₂ is the greatest among
92 major grain legumes cultivated in Europe (153 kg N ha⁻¹ on average) (Jensen et al. 2010). It is
93 a high-biomass crop leaving more residues and giving a greater nitrogen-related yield effect
94 on the subsequent crop compared with low biomass crop like chickpea and lentil for example
95 (Watson et al., 2017). However faba bean, like other legume crops, can suffer from strong

96 yield and N₂ fixation reduction due to abiotic factors (Bishop et al., 2016; Khan et al., 2010;
97 López-Bellido et al., 2011) and pests and diseases (Stoddard et al., 2010).

98 Winter faba bean experiments were conducted in southwestern France over several growing
99 seasons (2002-2015) with limited pest, disease and weeds pressure, This dataset provides a
100 rich basis to adapt *STICS* to faba bean and analyse the capacity of the model to unravel the
101 role of abiotic factors in driving yield and N₂ fixation variability. Our first objective was to
102 calibrate and assess the performance of *STICS* to simulate N acquisition by soil mineral
103 uptake and biological N₂ fixation, crop development and shoot biomass production, grain
104 yield formation, N content in grain and straw, and soil water and mineral N contents along the
105 whole profile during crop growth and after harvest. By doing so, we explored the hypothesis
106 that the generic model -(i.e. with the same formalism for all crops) can take into account the
107 specificities of faba bean (N₂ fixation) and can be robustly calibrated for this grain legume.
108 The second objective was to analyze the ability of *STICS* to generate a robust prediction for
109 an independent dataset and allow a credible agronomic diagnosis of yield and N₂ fixation
110 variability due to abiotic stresses. For this objective, our hypothesis was that the spatio-
111 temporal adequacy of soil/crop relationships (e.g. N nutrition based on both mineral-N uptake
112 and N₂ fixation) and the realism of the implemented process equations allow for an accurate
113 prediction of abiotic stresses.

114

115 **2. Materials and Methods**

116 **2.1. *STICS*, a soil-crop model**

117 **2.1.1. Overview of the model**

118 The soil–crop model (as well as cropping system model) *STICS* (Brisson et al., 2008, 2002,
119 1998) was chosen for its agro-environmental purpose, crop genericity (allowing the
120 simulation of crop successions with the same model) and robustness. *STICS* simulates carbon,
121 water and nitrogen dynamics in the soil–crop system on a daily time step over the crop cycle.
122 Unlike crop models that combine crop modules with different structures, *e.g.* *DSSAT*
123 (Decision Support System for Agrotechnology Transfer, Jones et al., 2003) or *APSIM* (
124 Agricultural Production Systems sIMulator, Keating et al., 2003), *STICS* uses a common and
125 generic structure for different crop species. Species-specific sets of parameters define the
126 differences between species. *STICS* has been adapted and tested for different type of crops
127 (*e.g.* winter wheat, maize, barley, sunflower, rapeseed, grassland, tomato, grapevines)
128 (Coucheney et al., 2015).

129 Inputs to the model include daily weather information (minimum and maximum temperature,
130 rainfall, wind and global radiation), soil characteristics (per-layer initial soil water and
131 mineral N content, field capacity and wilting point) and crop/soil management (date and depth
132 of planting, planting density, soil tillage, residues management, organic and mineral
133 fertilisation, irrigation).

134 Crops are defined by species parameters, ecophysiological options (*e.g.* effect of photoperiod
135 and/or cold requirements on crop phenology, potential radiation use efficiency) and cultivar
136 specific parameters (*e.g.* flowering precocity, maximum number of grains per m²). Crop
137 temperature (calculated from weather variables) and photoperiod drive crop phenology. The
138 model dynamically simulates (i) development of the root system that takes up N and water
139 according to root density over the whole soil profile and (ii) the establishment of the canopy
140 that transpires water and intercepts light to produce the crop biomass.

141 Two processes account for yield formation in the model: (i) setting of grain number per
142 square meter and (ii) accumulation of biomass in grain. The number of grains before the start
143 of grain filling is a function of: (i) the number of days before the beginning of grain filling
144 during which grain number is determined (crop parameter), (ii) the mean canopy growth rate
145 during this phase (calculated by the model), (iii) the sensitivity of grain onset to growth
146 conditions (crop parameter) and (iv) the maximum number of grain (crop parameter). Dry
147 matter accumulation in grains is calculated by applying a dynamic harvest index (grain to
148 shoot biomass ratio) to the dry weight of the plant (Amir and Sinclair, 1991). This harvest
149 index increases with time from the beginning of grain filling to physiological maturity, the
150 rate of increase being a crop parameter. A maximum final harvest index (crop parameter)
151 prevent unrealistic remobilization levels. A maximum grain yield corresponding to the
152 simulated number of grains multiplied by the maximum weight of one grain (crop parameter)
153 is computed to avoid unrealistic yield level.

154 The model also accounts for soil water and N dynamics. Net N mineralization from crop
155 residues and soil organic matter (affected by clay and CaCO_3 content in the topsoil and
156 governed by soil moisture and temperature), nitrification (affected by pH in the topsoil),
157 nitrate leaching and ammonia and nitrous oxide gaseous emissions are daily simulated as well
158 as vertical water drainage when field capacity is exceeded.

159 *STICS* also simulates N acquisition by N_2 fixation for legumes. Nodule formation is a function
160 of soil thermal time and sets the potential fixation. Actual N_2 fixation then depends on shoot
161 growth rate (C limitation for N_2 fixation), soil temperature, soil moisture, and a nitrate
162 inhibition effect linked with nitrate-N concentration in the nodulation layer (see section 2.1.2).

163 The equations governing physical and biological processes occurring in the soil/crop system
164 are based on a unique set of general parameters. Model parameters and equations describing

165 yield formation are of particular interest in this study and are described in details in Table S2.
166 An exhaustive description of inputs, equations and default parameter values of the *STICS*
167 model is given in Brisson et al. (2008). Bergez et al. (2014) give an overview of the latest
168 plant and soil process-based developments of the *STICS* model, and Coucheney et al. (2015)
169 detailed the *STICS* version 8.5 used in this study.

