**KEYWORDS:** Plasmonic Nanoparticles, LSPR, Gold/Silver Core-Shell, Surface Functionalization, Biotoxin Detection, Naked-Eye Readout, Biosensors

---

**ABSTRACT:** The Localized Surface Plasmon Resonance (LSPR) phenomenon provides a versatile property for biodetection. Herein, this unique feature was employed to build up a homogeneous optical biosensor to detect staphylococcal enterotoxin A (SEA) in solution down to very low levels by naked-eye readout. If the initial position of the LSPR band is located in the cyan region, even a small red shift (~2-3 nm) induced by Refractive index (RI) change close to the surface of nanoparticles (NPs), could make the light absorption transit from cyan to green and become visually detectable *via* a concomitant change in the complementary colors. In this work, we aimed at synthesizing two types of NPs based on compositionally complex core-shell NPs - Ag shell on AuNPs (Au@AgNPs) and Ag inside gold nanoshell (Ag@AuNPs). By controlling the thickness of the shells as well as their surface chemistry with anti-SEA antibody, the LSPR band was tuned to near 495 and 520 nm, for Ag@AuNPs and Au@AgNPs, respectively. The two particle systems were subsequently applied as transducers to spectroscopically and visually detect anti-SEA antibody - SEA interactions. Upon addition of SEA large red-shifts of the LSPR band were observed spectroscopically and the limits of detection (LOD) were estimated to 0.2 nM and 0.4 nM for the Au@AgNPs and Ag@AuNPs, respectively. Although the two sets of NPs gave almost identical LOD, the Ag@AuNPs whose initial position of the LSPR band was tuned in the cyan to green region (~500 nm) displayed a substantially more distinct color change from orange to red, as revealed by the by naked-eye. We foresee significant potential to this strategy in medical diagnostic and environmental monitoring, especially when basic laboratory infrastructure is sparse or non-existent.

---

## INTRODUCTION

Plasmonic metal nanoparticles (NPs) have shown a great potential for chemical and biological sensor applications over the past decades.<sup>1-5</sup> This is mainly due to their unique optical properties originating from localized surface plasmon resonance (LSPR) phenomenon, which is responsible for the bright color of the NPs suspensions.<sup>6-8</sup> This feature led to the design of numerous homogeneous and solid-phase schemes enabling naked-eye detection of analytes. Indeed, plasmonic NPs are the most commonly used labels for lateral-flow assays reported in the literature.<sup>9</sup> For homogeneous assays, the most common format allowing for naked-eye readout relies on aggregation/dispersion phenomena: plasmonic particles aggregation results in a distinct red shift of the LSPR band and to a color change from red to blue. Since the introduction of this format by Mirkin *et al.*<sup>1</sup> it has been extensively applied for the detection of various targets.<sup>10</sup> Other strategies based on etching and/or growth of plasmonic particles have been designed during the last decades to allow for a visual reading of the biosensing events (see reference<sup>11</sup> and references therein). Apart from these colorimetric assays, plasmonic NPs are widely utilized as LSPR-biosensors using UV-Visible spectrometers as transducers. Indeed, the position of the LSPR band is very sensitive to local changes of the refractive index (RI) and can be correlated to the changes in chemical and/or physical environment near the NPs surface.<sup>12-13</sup> In 1998, Englebienne reported the first use of gold nanoparticles to monitor antibody/antigen recognition.<sup>14</sup> These LSPR-biosensors exploiting local RI changes led to extremely sensitive devices capable of detecting LSPR band shifts at the nm level and applicable to numerous targets.<sup>15-16</sup> However, this sensitivity can only be achieved using a UV-Vis spectrometer as the color change induced by such small shifts in the wavelength is not observable by the naked-eye. In a recent study,<sup>17</sup> we highlighted the importance of tuning the optical properties of noble metal NPs to enable sensitive detection of minute optical transitions (wavelength shifts) by the naked-eye. This work showed that by tuning the NP composition and thereby the optical extinction to the cyan-green range (just below 500 nm) it is possible to overlap with the sensitivity function of our vision system and locate the transducer response in a region displaying a sharp transition in optical response. As a consequence, an LSPR shift as small as 2 nm could be observed by the naked-eye.<sup>17</sup> Locating the LSPR band in this region is possible by combining Au and Ag within the nanoparticle.

