Introduction

Injuries are one of the biggest determinants of performance in professional soccer. Injury prediction is best suited to machine learning techniques [1] that can adequately describe the interaction between variables that play a role into injury cause.

This study seeks to (i) construct a mixed dataset aggregating GPS data, questionnaire metrics and subjective measures as well as injury history data, and (ii) use various machine learning models in order to be able to predict the occurrence of injury (at 1 week and 1 month) from the GPS and subjective measures.

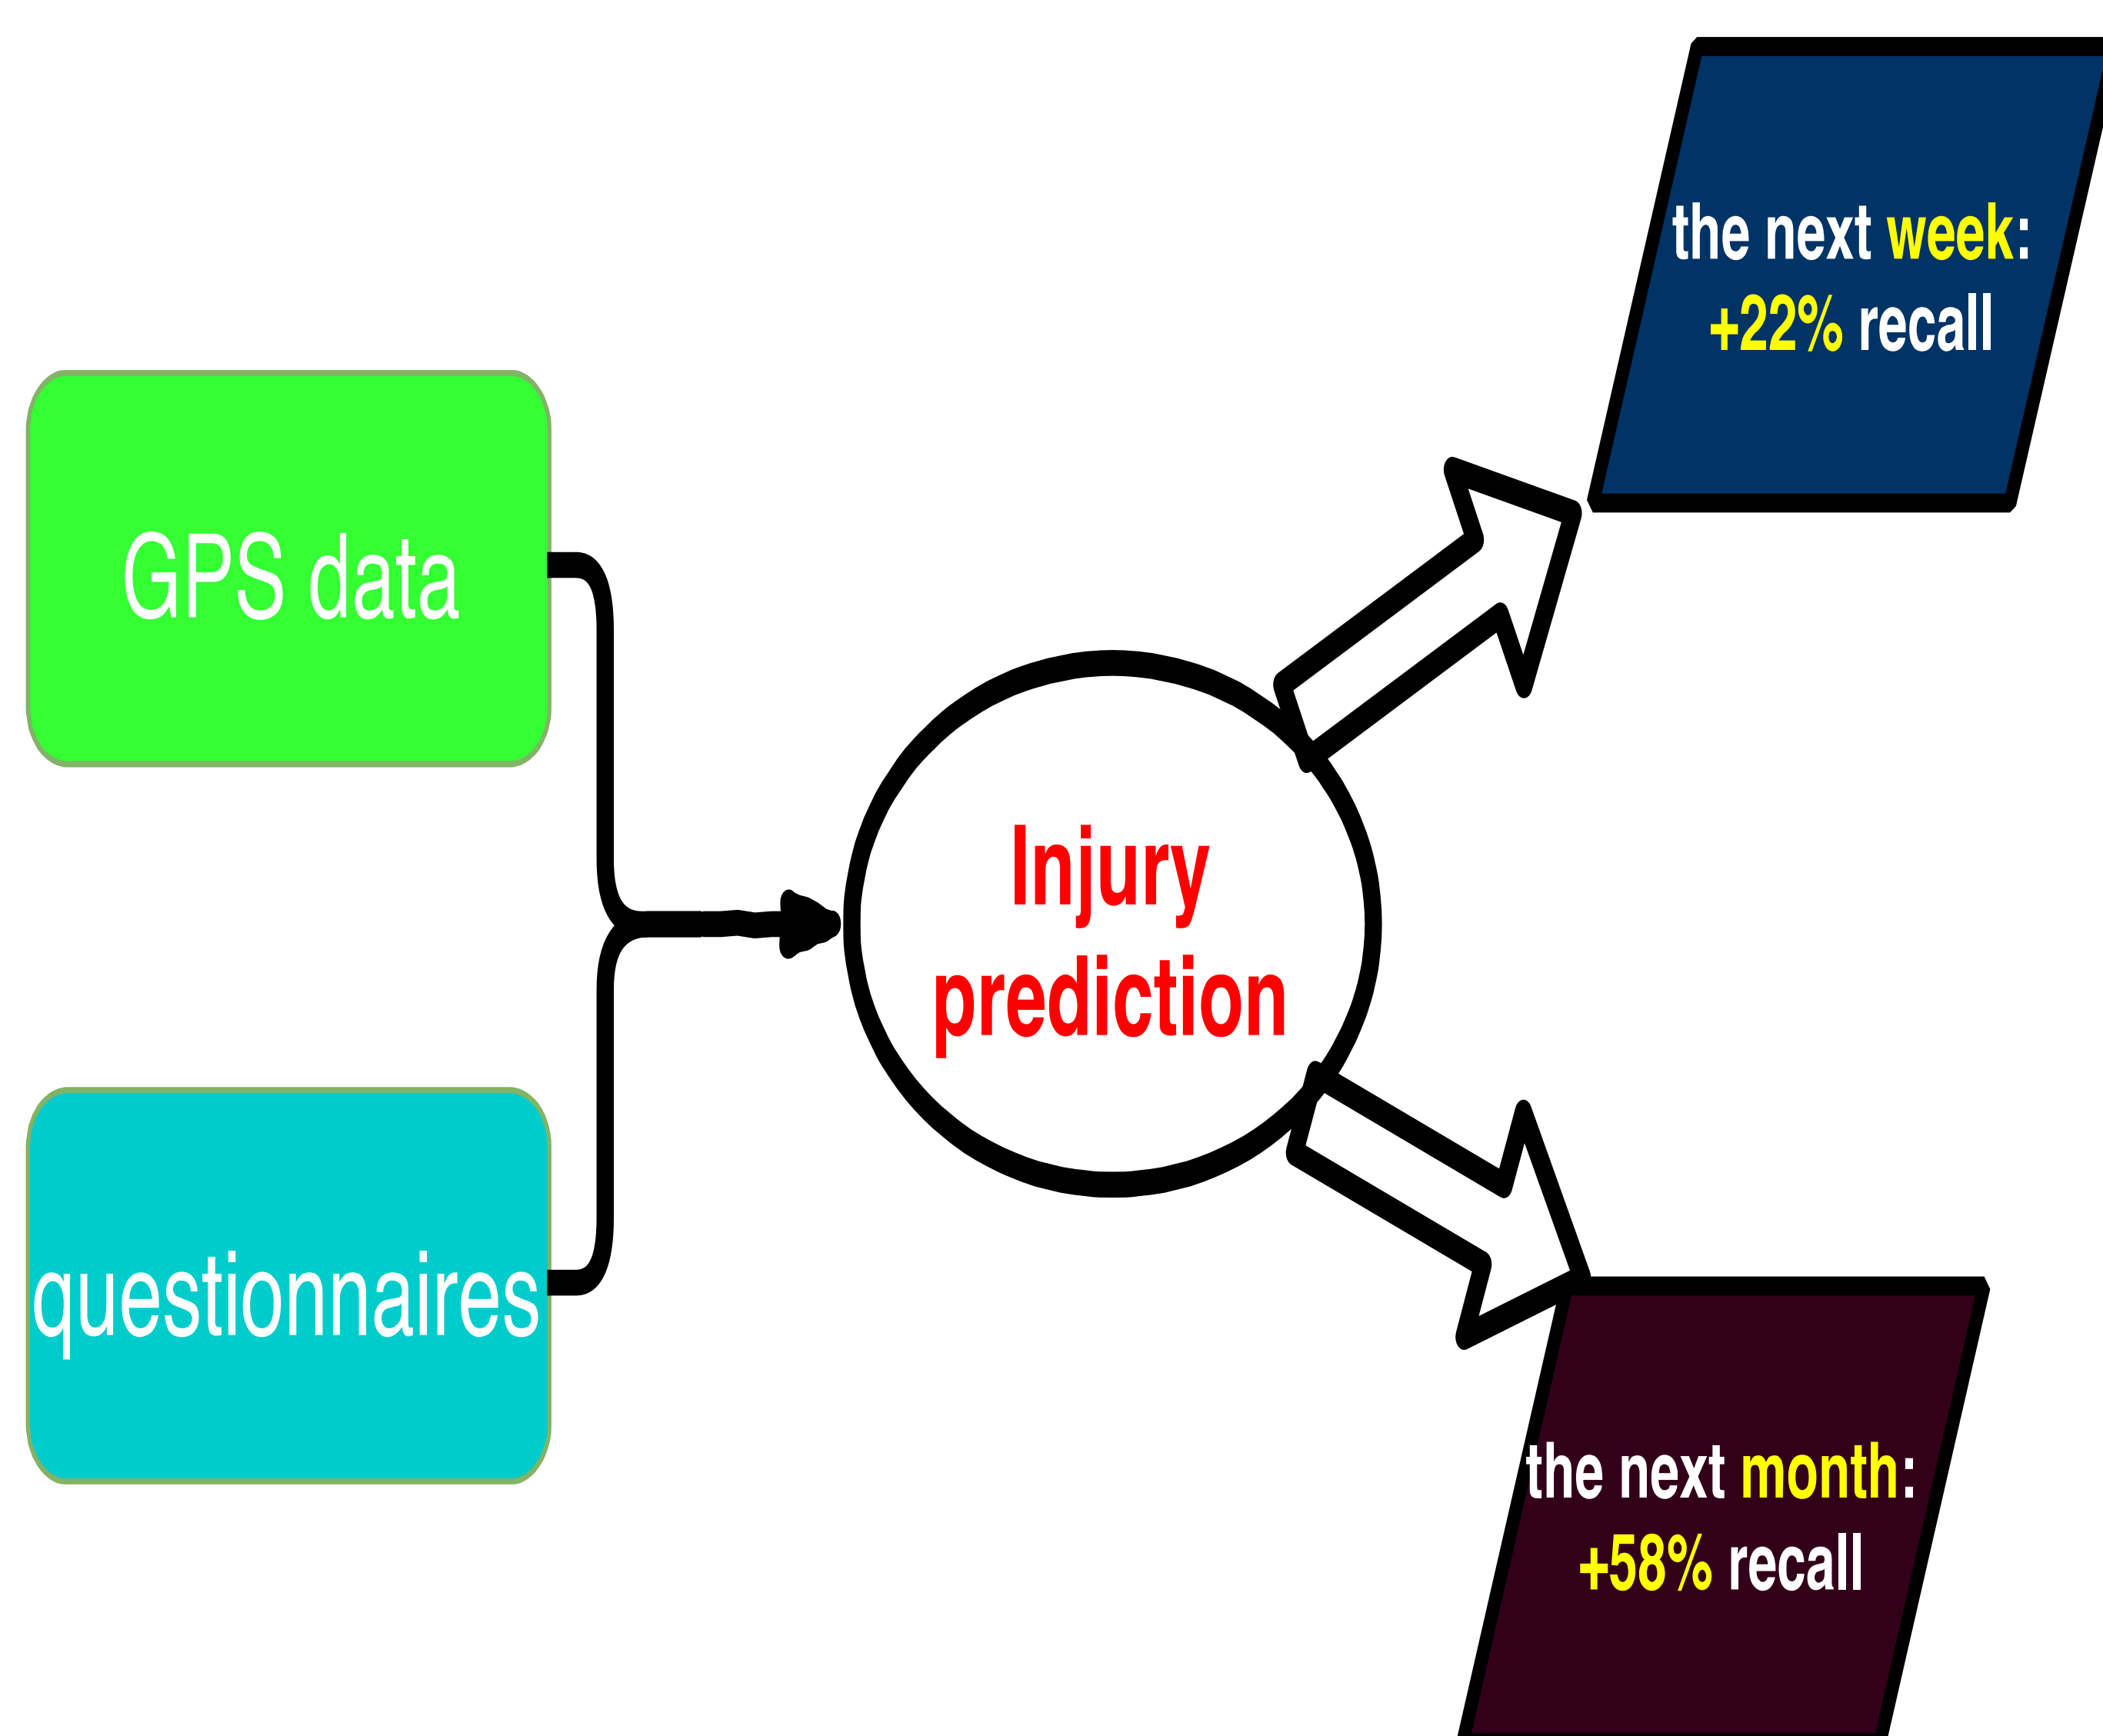

Methods

- 10-fold cross validation scheme (30 times)
- Evaluation metrics for classification models: accuracy, recall, precision, AUC (area under the ROC curve)

Results

- **Decision tree classifier** → best predictive evaluations (accuracy+precision+recall+AUC)

- The first nodes were often associated with subjective variables (questionnaires).

Discussion

- Preliminary results are in agreement with Rossi et al. [2].
- Our machine learning method would be able to classify more precisely the so-called at-risk players regarding the occurrence of injuries, and without being disturbed by "false alarms".
- The excellent accuracy of the decision tree, especially at 1 week, which differs from Rossi et al. [2], is allowed by combining GPS data and subjective questionnaires.
- Subjective measures of training load may be able to reflect mental load, which appears to be an important moderator of training load's relationship with injury.

Conclusion - Perspectives

The internal load could be a determining factor in the prediction of injury

Individualize GPS reports based on the player's profile, on the player's position on the field.

Individualize all questions based on the player's personality.

Extend the machine learning applications to several teams with different training strategies.