170 **2.1.2. Stress factors**

171 Physical and biological processes are successively addressed in two types of equations: 1) the
172 calculation of the potential flux or rate of the process; 2) the effect of the environmental
173 limiting factors, including the stress factors of the crop (light, C, N and water). Four stress
174 factors can indirectly affect grain yield through plant growth. The first is a water stress factor
175 that affects radiation use efficiency and plant transpiration, and is computed as the ratio of
176 actual evapotranspiration over potential evapotranspiration. Potential transpiration is function
177 of Leaf Area Index (LAI) and daily potential Penman evapotranspiration, as calculated by the
178 model. Actual transpiration is calculated as the minimum between water soil supply and
179 maximal crop demand. The second stress factor is a Nitrogen stress that affects 1) LAI
180 increase, 2) radiation use efficiency and 3) possibly senescence. The N stress index is
181 computed as the ratio of actual Nitrogen concentration over Critical crop N concentration.
182 Critical crop N concentration is the minimum N concentration that allow to maximise biomass
183 production (Lemaire and Gastal, 1997). Actual N uptake is calculated as the minimum
184 between soil supply and maximal crop demand. The third stress is a heat reduction factor on
185 radiation use efficiency that increases when daily average crop temperature exceeds optimal
186 crop temperature and is maximal when daily average crop temperature exceeds maximal crop
187 temperature. The fourth is a heat stress factor that stops grain yield when daily average crop
188 temperature exceeds maximal temperature for grain filling.

189 For legumes, *STICS* also calculates water, heat, anoxia and nitrogen stress factors for N₂
190 fixation. The water deficit factor for N₂ fixation is the proportion of soil layers in the
191 nodulation area (crop parameter “*profnod*”, set to 30 cm in our study) for which moisture is
192 above wilting point. The heat stress factor for N₂ fixation increases and is maximal when soil
193 temperature in nodulation zone exceeds optimal and maximal temperature thresholds.
194 Nitrogen stress for N₂ fixation increases and is maximal when the mean amount of mineral
195 nitrogen in the rooting zone (*i.e.* the upper soil layers where the bacterial symbiosis is the
196 most active) exceeds an optimal or maximal N concentration threshold. Eventually, anoxia
197 stress factor for N₂ fixation increases with the proportion of soil layers in anaerobic
198 conditions.

199 Stress factors are computed daily and vary between 0 (complete stress) and 1 (no stress).
200 Model parameters and equations used to compute water stress factor and water deficit factor
201 for N₂ fixation are of particular interest in this study and are described in details in Table S2.
202 The exhaustive description of the equations and parameters governing the stresses definition
203 can be found in Brisson et al. (2008).

204 **2.2. Experimental data**

205 **2.2.1. Sites and experimental design**

206 The experimental data was collected in south of France at the experimental sites of INRA in
207 Auzeville (43°31’N 1°28’E), and of CREAB-MP in Auch (43°38’N 0°36’E) during seven
208 growing seasons in each site. In both sites, the climate is oceanic temperate under
209 mediterranean influence and characterized by summer droughts and cool wet winters.
210 Cumulative global radiation, growing degree-days and rainfall during crop growth
211 (November-July), averaged across growing seasons, were similar in Auch and Auzeville
212 (Table 1). Experimental plots were in the valley on deep (*i.e.* average maximum rooting depth

213 of 135 cm) clay-loamy soils in Auzeville and on the hillside on shallow (*i.e.* average
214 maximum rooting depth of 70 cm) clay loamy soils in Auch. As a result, average maximum
215 available water to maximum rooting depth (*i.e.* soil water content at field capacity minus soil
216 water content at wilting point) was higher in Auzeville (167 mm) than in Auch (64 mm)
217 (Table 1).

218 **Cropping systems strongly differed between experimental sites.** In Auzeville, the data
219 originated from two distinct types of experiments. The first type was annual experiments with
220 replicated plots (1.62 m wide x 13m long) of sole faba bean (see Bedoussac and Justes (2010)
221 and Kammoun (2014) for a detailed description of experimental design). The second type was
222 a long-term cropping system experiment established in 2003 on 200 x 30 m plots with
223 different three-years rotations varying in the frequency of grain legumes and the use or not of
224 cover crops (Plaza-Bonilla et al., 2017). Appropriate herbicide and pesticides were applied to
225 control weeds, pests and diseases and no N fertilizer was applied on legumes. In Auch, the
226 data originated from an organic long-term soil fertility monitoring experiment (2002-2013)
227 with 50 x 50 m plots with Faba bean – Oat or wheat – Sunflower rotations (Colomb et al.,
228 2013). Auch was managed without mineral fertiliser, herbicides and pesticides. As a result,
229 only the plots where the monitoring revealed negligible pests, disease and weed pressure were
230 considered. In both sites, the land was plowed prior to sowing and only in 2007 in Auzeville
231 small amounts of irrigation water (20-50mm) was applied after sowing (Table 2) to ensure
232 satisfactory crop establishment.

233 The considered faba bean cultivars were Castel and Irena (Table 2). These winter-type
234 cultivars sown between November and January have similar phenology and yield potential
235 (Flores et al., 2012). Site, year, and management factors (cultivar, crop density, incorporation
236 of a cover crop before planting and sowing date) defined 35 Site-Year-Management units
237 (Table 2). Site-year-management units covering a broad range of soil types, growing seasons

238 and management situations (He et al., 2017) were chosen for the calibration dataset (Table 2).
239 The remaining units, differing in growing season and/or management (compared with
240 calibration dataset) formed the evaluation dataset (Table 2).

241 **2.2.2. Measurements**

242 Faba bean development stages were recorded in the annual experiments in Auzeville
243 following BBCH scale (Meier, 2001), namely (i) BBCH 09: 50% of shoot have emerged
244 through soil surface (ii) BBCH 70: first pods have reached final length (corresponding to
245 “drp” stage in *STICS*, *i.e.* the beginning of grain filling). Additionally, interpolation of
246 discontinuous LAI observations allowed for determining the date of the end of juvenile phase
247 (*amf* stage in *STICS*, corresponding to maximum growth rate of LAI). The interpolation was
248 carried out with the tool integrated in *STICS* that uses an functional equation to differentiate
249 LAI growth (logistic equation) and senescence (exponential equation), the difference between
250 the two functions giving the green LAI (see Casa et al., 2012, for detailed equations and
251 procedure).