Among all the plasmonic NPs, gold and silver NPs (AuNPs and AgNPs, respectively) have attracted great attention for biosensing platform development due to their extremely high extinction coefficient in the visible spectral range.<sup>3, 12, 18-20</sup> Spherical AuNPs and AgNPs display LSPR bands in the green and blue regions of the visible spectrum, respectively,<sup>21</sup> which can be tuned by varying their size and shape.<sup>22-23</sup> For small spherical AuNPs (of an average diameter of about 10 nm), the LSPR band of the red-colored NPs suspensions is around 520 nm, while for spherical AgNPs with the same average diameter, the absorption band is around 395 nm, making the suspensions yellow-colored.<sup>5, 20, 24</sup> Even if AuNPs remain the most

studied system for biosensors because of their excellent chemical stability and biocompatibility,<sup>25-26</sup> AgNPs offer improved extinction coefficients and a higher sensitivity to RI than AuNPs for a given size and shape.<sup>13, 24</sup> As an example, the optical response (LSPR shift) due to the addition of avidin to biocytin-coated metallic spherical NPs of similar size, was five times higher for AgNPs than for AuNPs.<sup>24</sup> However, AgNPs might have a toxic effect in biological systems. They are also less stable under identical chemical conditions and barely reusable, which makes their use in repeated cycles more difficult than AuNPs.<sup>27-28</sup> Mixing Au and Ag to form either alloys or core-shell AgAuNPs leads to a hybrid LSPR band that can be tuned continuously from 400 to 520 nm *via* changing the Au/Ag ratio.<sup>29</sup> Yet, to date, very few studies have involved mixed Au/Ag NPs for RI-based LSPR biosensing. Works dealing with the streptavidin/biotin couple as a model of biomolecular interaction were reported.<sup>30-31</sup> Other examples such as sulfide detection,<sup>32</sup> and antibiotics SERS aptasensing<sup>33</sup> and, more recently, colorimetric detection of DNA<sup>34</sup> and illicit drugs<sup>35</sup> were described. However, to the best of our knowledge, mixed Au/Ag NPs plasmonic NPs have never been used for LSPR-immunosensing of a bio-toxin.

As the surface chemistry of mixed Au-Ag alloys is difficult to master, the core-shell structure is preferred to engineer mixed Au/Ag NPs and leads to well-distributed colloids in size and shape.<sup>36-37</sup> Au-Ag core-shell nanoparticles (Au@AgNPs) were first synthesized by Morriss and Collins,<sup>38</sup> and have since received great attention for plasmonic applications.<sup>5, 18, 34-35, 39</sup> This configuration, Au@AgNPs, where a gold core is coated by a silver shell is quite simple to achieve by growing a layer of Ag on previously prepared AuNPs and offers a homogeneous size distribution.<sup>40</sup> Synthesizing Ag-Au core-shell NPs (Ag@AuNPs) is less straightforward. Indeed, when gold salt is added to a suspension containing AgNPs, hollow gold nanoshells (AuNS) are formed by galvanic replacement.<sup>41-43</sup> This is due to the lower redox potential of the Ag<sup>+</sup>/Ag couple compared to the Au<sup>3+</sup>/Au couple (0.80 V/SHE vs 0.99 V/SHE for Ag<sup>+</sup>/Ag and Au<sup>3+</sup>/Au, respectively).<sup>44</sup> Although some papers describe gold growth on silver NPs, the resulting core-shell particles have imperfections, mainly holes, and sometimes complete removal of Ag core; TEM images of the so-synthesized Ag@AuNPs often show brighter central and darker outer nanostructure.<sup>45-47</sup>

Recently, we introduced an original pathway to form Ag-Au core-shell NPs (Ag@AuNPs) from AuNS.<sup>48</sup> Porous AuNS were prepared by galvanic replacement from AgNPs, and we showed that the nanoconfinement effect caused pH-triggered silver reduction to preferentially occur at the inner walls of AuNS until a solid Ag core is formed inside the AuNS to form Ag@AuNPs.<sup>48</sup> The presence of Au at the external sphere of Ag@AuNPs leads to a better stability of the colloids as mentioned previously and also allow for the use of gold chemistry to engineer bioconjugates that we showed to be stable over a year of storage at 4°C with preserved analytical performances.<sup>20</sup> In addition, the synthesis method of Ag@AuNPs allows for a precise control of the amount of Ag within the shell and we were able to precisely tune the position of the LSPR band and locate it in the desired spectral region for naked-eye biosensing applications.<sup>48</sup>

In this study, we investigate two configurations of plasmonic core-shell nanoparticles: Au@AgNPs and Ag@AuNPs for LSPR-based naked-eye biosensing. The optical properties of these nano-objects were tuned to the cyan-green region by changing the silver shell thickness on the gold core for Au@AgNPs or by filling the inner volume in the hollow gold nanoshell particles Ag@AuNPs with silver. These plasmonic core-shell NPs were modified to engineer antibody-conjugated Au@AgNPs and Ag@AuNPs to be used as transducers for naked-eye immunosensing of a harmful biotoxin; staphylococcal enterotoxin A (SEA). For several years, our group has been especially interested in the detection of SEA.<sup>20, 49-51</sup> SEA is a small monomeric protein (Mw = 28 kDa) with high thermal and proteolytic stability.<sup>52</sup> It is the most commonly encountered biotoxin involved in staphylococcal food poisoning outbreaks.<sup>53</sup> Ingestion of raw or even cooked food contaminated by SEA induces severe gastroenteritis, sometimes fatal to humans.<sup>20, 50, 54</sup> In previous works, we mastered the engineering of stable antibody-AuNPs bioconjugates by covalent attachment of anti-SEA antibodies to spherical AuNPs to afford an immunoprobe to detect SEA.<sup>20, 50-51</sup> We then set up a homogeneous, solution-based assay, for which binding of SEA in the ng/mL range resulted in a red-shift of the LSPR band of the immunoprobe, only measurable by a dedicated instrument.<sup>20</sup> Using the newly developed Ag@AuNPs we aim at achieving a naked-eye readout of the immunorecognition. The nanomaterials synthesized here were carefully characterized using a suite of highly sophisticated surface analytical techniques such as Transmission Electron Microscopy (TEM and STEM), X-EDS, UV-Vis spectroscopy, Dynamic Light Scattering (DLS), and zeta potential (ELS) measurements. The resulting bioconjugates were then used for SEA biosensing, and their analytical performances in terms of sensitivity and their limits of detection (LOD) were measured prior to their use for naked-eye readout of the biosensing event. We foresee significant potential of this strategy in medical diagnostic and environmental monitoring, especially in situations where basic laboratory infrastructure is sparse or non-existent.