252 In each experimental field, soil texture and pH were measured over the whole soil profile (0-
253 120 cm). Soil mineral N and water content were measured by layers of 30 cm three times per
254 year: (1) end of autumn prior to sowing, (2) mid-winter and (3) at harvest. Crop variables
255 such as LAI, above-ground biomass, fixed N₂ and total accumulated N, grain yield and grain
256 N content were measured from 1 to 5 times depending on site, year and experiment (Table 2):
257 (1) in mid-March *i.e.* wheat ‘1cm ear’ stage, (2) in mid-April, *i.e.* legume flowering, (3) in
258 mid-may *i.e.* wheat flowering, (4) in early June *i.e.* wheat ripening, and (5) in early July, *i.e.*
259 legume maturity. At each measurement, six central rows 0.5 m long (annual experiments in
260 Auzeville), six m² (long term cropping system experiment in Auzeville) and nine subplots of
261 two rows 1 m long (in Auch) were harvested by cutting plants at the soil surface. In the annual

262 experiments in Auzeville, a LI-3100 planimeter (LI-COR, Lincoln, NE) was used to
263 determine green leaf area. In all experiments, plant biomass samples were dried at 80°C for
264 48 h and weighted. At maturity, plants were threshed to determine grain yield and harvest
265 index. Above-ground plant and grain N concentration were determined on finely ground plant
266 material with the Dumas combustion method using a Leco-2000 analyzer (LECO, St. Joseph,
267 MI, US). In Auzeville, N₂ fixation ratio, *i.e.* the proportion of plant N derived from
268 atmosphere (%Ndfa) was determined using the ¹⁵N natural abundance method (Unkovich,
269 2008) with unfertilized wheat and non-legume weeds as reference plants in the annual and
270 long-term experiments respectively. %Ndfa was calculated as follows:

$$271 \quad \%Ndfa = 100 \times \frac{\delta^{15}N_{ref} - \delta^{15}N_{fababean}}{\delta^{15}N_{ref} - \beta} \quad (1)$$

272 where $\delta^{15}N$ is the deviation from the international standard of atmospheric N₂ (0.3663% ¹⁵N)
273 for faba bean ($\delta^{15}N_{fababean}$) and for the reference crop ($\delta^{15}N_{ref}$), and β is the $\delta^{15}N$ of shoots of
274 faba bean fully dependent upon N₂ fixation, assumed equal to -0.63 ‰ (Unkovich, 2008).
275 The amount of N₂ fixed was calculated as the product of %Ndfa and total above-ground plant
276 N.

277 Moreover, dynamics of maximum rooting depth of faba bean was monitored in 2013 during
278 the annual experiment in Auzeville (Table 2) using a rotary scanner-based minirhizotron
279 system (CI-600, CID Bio-science, Camas, WA, USA) six times during crop growth (16 and
280 28 March, 12 April, 6 May, 3 June, 17 July).

281 **2.3. Calibration procedure**

282 The calibration consisted in choosing the formalisms and corresponding parameters involved
283 in the simulation of crop phenology, leaf area and root system expansion, biomass
284 accumulation, biological nitrogen fixation, nitrogen uptake and grain yield elaboration.

285 The parameterization procedure included three steps (Figure 1). The first step was a literature
 286 review to select the options offered by the model to simulate the different crop processes and
 287 determine existing parameter values s . The second step corresponded to the determination of
 288 parameters from experimental data by direct measurement or observation (phenology). The
 289 last step consisted in a mathematical optimisation based on the approach developed by
 290 Guillaume et al. (2011), including nine stages representing the different key processes in the
 291 simulation of the final outputs of the model (Table 3). For each stage, sensitivity analysis
 292 (Ruget et al., 2002) and expert knowledge were used to select the parameters having the
 293 strongest impact on model outputs. In total, 29 crop parameters were mathematically
 294 optimised (Table 3). Stage-specific target variables were selected: (i) dates of key
 295 development stages (emergence, end of juvenile phase, beginning of grain filling and
 296 physiological maturity), (ii) dynamic variables (Leaf Area Index, above-ground biomass,
 297 fixed N and total plant N, overall soil moisture content and overall soil N content) and (iii)
 298 variables at crop maturity (yield components, grain yield and grain N content) (Table 3). The
 299 calibration stages were carried out by using the software package *OptimiSTICS* (Wallach et
 300 al., 2011) and the methodology detailed by Buis et al. (2011). Model error was computed as
 301 the difference between measured and simulated values for a given target variable at a given
 302 date. The goodness of fit C_v was obtained following the formula:

$$303 \quad C_v = \sum_s \frac{1}{n_s} \sum_i [O_{s,i} - P_{s,i}(\theta)]^2 \quad (2)$$

304

305

306 Where v is the target variable, s is the site-year-management unit and n_s is the number of
 307 measurements in s , $O_{s,i}$ is the measured value in site-year-management s on the i th date and
 308 $P_{s,i}(\theta)$ is the corresponding simulated value with the parameter set θ .

309 This average squared error for a given target variable was minimised using a simplex
310 algorithm. For each optimised parameter, , lower and upper limits corresponding to
311 reasonable physiological values were fixed based on literature and expert knowledge (Table
312 3). The optimised parameter values at a given stage were the default values of the next steps.
313 The initial plant parameters before optimisation were taken from the spring pea plant file
314 (Corre-Hellou et al., 2009). Given the similarities in crop functioning and yield potential
315 observed in our experiments between the two studied faba bean cultivars (Irena and Castel),
316 we did not calibrate specific cultivar parameters.

317 Soil analysis informed the input parameters required for soil in *STICS*. Moisture at field
318 capacity and wilting point were first obtained using pedo-transfer functions (Saxton and
319 Rawls, 2006) and also based on laboratory measurements on sieved soil for field capacity, and
320 then adjusted by trial and error to minimize the error between simulated and observed soil
321 water content in mid-winter. The recorded crop managements (Table 2) were used to create
322 management files used for each simulation. Initial soil mineral nitrogen (nitrate ammonium)
323 and water content were measured for each experiment and set between 13 and 120 kg N ha⁻¹
324 and 162 and 342 mm respectively, depending on the different Site-year-management units
325 (Table 2).

326

327

328 **2.4. Model evaluation**

329 Model performance (with optimised parameter set) was evaluated graphically and quantified
330 by calculating Mean Bias Error (MBE) and its relative value (rMBE), Model Efficiency (EF),
331 Root Mean Square Error (RMSE) and its relative value (rRMSE):

$$332 \quad MBE = \frac{1}{n} \sum_{i=1}^n (P_i - O_i) \quad (3)$$

$$333 \quad rMBE = \frac{MBE}{\bar{O}} \times 100 \quad (4)$$

$$334 \quad EF = 1 - \frac{\sum_{i=1}^n (O_i - P_i)^2}{\sum_{i=1}^n (O_i - \bar{O})^2} \quad (5)$$

$$335 \quad RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (O_i - P_i)^2} \quad (6)$$

$$336 \quad rRMSE = \frac{RMSE}{\bar{O}} \times 100 \quad (7)$$

337 where O_i and P_i are the observed and simulated values for the i^{th} measurement, n is the number
 338 of observations and \bar{O} is the mean of the observed values.

339 MBE and rMBE indicate whether the model under/overestimate a given variable, and gives
 340 the absolute and relative magnitude and direction of the bias. EF is based on the comparison
 341 of the simulation model with a constant model (*i.e.* the average of measured data) and ranges
 342 between $-\infty$ and one. Negative EF values indicate that the constant model performs better than
 343 or as well as the simulation model. A value of one indicate a perfect model. EF is a good
 344 indicator to compare model simulations with two different sets of parameters (*e.g.* before/after
 345 calibration) against the same dataset. It is however of little value to compare two simulations
 346 with the same set of parameters against two different datasets, because it depends on the
 347 variance of the observed dataset. RMSE and rRMSE are the model absolute and relative
 348 prediction error. The combined analysis of these four indicators give a robust assessment of
 349 model accuracy. Similarly to Beaudoin et al. (2008) and Constantin et al. (2015), model
 350 predictions were judged satisfactory when EF value were greater than 0.5 and rMBE lower
 351 than 10%. A summary of the calibration and evaluation procedure can be found in Figure 1.

352 **2.5. Stress factors and variability in grain yield and total N_2 fixed**

353 Stress factors calculated by *STICS* (see section 2.1.2 and Table S2) were averaged over
 354 periods ranging from -60 to + 60 days before/after the beginning of grain filling. For each

355 period, the Pearson correlation coefficient (R^2) between observed grain yield (total fixed N_2
356 respectively) and stress factor affecting grain yield (N_2 fixation respectively) over the period
357 was computed. The period corresponding to the maximum R^2 was determined. For this
358 analysis, calibration and evaluation datasets were pooled.

359

360 **3. Results**

361 **3.1. Parameter values obtained from literature, experimental data and optimisation**

362 Eight parameters values were obtained from literature (Table 4). Faba bean shows a long day
363 response to photoperiod (Ellis et al., 1988) and needs vernalisation (Patrick and Stoddard,
364 2010) so we activated these physiological options in the faba bean plant file. Faba bean base
365 temperature for crop development (*t_{dmin}*) was set to 0°C (Tribouillois et al., 2016). Because
366 there was no available data in the literature, base and optimal temperature for photosynthesis
367 (*t_{emin}* and *t_{eo_{pt}}*) were approximated from those for emergence rate (Tribouillois et al., 2016)
368 (Table 4), based on the assumption that cardinal temperatures for developmental processes are
369 close for a given species (*e.g.* Parent and Tardieu, 2012). Cardinal temperatures for nodulation
370 (*temp_{nod1}*, *temp_{nod2}*, *temp_{nod3}*, *temp_{nod4}*) were obtained from Boote et al. (2002) (Table
371 4).

372 Four parameters values were obtained using direct in-field measurement (Table 4). Maximum
373 and minimum number of grain per square meter (*nbgr_{max}* and *nbgr_{min}*), maximum grain
374 weight (*pgrain_{maxi}*) and maximum harvest index (*ir_{max}*) were set to the maximum or
375 minimum measured values in the experiments in Auzeville and Auch with an added or
376 subtracted 10% respectively to reach assumed potential values (Table 4 and Figure 2).

377 The other 30 parameters values were set according to the result of the sequential optimisation
378 with *OptimiSTICS* using measured variables (Table 4).

379 **3.2. Agreement between simulated and observed values**

380 **3.2.1. Crop development and LAI**

381 Calibration led to satisfactory prediction of the dates of emergence, end of juvenile phase,
382 beginning of grain filling and physiological maturity. Relative bias was low (0 – 10%) with
383 fair EF values (Figure 3), indicating the relevance of calculating crop development based on
384 vernalisation and photoperiodic and thermal time-course formalisms. Simulated LAI values
385 for the calibration dataset were close to observed values with a low relative bias of 1% and a
386 satisfactory EF of 0.69. Prediction error was however great due to a bias of a few days in the
387 senescence dynamic that had large consequences on the daily agreement between observed
388 and simulated LAI values (rRMSE=56%) (Figure 4a).

389 **3.2.2. Above ground biomass, N₂ fixation and N acquisition**

390 Predicted biomass agreed with observation throughout the growth seasons in both calibration
391 and validation datasets (EF>0.77 and -7% < bias < 0%). Prediction error was high due to
392 senescence defoliation between grain physiological maturity and harvest that was difficult to
393 precisely simulate (rRMSE of 41 and 31% for calibration and evaluation respectively). There
394 was a large variation in faba bean biomass at harvest (1.5 - 11.6 t ha⁻¹ and 2.8 - 7.2 t ha⁻¹ for
395 calibration and evaluation datasets respectively) depending on site, year and management
396 (Figure 4c, d) and the model was able to reproduce this behaviour.

397 The calibration of parameters related to N₂ fixation (Table 3 and Table 4) allowed to reach a
398 good agreement of simulated versus observed values throughout crop growth (Figure 4e,f)
399 (EF = 0.77 with negligible bias). EF remained high and bias remained low in the evaluation
400 indicating that the model was able to reproduce the wide range of final N₂ fixed at harvest
401 (62-166 kg N ha⁻¹, Figure 4f). N acquired (N content in crop aerial parts) was adequately

402 simulated with low bias both in calibration and evaluation (-7 and 2% respectively) and EF
403 values above 0.5 (Figure 4g, h).

404 **3.2.3. Grain yield and grain N content**

405 Observed grain yield greatly varied depending on site-year-management ($0.42 - 4.7 \text{ t ha}^{-1}$,
406 Figure 5a). The model performed well in simulating grain yield (EF=0.66 with low relative
407 bias) for calibration dataset. Model performance remained satisfactory during evaluation, with
408 an EF value of 0.65 and a relative bias of -1% (Figure 5b).

409 Simulated grain N content was slightly underestimated (relative bias of -10%) in the
410 calibration dataset with a satisfactory EF value of 0.60 (Figure 5c). In the evaluation, grain N
411 content was predicted with a low relative bias (3%). The EF was low (0.27) but the range of
412 observed values for evaluation ($65\text{-}162 \text{ kg N ha}^{-1}$) was narrower than for calibration ($21\text{-}200$
413 kg N ha^{-1}).

414 **3.2.4. Soil water and soil mineral N contents**

415 Soil water content over the entire profile was correctly simulated by the model, both during
416 calibration and evaluation (EF>0.70 with small relative bias) (Figure 5e, f). Soil N content
417 was less adequately predicted, with small (0.22) and negative (-1.42) EF values, in calibration
418 and evaluation respectively (Figure 5g, h). Bias was low in the evaluation (-10%), indicating
419 that though the model was not able to reproduce precisely the differences between site, year
420 and management, it predicted soil mineral N content within the range of the rather low
421 observed values.