## EXPERIMENTAL SECTION

**Materials.** Hydrogen tetrachloroaurate(III) trihydrate (HAuCl<sub>4</sub>·3H<sub>2</sub>O; ≥ 99.99%) was purchased from Alfa Aesar. Sodium citrate dihydrate (Na<sub>3</sub>C<sub>6</sub>H<sub>5</sub>O<sub>7</sub>·2H<sub>2</sub>O; ≥ 99%), tannic acid (C<sub>76</sub>H<sub>52</sub>O<sub>46</sub>), sodium borohydride (98%), hydroxylamine hydrochloride (99%), sodium hydroxide, bovine serum albumin (BSA), 2-iminothiolane hydrochloride (Traut's reagent: C<sub>4</sub>H<sub>7</sub>NS.HCl; ≥ 98%) and staphylococcal enterotoxin A (SEA) were purchased from Sigma Aldrich. Silver nitrate (AgNO<sub>3</sub>; ≥ 99%) was purchased from Honeywell, Fluka. Hydrochloric acid (37%) and nitric acid (68%) were purchased from VWR chemicals. Affinity purified rabbit polyclonal anti-SEA antibody (Ab, reference in toxin technology catalog: LAI101) was purchased from Toxin Technology (Sarasota, FL, www.toxintechnology.com). All glassware was cleaned in a bath of freshly prepared aqua regia solution, and then rinsed thoroughly with Milli-Q water before use.

**Au-Ag core-shell nanoparticle preparation (Au@AgNPs).** Colloidal AuNPs were synthesized according to the citrate/tannic acid (TA) reduction method adapted from ref.<sup>55-56</sup> and optimized in ref.<sup>20, 51</sup> 100 mL of citrate-coated AuNPs

were prepared from two stock solutions expected to afford particles with an average size of 13.5 nm (**Figure S1 in supporting information**): A solution A (HAuCl<sub>4</sub>·3H<sub>2</sub>O (1.16 mL; 1% [w/v]) and Milli-Q water (78.84 mL); and a solution B (sodium citrate (4 mL; 1.14%), tannic acid (TA) (0.025 mL; 1%) and Milli-Q water (16 mL)). Solutions A and B were heated to 60°C under reflux and stirring then mixed. The molar ratio between gold ions and citrate was [1:6.1]. The mixture was then heated up to 90°C for a few minutes to form spherical AuNPs. When the color turned ruby-red, a portion of the sample suspension (portion I) was heated up for 30 min under reflux and stirring to increase the colloidal stability after which the suspension was cooled on ice bath. The other portion (portion II) was used to form gold-silver core-shell NPs and is described later. Finally, gold suspension was kept in amber glassware and stored at 4°C.

Then, the deposition of Ag shell on AuNPs was realized through reduction of Ag<sup>+</sup> on AuNPs to obtain Au-Ag core-shell NPs (Au@AgNPs). The molar ratio between Ag<sup>+</sup> and citrate was also [1:6.1]. The volumes of silver nitrate and sodium citrate stock solutions were determined by estimating a silver shell with uniform thickness of 2 nm and assuming that the average size of gold core was 13.5 nm. The silver nitrate stock solution (10 mM) was freshly prepared by dissolving AgNO<sub>3</sub> crystals in Milli-Q water. A volume of AgNO<sub>3</sub> stock solution (258 µL) was added to the portion II of AuNPs suspension at 90°C after the color change, under reflux and stirring, followed by the rapid addition of the reducing solution (sodium citrate 1%; 454 µL). The equations describing the concentration of (~13.5 nm) AuNPs formed and the volume required to generate a 2 nm thick Ag shell on such AuNPs are shown in SI (**Equation S1 and Equation S2**). After addition, suspension was heated up to boiling for 1 h under reflux and stirring and then cooled on ice bath. Finally, the orange suspension of Au@AgNPs was kept in amber glassware and stored at 4°C.