422 **3.3. Impact of temporal dynamics of stress factors**

423 With regard to grain yield, the water stress factor (*i.e.* water supply/demand ratio, see section
424 2.1.2 and Table S2) had the strongest explanatory power. Indeed, when averaged over a

425 period of 6 days before the beginning of grain filling (i.e. the end of grain onset), it explained
426 78% of the observed grain yield variability in the overall dataset (Figure 6a). The model fairly
427 reproduced the temporal dynamic of above ground biomass (Figure 7d, e, f). Water stress
428 during the end of grain onset (Figure 7a, b, c) affected the growth rate of above ground
429 biomass (Figure 7d, e, f), which in turn influenced the final number of grains (Figure 7g, h, i).
430 In the end, the model was able to simulate contrasting water stresses that occurred in different
431 soil types (valley/hillside) for a range of climatic conditions and their final impact on the
432 number of grain and grain yield (Figure 7). Heat stress effect on radiation use efficiency,
433 conversely, had a limited explanatory power in our conditions. Indeed, when averaged over a
434 period of 26 days after the beginning of grain filling (the period with the best correlation),
435 heat stress explained only 25% of the observed grain yield variability. The model diagnosed
436 no heat stress on grain filling in the majority of the site-year-management units. There were
437 only five days in 2002 in Auch during which crop temperature exceeded the maximal
438 temperature above which grain filling stops (Figure S1).

439 With regard to N₂ fixation, the water deficit factor had also the strongest explanatory power.
440 Thus, when averaged over a period of 20 days after the beginning of grain filling, it explained
441 82% of the observed variability in total fixed N₂ at harvest (Figure 6b). Despite a limited
442 number of within-season measurements in some situations (Figure 8d), the model reproduced
443 reasonably well the temporal dynamic of N₂ fixation (Figure 8c, d). In the end, the model was
444 able to reproduce the wide range of total fixed N₂ at harvest (62-172 kg ha⁻¹, see Figure 6).
445 The model diagnosed no stress due to anoxia in any of the cropping situations of this study.
446 Though the model diagnosed limited heat and nitrogen stresses in some situations (value of
447 0.67 and 0.58 respectively) the correlation with the amount of N₂ fixed was not significant for
448 any of the periods considered.

449 **4. Discussion**

450 **4.1. A method to adapt a generic crop model to a new crop**

451 While the process of calibrating a new cultivar is well described (*e.g.* (Jégo et al., 2010), less
452 emphasis has been put on the description of the adaptation of a generic soil-crop model to a
453 new crop. Previous studies [mainly described a partial calibration based on a limited set of](#)
454 [target variables, e.g. LAI or AGB and Soil water](#) (Confalonieri and Bechini, 2004; Ko et al.,
455 2009), and did not address the broad range of processes available in the model (*e.g.* [root](#)
456 [system expansion, Nitrogen uptake, yield formation](#)). Our study shows that the generic *STICS*
457 soil-crop model can be successfully adapted to a new crop, and in particular a grain legume
458 having the specificity of N₂ fixation. The adaptation was based on two steps, namely: (i) a
459 parameter estimation based on measurement and literature and (ii) a sound and careful
460 sequential optimisation of crop parameters that were not measured nor estimated using
461 existing literature. Therefore, our work contributes to establish a generic method to calibrate a
462 new annual crop for soil-crop models that (i) have a common structure for different crop
463 species, (ii) are functional deterministic models considering water, C and N cycles, on a daily
464 time step (Di Paola et al., 2016) and (iii) have an available parameter optimisation tool.

465 Estimating a parameter from direct measurements and literature has the advantage of not
466 being based on the assumption that model formalism and all other parameters are reliable, as
467 it is the case with mathematical optimisation (Grant, 2001). It should be therefore prioritised
468 and in our approach we had 9 parameters estimated in this way (Table 4). However, this
469 procedure is not always possible for many reasons. Firstly, field measurements of parameters
470 is expensive and time consuming (Anothai et al., 2008). Secondly, the dataset used for model
471 calibration may not be originally intended to cover model calibration issues (as it was the case
472 in our study), so that most of crop model parameters are not directly measured (*e.g.* radiation
473 use efficiency). Thirdly, the need for similar environmental conditions, varieties and exact
474 correspondence of the measured variable to the process represented by the model limit the

475 number of parameters that can be derived from a literature review. For example, the radiation
476 use efficiency parameters in *STICS* (*efcroijuv*, *efcroiveg* and *efcroirepro*, see Table 3)
477 correspond to potential conditions with no stress, and the presence or absence of stress is not
478 necessarily mentioned in the literature. Finally, there is a risk of error accumulation when
479 extensively relying on approximate or conflicting literature values (Wallach et al., 2011). For
480 all these reasons, recourse to optimisation is advisable. The strength of our approach lies in
481 the rational stepwise optimisation procedure chosen. Rather than an empirical trial and error
482 procedure (Flénet et al., 2004; Hartkamp et al., 2002), we chose a sequential optimisation
483 procedure that is fully documented and is easily replicable for other crops and cultivars with
484 the *STICS* model. =Breaking down the optimisation into several stages and using it at the
485 module-scale rather than the scale of the entire model allow to avoid unrealistic simulations
486 where errors in parameter values would offset each other (Bechini et al., 2006; Grant, 2001).
487 Taking into account within-season dynamic measurements to successively calibrate the
488 different model components allows to estimate few parameters simultaneously and therefore
489 to reduce numerical problems (Guillaume et al., 2011; Wallach et al., 2011). The lower and
490 upper boundaries fixed for each parameter during the optimisation ensures that the obtained
491 values correspond to reasonable physiological values thus limiting compensations due to
492 model structure weaknesses. The different optimisation stages and their order following crop
493 development (*i.e.* phenology, LAI, biomass production and then partitioning) ensure that the
494 parameterisation is relevant according to plant functioning. The order chosen is consistent
495 with previously published calibrations using *STICS* (Corre-Hellou et al., 2009; Flénet et al.,
496 2004) and *DSSAT* (Hartkamp et al., 2002). Finally this method led to a satisfactory match of
497 observed and simulated values, with ranges for statistical indicators (EF, rMBE and rRMSE)
498 consistent with those obtained for the adaption of *STICS* to wheat and maize (Brisson et al.,
499 2002), linseed (Flénet et al., 2004) and spring pea (Corre-Hellou et al., 2009). This approach

500 can be valuable to calibrate new annual crops and other grain legumes (*e.g.* winter pea, lentil
501 and chick pea) for the *STICS* model, and probably other generic soil-crop models that have a
502 common structure for all species, *e.g.* *CROPSYST* model (Stöckle et al., 2003).

503 **4.2. A robust and credible agronomic diagnosis**

504 Agronomic diagnosis is crucial for the identification of constraints affecting crop growth and
505 to help the identification of sound agronomic management. The diagnosis needs to be robust,
506 *i.e.* reliable under different sets of experimental conditions (Sinclair and Seligman, 2000), and
507 credible, *i.e.* offering trustworthy causal explanations (Cash et al., 2002). Robustness can be
508 ensured by an explicit reference to physical processes in the construction of mathematical
509 relationships so that the model accurately captures the underlying processes driving the
510 system (Bellocchi et al., 2010). Lack of robustness can lead to a model being “right for the
511 wrong reasons” (Bellocchi et al., 2010). In this section, we want to highlight that we averted
512 these pitfalls, ensuring that our diagnosis was robust and credible.

513 Our study adds to the body of literature showing that in a temperate climate with rain fed
514 conditions and appropriate control of pest pressure, drought is the prevailing stress and the
515 main driver of yield variability (Karrou and Oweis, 2012; Mafakheri et al., 2010). The
516 explanations we found to explain yield variability (water stress during grain onset) and N₂
517 fixation variability (water deficit factor during grain filling) are supported by principles of
518 crop physiology derived from experiments and knowledge on response of legume grain yield
519 and N₂ fixation to water stress. With regard to grain yield, water deficit during grain onset
520 reduces grain legume biomass accumulation (decrease of photosynthesis and reduction of leaf
521 area) and assimilate availability that in turn reduce final seed number (Guilioni et al., 2003;
522 Jiang and Egli, 1995; Lake and Sadras, 2016). With regard to N₂ fixation, water stress directly
523 reduce faba bean nodules activity (Sprent, 1972) and sensitivity of N₂ fixation to drought is
524 often maximum during grain filling (Chalk et al., 2010; Mastrodomenico et al., 2013). These

525 two stress responses are implemented in *STICS*. Firstly, final seed number depends on plant
526 growth rate during the grain onset period (see section 2.1.1 and Table S2). . Thus, the
527 magnitude of water stress during grain set and its impact on plant growth rate determines the
528 extent to which the plant can reach the maximum grain number (*nbgrmax*, see Table and
529 Figure 2). Secondly, in the model, water deficit reduces the potential N₂ fixation, *i.e.*
530 nodulation and nitrogen fixation are partially or totally inhibited according to nitrate
531 concentration in the topsoil and when soil moisture in the topsoil drops below permanent
532 wilting point (see section 2.1.2 and Table S2). This careful check of the behaviour of different
533 model functional modules (Figure 7, Figure 8) strongly suggests that the *STICS* model
534 accurately captured the underlying processes driving grain yield formation, N₂ fixation and
535 water stress. We can therefore be confident in the diagnosis drawn from our site-year-
536 management units with regard to water stress. Thus, the generic *STICS* processes describing
537 yield formation and water stress, when calibrated for faba bean with the proper options
538 activated, have proven useful in explaining variability in yield for this particular legume crop,
539 without the need to build new processes into the generic model.

540 The good fit obtained with the evaluation dataset indicates that the current set of parameters
541 could be reliably used in other situations different from the ones in the calibration. This
542 however needs to be confirmed with other studies, *e.g.* for situations where soil mineral N
543 levels would be higher than in our study (on average 47 kg ha⁻¹ at sowing over the whole
544 profile), which could affect N₂ fixation. We verified by virtual experiment - corresponding to
545 a local sensitivity analysis - that *STICS* was able to simulate a strong reduction in N₂ fixation
546 when soil nitrate content was higher in the upper layers.

547 Eventually, by considering both a water deficit factor for N₂ fixation and a water
548 supply/demand ratio (acting on crop biomass), the model allowed unravelling interesting
549 situations where similar faba bean biomass masked differences in the amounts of fixed N₂.For

550 example, crop biomass and water/supply demand ratio were similarly low in Auzeville in
551 2011 (3 t ha⁻¹) and 2015 (4.1 t ha⁻¹) due to similar water stress on biomass (water supply-
552 demand ratio = 0.3). However, the amount of N₂ fixed was doubled (88 kg ha⁻¹) in 2015
553 compared with 2011 (46 kg ha⁻¹). The model indicated a stronger water deficit for N₂ fixation
554 in 2011 (water deficit factor = 0.12) compared with 2015 (water deficit factor = 0.32). This
555 understanding of nonlinearities is crucial for the assessment of innovative cropping system.
556 Pests and diseases can also reduce faba bean grain yield. Coupling *STICS* with an
557 epidemiological model (Donatelli et al., 2017) would be relevant to refine the diagnosis in
558 situations where damages on leaves (*e.g.* rust, *Uromyces viciae-fabae*, or chocolate spot,
559 *Botrytis fabae*) and nodules (*e.g.* sitonia beetles, *Sitonia lineatus*) can occur.

560

561 **4.3. New opportunities to design and assess resilient cropping systems**

562 Though the effects of climate change on cereals in Europe have deserved a great attention
563 (*e.g.* Bregaglio et al., 2017; Dettori et al., 2017), studies on effects of climate change on
564 legume productivity remain scarce. Climate change projections for the temperate and
565 mediterranean regions of Europe point to a decrease in precipitations during spring and
566 summer (Gao and Giorgi, 2008; Giannakopoulos et al., 2009). Water stress will therefore
567 become even more acute with future climate. Our model calibration offers a good opportunity
568 to assess the impact of increased drought-induced stress on faba bean productivity and
569 therefore the potential contribution of legume to sustainable cropping systems in the future.

570 Dynamic models have often been criticised for putting too much emphasis on single crop
571 assessment on a year-to-year basis (Reckling et al., 2016). Taking into account pre-crop and
572 rotational effects (*e.g.* nutrient carry-over and alteration of soil water content) will be crucial
573 to accurately assess the contribution of faba bean and grain legumes in building more
574 diversified and resilient cropping systems. Our robust crop calibration and *STICS* ability to

575 simulate residues mineralisation (Justes et al., 2009), nitrate leaching and water drainage
576 (Plaza-Bonilla et al., 2015), would allow deriving probabilities to achieve a certain level of
577 yield and N provision to the subsequent crop when inserting legumes in cropping systems.

578 *STICS* can also simulate intercropping (Brisson et al., 2008). Cereal-legume intercropping
579 (e.g. wheat and faba bean) is a promising integration of legumes in cropping systems in
580 particular in low input cropping systems (Bedoussac et al., 2015). Many processes (e.g. soil N
581 and water sharing) are simulated similarly in sole crop and intercrops (Corre-Hellou et al.,
582 2009), our calibration would therefore allow exploring intercropping performance for a
583 diversity of soils and rainfall patterns. Nevertheless, some formalisms specific to intercrops
584 (e.g. the competition for light) and the corresponding parameters may deserve potential re-
585 calibration before the set of parameters proposed here for sole crops can be used.