**Ag-Au core-shell nanoparticle preparation (Ag@AuNPs).** The AuNS particles were synthesized *via* the galvanic replacement method, where the AgNPs served as sacrificial template according to slightly modified procedures.<sup>42, 48</sup> In a typical synthesis, AgNPs were first synthesized by reduction of AgNO<sub>3</sub>. Sodium citrate solution (1 M, 50 µL) was added to AgNO<sub>3</sub> (0.2 mM, 50 mL) at 60°C. After 5 min, NaBH<sub>4</sub> (100 mM, 1 mL) was injected into the solution. The solution was stirred for 2 h at 60°C and allowed to cool down to room temperature. Galvanic replacement of Ag by Au occurs at room temperature. A 200 mM NH<sub>2</sub>OH.HCl solution (1 mL) was added to as prepared AgNPs followed by addition of AgNO<sub>3</sub> (0.1 M, 141 µL) and citrate (1 M, 50 µL) solutions 5 min later to minimize the formation of AuNPs.<sup>57</sup> The well stirred solution was kept overnight to allow the reaction to reach completion. At 60°C, HAuCl<sub>4</sub> (25 mM, 713 µL) was added dropwise to the solution under magnetic stirring at 500 rpm. The reaction was stopped after 4 h by lowering the temperature to 25°C. The final pH was 4.5.

An additional silver nitrate solution was added dropwise to a concentration of 0.48 mM, which corresponded to the used concentration of AgNPs as template in AuNS synthesis, described previously. This enabled reduction of silver inside gold nanoshell (Ag@AuNPs) and the process was initiated by increasing the pH of purple-colored suspension of AuNS. Thus, after reaching the final concentration, the pH of the AuNS suspension was adjusted from 4.5 to 8 by adding NaOH (0.1 M) under magnetic stirring at 500 rpm to afford an orange-colored suspension. Ag@AuNPs suspension was kept in amber glassware and stored at 4°C.

**Engineering of antibody-conjugated nanoparticles.** A covalent approach was used to engineer antibody-conjugated NPs *via* pre-thiolation of antibody (Ab).<sup>58-59</sup> Traut's reagent (170 µM) was reacted with Ab (0.63 mg/mL; 4.1 µM) in 40 mM phosphate buffer (pH 8) at room temperature (RT) to generate sulfhydryl groups.<sup>60</sup> After 1 h, the thiolated Ab was separated from excess Traut's reagent by purification on Dextran desalting 10 mL gel filtration column (Hitrap desalt 10 mL, GE Healthcare) using phosphate buffer (pH 7.4) as eluent.

Thiolated Ab (70 µg/mL, 1 mL) was added to Au@AgNPs or Ag@AuNPs suspension (pre-concentrated by seven times, 350 µL) and the mixture was incubated for 30 min at RT. Then, BSA (0.25% [w/v]) was added to the bioconjugate suspension to block non-specific binding sites.<sup>20, 51</sup> Finally, the biofunctionalized NPs were concentrated by centrifugation at 10,300 g for 40 min and washed twice to remove excess non-bound Ab or weakly bound Ab. Finally, Ab-NPs were resuspended in 10 mM phosphate buffer (pH 7.4) with BSA (0.25% [w/v]).

**Antibody quantification by ELISA.** After the first centrifugation, the supernatants were collected and Ab concentration was determined by ELISA. SEA (1 µg/mL in 0.1 M carbonate buffer, pH 9.5, 100 µL) was pipetted into each well of a flat-bottomed polystyrene 96-well plate (Greiner bio-one) and incubated overnight at 4°C. The content was discarded and non-specific sites were blocked by PBS-0.1% BSA (100 µL) for 1 h at room temperature. Wells were washed 3 times with PBS-0.05% Tween 20 (150 µL). Standard solutions of Ab or diluted supernatants (100 µL) to be quantified were dispensed into the wells. The plate was incubated for 2 h at room temperature. After washing with PBS-0.05% Tween 20 (3x150 µL), HRP-labelled goat anti-rabbit IgG conjugate (1/4000, 100 µL) was added to each well and incubated for 1 h at room temperature. After washing with PBS-0.05% Tween 20 (3x150 µL), a mixture of *o*-phenylenediamine dihydrochloride (OPD) and H<sub>2</sub>O<sub>2</sub> (7 mg OPD and 4 µL H<sub>2</sub>O<sub>2</sub> in 10 mL of citrate-phosphate buffer, pH 5, 100 µL) substrate solution was added to each well. After the color developed, H<sub>2</sub>SO<sub>4</sub> (2.5 M, 50 µL) was added to each well to stop the enzymatic reaction. After 10 min in the dark, the absorbance of each well was read at 485 nm and 415 nm as reference with a microplate reader (Fluostar Optima, BMG Labtech). The concentration of Ab in diluted supernatants was deduced from the calibration curve established by plotting ΔAbs (Abs<sub>485</sub>-Abs<sub>415</sub>) vs Ab concentration. The resulting value was multiplied by the dilution factor (x200) to determine the actual concentration of Ab in the supernatants.