586

587 **Conclusion**

588 Based on literature and cropping experiments in two contrasting sites of southwestern France,
589 we successfully adapted the *STICS* soil-crop model to faba bean. [We developed and validated](#)
590 [a method smartly combining the mobilization of literature references, direct field](#)
591 [measurements and a transparent and sequential optimisation procedure to derive crop](#)
592 [parameters](#) . The obtained set of parameters allowed a satisfactory prediction of plant growth,
593 N₂ fixation, mineral N uptake, grain yield and grain N content. Careful assessment of dynamic
594 variables (plant growth, grain number, N₂ fixation) and the associated stress factors allowed to
595 carry-out a credible and robust diagnosis of grain yield and N₂ fixation variability in the sites
596 of this study. The proposed set of parameter could then be used for (i) [\(i\) yield gap analysis in](#)
597 [organic fields affected by biotic as well as abiotic stress](#), (ii) exploration studies on the effect
598 of climate change and more frequent droughts on faba bean, and (iii) the effect of its insertion
599 in crop rotations (as sole crop or intercrop) on N provision to the subsequent crop. Calibration

600 of other grain legumes like chickpea and lentils using the proposed methodology will broaden
601 the capacity of the *STICS* model to simulate innovative cropping systems including grain
602 legumes.

603 **Acknowledgments:**

604 This research was supported by the European Commission (REA) through the LEGATO
605 project (FP7-613551) and the French National Research Agency (ANR) through the
606 LEGITIMES French project (ANR-13-AGRO-0004), the 7th PIREN-Seine program and the
607 Climate-CAFE European project (selected by the European FACCE-JPI ERA-NET Plus
608 program).

609 We thank the Centre Régional de Recherche et d'Expérimentation en Agriculture Biologique
610 de Midi-Pyrénées (CREAB-MP) in Auch, France, for making available their faba bean
611 dataset. We are grateful to Loïc Prieur, Didier Rafaillac, Michel Labarrère and several
612 trainees who assisted in data collection and Didier Chesneau and Eric Lecloux who performed
613 the extraction and the analysis of soil mineral N. We thank Patrice Lecharpentier for his help
614 with the *Optimistics* software.

21 Figure 2: Boxplots of number of grain per square meter (a), weigh of one grain (b) and
 22 harvest index (c) in the 35 site-year-management units of the study. The horizontal line in the
 23 box indicates the median. The height of the box represents the interquartile range. The
 24 whiskers extend to the maximum values. The horizontal dotted line correspond to the
 25 maximum measured values with an added 10% to define potential maximum values in the
 26 *STICS* model.

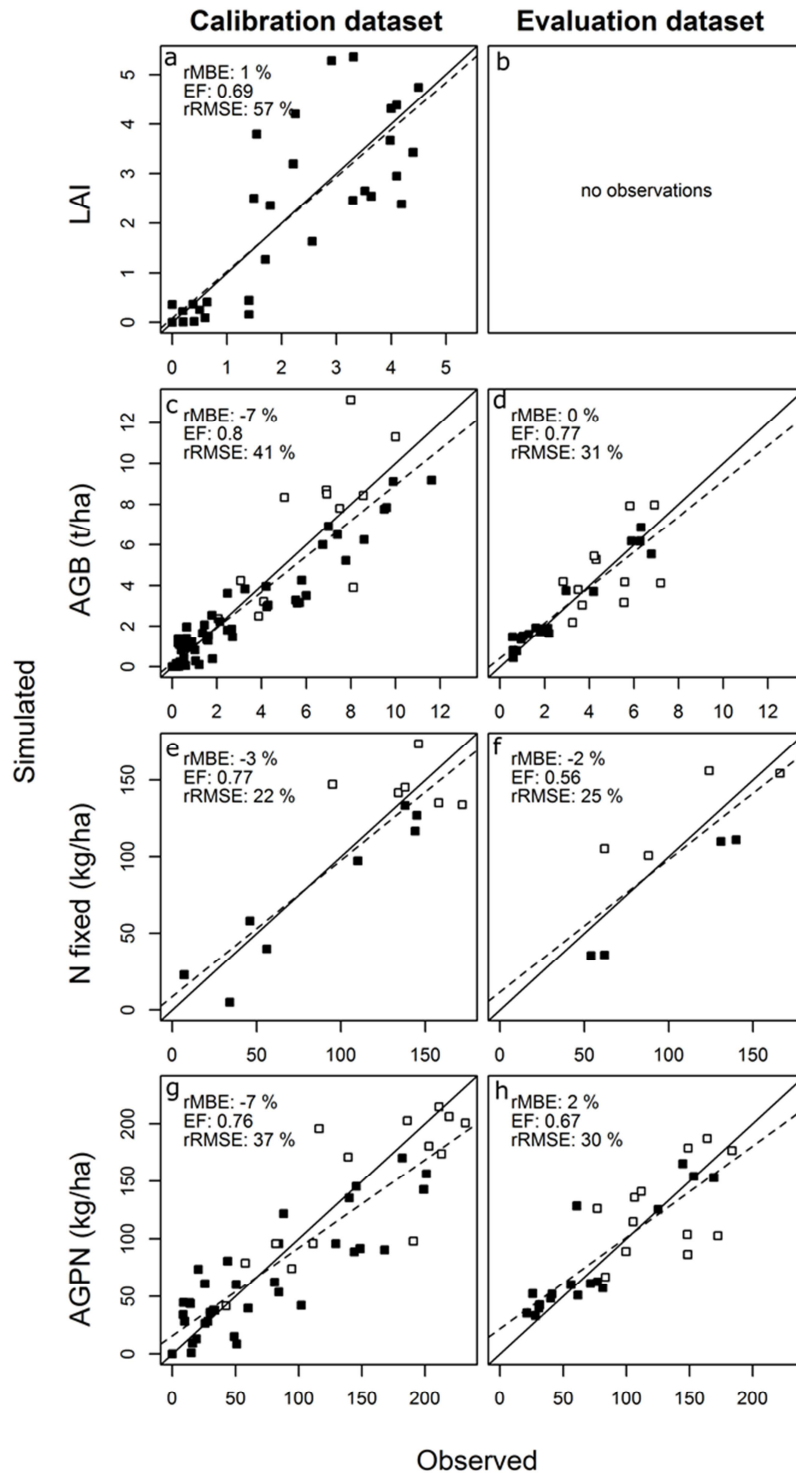

27

28

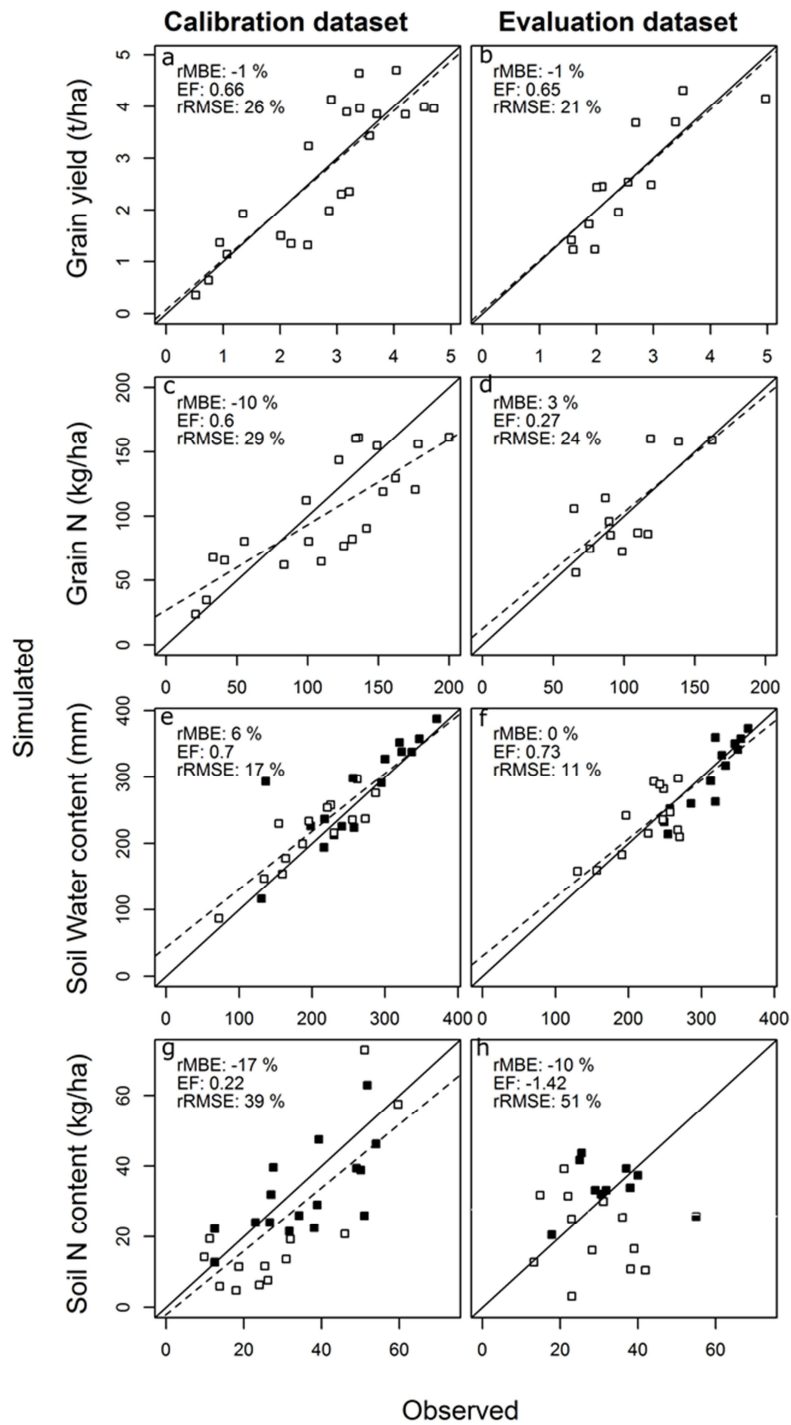

29 Figure 3: Comparison of observed and simulated (*STICS* model) faba bean phenology.

30

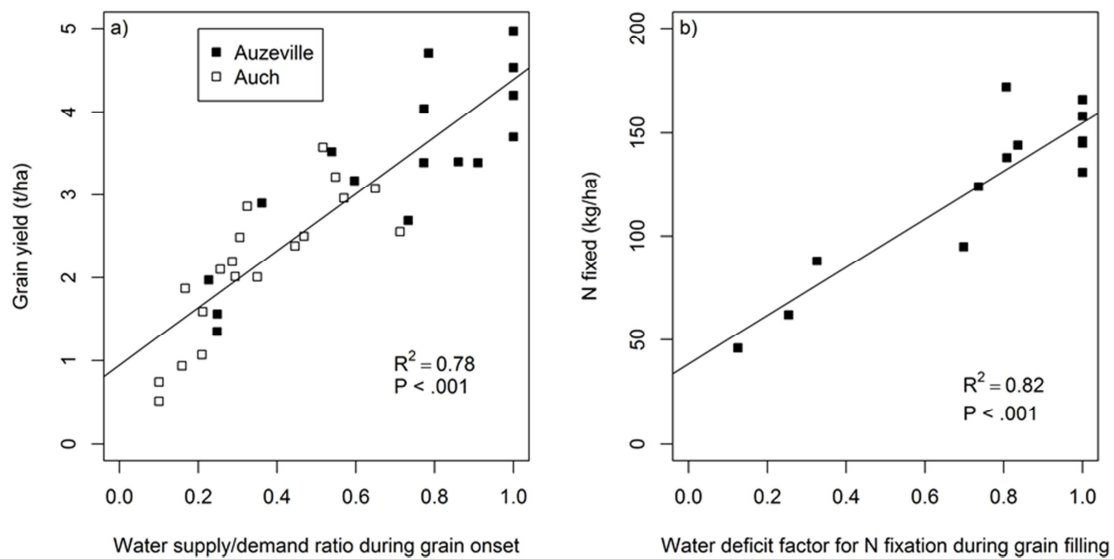

31

32 Figure 4: Comparison of observed and *STICS* simulated LAI, Above ground biomass (AGB),
 33 N₂ fixed, and Above ground plant N (AGPN) for calibration and evaluation dataset. rMBE =
 34 relative mean bias error, EF= model efficiency, rRMSE = relative Root Mean Square Error.
 35 The black line is the 1:1 line. The dotted line represent the regression of simulated against
 36 observed values. White symbols correspond to the end of growing season.

37

38 Figure 5: Comparison of observed and *STICS* simulated grain yield, grain N, soil water
 39 content, and soil mineral N content for calibration and evaluation dataset. rMBE = relative
 40 mean bias error, EF= model efficiency, rRMSE = relative Root Mean Square Error. The black
 41 line is the 1:1 line. The dotted line represent the regression of simulated against observed
 42 values (plotted when significant at 5% risk level). White symbols correspond to the end of
 43 growing season.

45

46 Figure 6: Correlation (a) between grain yield and average water supply/demand ratio during
 47 grain onset (over the six days before beginning of grain filling) and (b) total N₂ fixed at
 48 harvest and average water deficit factor for N₂ fixation during grain filling (over the first 20
 49 days after beginning of grain filling). Calibration and evaluation datasets were pooled
 50 together.