**SEA immunosensing.** Aliquots of SEA solution were serially added to the antibody-conjugated nanoparticles suspension (1.6 mL) in a plastic cuvette (final SEA concentration: 50, 100, 200, 500 and 1000 ng/mL). Absorption spectra were

measured in real time (millisecond temporal resolution and  $10^{-2}$  nm spectral resolution) using Inspilorion XNano II instrument until equilibrium was reached ( $\sim 90$  min). The position of the LSPR band was plotted as a function of time using the software provided with the instrument.

**UV-Vis spectroscopy.** UV-Vis spectra were recorded on a Cary 50 spectrophotometer (Varian, Inc.). Spectral analysis of colloidal suspensions was performed in the range 300-800 nm. Milli-Q  $H_2O$  was used as the blank. Mathematical determination of  $\lambda_{max}$  was done according to reference.<sup>61</sup>

**DLS and zeta potential.** Dynamic Light Scattering (DLS), and zeta potential (ELS) measurements were performed using Litesizer™ 500 apparatus (Anton Paar) equipped with a 658 nm laser operating at 40 mW. The backscattered light collection angle was set at  $90^\circ$ . The zeta potential cuvette has a  $\Omega$ -shaped capillary tube cuvette with an applied potential of 150 V. The same suspensions were used for DLS and ELS measurements. Each sample was analyzed in triplicate and each measurement was an average of three 30 s runs.

**Electron microscopy.** Transmission Electron Microscopy (TEM) micrographs of AuNPs, AuNS, Ag@AuNPs and Au@AgNPs were obtained using a JEOL JEM-2100 plus LaB6 (JEOL, Japan) microscope with an acceleration voltage of 200 kV and equipped with an Orius 4 K CDD camera (Gatan, USA). STEM mode coupled with X-ray Energy-Dispersive Spectroscopy (X-EDS) was used to perform elemental mapping of the two metals (lines: Au-L and Ag-L). X-EDS analysis was realized with an Oxford Instrument SDD detector of  $80\text{ mm}^2$ . X-ray spectra were recorded and processed with Aztec software. The samples were prepared by dropping a dilute suspension onto the carbon-coated copper grids and dried at room temperature before imagining. Size distribution was established by counting a minimum of 400 particles for TEM and was determined using ImageJ Software.

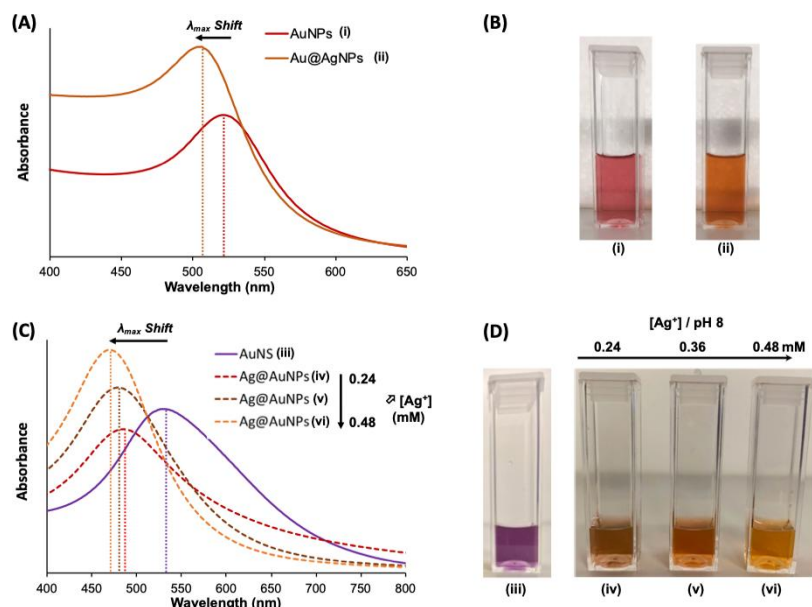

## RESULTS AND DISCUSSION

**Nanoparticle synthesis.** Two sets of core-shell NPs were prepared: Au@AgNPs and Ag@AuNPs. Prior to synthesis of gold-silver core-shell NPs (Au@AgNPs), pure gold NPs with a core of approx. 14 nm were prepared following the strategy described in **Figure 1A**.

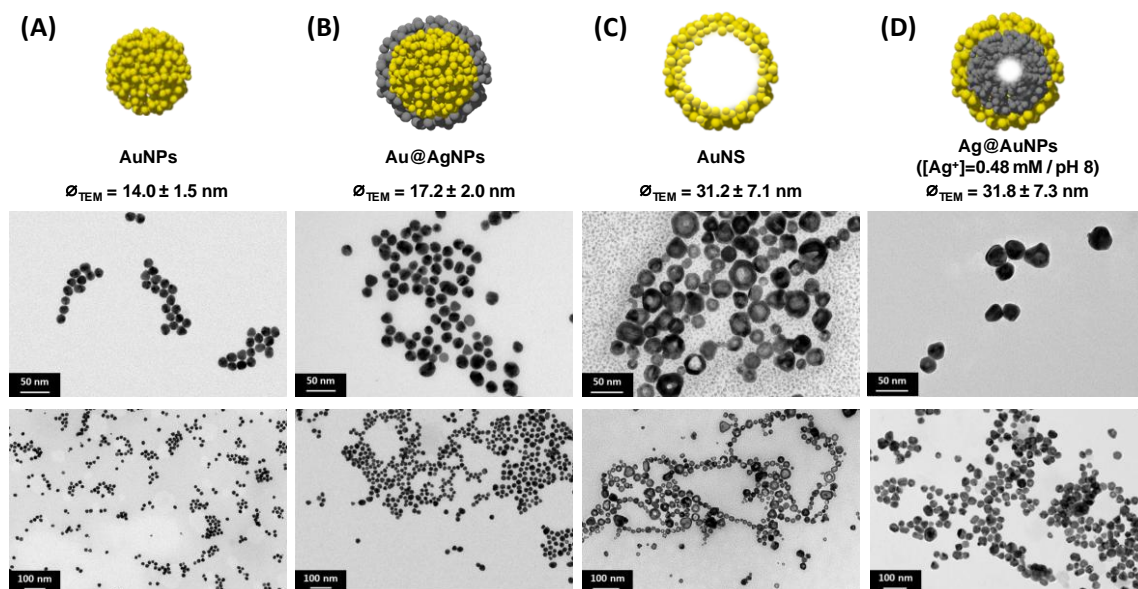

**Figure 1.** Strategy adopted for the synthesis of core-shell (A) Au@AgNPs and (B) Ag@AuNPs and covalent bioconjugation of anti-SEA antibody as well as the detection of SEA.

Then an Ag shell was grown on the particles to form Au@AgNPs. Silver-gold core-shell NPs (Ag@AuNPs) were synthesized by an original pathway from hollow gold nanoshell (AuNS) by controlling the Ag content in AuNS (**Figure 1B**). Ag ions up to a concentration of 0.48 mM were added externally to AuNS to yield Ag@AuNPs by pH-triggered reduction (up to 8) in nanoconfinement.<sup>37</sup> All these colloids were first characterized by UV-Vis spectroscopy, DLS, and zeta potential measurements. The results are displayed in **Figure 2** and are summarized in **Table 1** (see also supporting information, **Figure S2**). Then, particles size and distribution were estimated by TEM, see **Figure 3**.

**Figure 2.** (A) Extinction spectra of (i) pure AuNPs and (ii) core-shell Au@AgNPs; (B) photos of corresponding suspensions. (C) Extinction spectra of (iii) AuNS and Ag@AuNPs, after adding silver nitrate and adjusting the pH from 4.5 to 8: (iv)  $[Ag^+] = 0.24$  mM, (v)  $[Ag^+] = 0.36$  mM and (vi)  $[Ag^+] = 0.48$  mM; (D) photos of corresponding suspensions.

As shown in **Figure 2**, the LSPR bands of AuNPs and AuNS are located at 521 nm and 532 nm (**Table 1**), and their color in suspension are red and purple, respectively. The position of the LSPR band of AuNPs is consistent with those previously measured for gold colloids of similar size.<sup>20</sup> Particle size and distribution were confirmed by TEM observations in **Figure 3A-C**, with an average size of  $14.0 \pm 1.5$  nm, for AuNPs, and  $31.2 \pm 7.1$  nm, for AuNS. Upon silver growth on AuNPs, the LSPR band is blue-shifted to 507 nm and the color of the core-shell Au@AgNPs colloidal solution turns orange (**Figure 2A-B**). This color and the position of the LSPR band are consistent with silver growth on the gold core.<sup>5, 62</sup> The same results are observed for Ag incorporation inside AuNS (**Figure 2C-D** and **Table 1**). Indeed, the blue-shift of LSPR band increases as the Ag content progressively increases in suspension (485 nm, 479 nm and 471 nm for Ag concentration of 0.24, 0.36 and 0.48 mM, respectively) and the color also turns to orange/yellow upon Ag addition. Consequently, the LSPR band of Ag@AuNPs can be tuned by controlling the Ag content within AuNS. The average size of Au@AgNPs, deduced from TEM images in **Figure 3B**, is in good agreement with the growth of a silver shell of  $\sim 3$  nm,  $17.2 \pm 2.0$  nm. The silver shell is slightly thicker than the targeted value of 2 nm, this is probably due to the higher mean diameter of the original AuNPs (14 vs 13.5 expected). We attempted to grow thicker layers of silver on AuNPs to further blue-shift the position of the LSPR band but this led to the growth of isolated AgNPs (**Figure S3**). TEM and STEM images (**Figure 3C-D** and **Figure S4**) also show that the size of the three different batches of Ag@AuNPs was similar to that of the starting AuNS particles, in agreement with silver growth within the hollow shells. Moreover, traces of residual citrate are visible in the TEM images for AuNS and are consumed during the reduction of silver ions after  $AgNO_3$  addition to form Ag@AuNPs by nanoconfinement effect (compare areas outside the NPs and NP clusters, **Figure 3C-D**).

**Figure 3.** TEM observations of (A) pure AuNPs, (B) core-shell Au@AgNPs, (C) AuNS and (D) core-shell Ag@AuNPs (after adding  $[Ag^+]=0.48$  mM in suspension and adjusting the pH to 8). Their average size was deduced from TEM by counting a minimum of 400 particles.

The hydrodynamic diameter of AuNPs, shown in **Table 1**, is higher than that obtained from TEM (24.2 nm vs 14.0 nm, respectively), as the measured value includes the surrounding environment. For the core-shell Au@AgNPs, the zeta potential is more negative, approx. -50 mV than that of AuNPs ( $\zeta \approx -40$  mV), a value typically observed for such particles (**Figure S2**). These observations suggest that silver-coated NPs require more citrates for their stabilization than gold particles. This naturally led to a higher hydrodynamic diameter for these Au@AgNPs, *i.e.*  $\sim 31$  nm. The results are very similar between AuNS and different Ag@AuNPs regarding hydrodynamic diameters and zeta potential measurements ( $\sim 52$  nm and  $\zeta \approx -39$  mV, respectively) (**Table 1** and **Figure S2**). However, a slight decrease in zeta potential is observed for Ag@AuNPs ( $[Ag^+]=0.24$  mM) resulting in an increase of the hydrodynamic diameter and resulting in less stable nanoparticles. Indeed, AuNS lose their colloidal stability by removing excess citrate in suspension. Progressive filling of the inner cavity of AuNS with Ag occurs until a solid core of Ag is formed and Ag@AuNPs remain stable in suspension. Consequently, we focused on Ag@AuNPs ( $[Ag^+]=0.48$  mM) and Au@AgNPs in order to compare their potential as well as their efficacy for SEA immunosensing after engineering the antibody-conjugated core-shell NPs and deploying them for naked-eye biosensing.

To ensure their successful synthesis, Au@AgNPs, AuNS and Ag@AuNPs were further characterized using HR-TEM and X-EDS. The resulting STEM elemental mapping (Ag, Au and overlay) and elemental profile are shown in **Figure 4**. These observations highlighted the silver growth on AuNPs to obtain Au@AgNPs (**Figure 4A**) and the pH-triggered silver reduction to completely fill the inner volume for Ag@AuNPs (**Figure 4B-C** and **Figure S4**). X-EDS data show that the grouped Au@AgNPs ( $\approx Au_{69}Ag_{31}$ ) (sample ii, **Table 1**) matched perfectly the theoretical atomic percentages of gold and silver in Au@AgNPs, *i.e.*  $\approx Au_{66}Ag_{34}$ . However, when looking at individual Au@AgNPs, the amount of silver is slightly lower with an average composition  $\approx Au_{79}Ag_{21}$ . This small difference may have two origins. First, some small silver nanoparticles, barely detectable on the TEM images and in the LSPR bands may be formed. This first assumption is consolidated by additional experiments we ran to increase the shell thickness in Au@AgNPs ( $>3$  nm, not shown) that led to formation separate AgNPs in the colloidal suspension. The second assumption would be that not all the silver introduced to the solution is reduced (note X-EDS analysis shows the element regardless of its oxidation state). In addition, elemental mapping (Ag, Au and overlay in **Figure 4A**) clearly shows a relatively homogeneous layer of silver on gold core. Regarding Ag@AuNPs, X-EDS data confirms the STEM findings with an incremental increase in Ag content in AuNS (**Table 1** and **Figure S4**). Therefore, we conclude that the synthesis of Au@AgNPs and Ag@AuNPs was successful.

**Figure 4.** STEM elemental mapping (Ag, Au and overlay) of (A) Au@AgNPs, (B) AuNS and (C) Ag@AuNPs ( $[Ag^+]=0.48$  mM) and elemental profiles along the white hatched line.

**Bioconjugate engineering.** Ab-NPs bioconjugates were engineered by attaching anti-SEA antibody to Au@AgNPs or Ag@AuNPs following the procedure schematized in **Figure 1**. Prior to grafting on the surfaces, Ab was derivatized by Traut's reagent to generate thiol groups allowing its covalent anchoring to the metallic nanoparticle surface by displacing the capping citrate ligands. The increase of particles size due to the grafted proteins was evidenced by DLS measurements as the hydrodynamic diameter of Ab-Au@AgNPs and Ab-Ag@AuNPs increased to 180.6 nm and 182 nm, respectively (**Table S1**). The zeta potential of these core-shell NPs in phosphate buffer (10 mM; pH 7.4) also increased from -50.5 to -18.8 mV for Ab-Au@AgNPs and from -38.9 to -15.6 mV for Ab-Ag@AuNPs (**Table S1**) in agreement with previously reported data.<sup>20, 51</sup> These successive steps were monitored by UV-Vis spectroscopy as shown in **Figure 5**. The position of the LSPR band ( $\lambda_{max}$  shift) was determined by calculating the first derivative of each spectrum.<sup>8, 61</sup>

**Table 1.** Summary of physical properties of (i) AuNPs, (ii) Au@AgNPs, (iii) AuNS and Ag@AuNPs with various addition content of Ag inside AuNS ((iv)  $[Ag^+]=0.24$  mM, (v)  $[Ag^+]=0.36$  mM, (vi)  $[Ag^+]=0.48$  mM).

Samples	$\lambda_{max}$ (nm)	DLS (nm)	$\zeta$ -potential (mV)	X-EDS (at. %)
i	521	24.2	-42.3	Au <sub>100</sub>

iii	532	50.9	-39.5	Ag <sub>60</sub> Au <sub>40</sub>
iv	485	61.2	-34.1	Ag <sub>67</sub> Au <sub>33</sub>
v	479	52.1	-39	Ag <sub>70</sub> Au <sub>30</sub>
vi	471	54.3	-38.9	Ag <sub>72</sub> Au <sub>28</sub>

The first observation is that under identical conditions, the LSPR band red-shift was more pronounced for the core-shell Ag@AuNPs compared to Au@AgNPs, 23 nm vs 17.8 nm, respectively (**Figure 5**). This corroborated the assumption that the RI sensitivity is improved with increasing Ag amount, as confirmed by X-EDS data (**Table 1**).<sup>5, 63</sup> Besides, a third batch of colloids, *i.e.* pure AuNPs of 17 nm in diameter, was prepared to have particles with similar sizes to Au@AgNPs for comparison of the efficiency of Ab chemisorption. The LSPR-shift for this AuNP is reduced by a factor two yielding a red-shift of 8 nm (**Figure S5**). In addition, and more importantly, the attachment of Ab to Au@AgNPs was readily observable by naked-eye as the color switched from orange to red (see **Figure 5A(ii)**), while AuNPs and Ab-AuNPs were both reddish (**Figure S5**). The color change for Ag@AuNPs is less obvious as the suspension changed from orange to deep orange/brownish (**Figure 5B(ii)**). Unfortunately, the LSPR signature of the resulting Ab-Au@AgNPs bioconjugates was no longer located in the desired spectral window, which compromises the visualization of SEA binding. Nevertheless, we pursued the immunosensing to see whether the better RI sensitivity of both core-shell colloids may enhance their response to SEA.

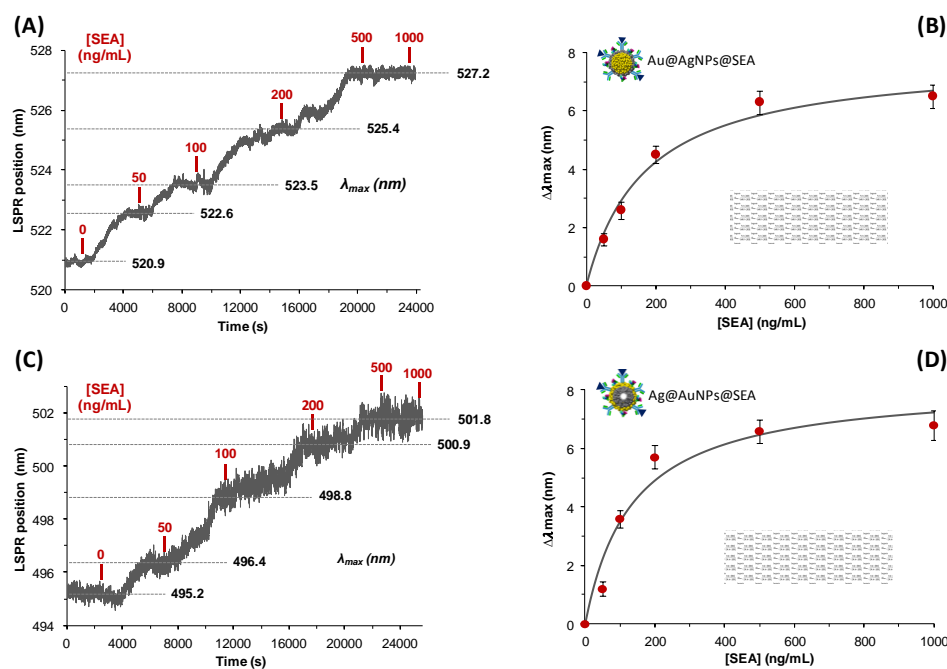

**Figure 5.** (A) (i) UV-Visible spectra and their first derivative recorded upon Ab conjugation to Au@AgNPs; (ii) photos of the suspensions before (left) and after (right) bioconjugation. (B) (i) UV-Visible spectra and their first derivative recorded upon Ab bioconjugation to Ag@AuNPs; (ii) photos of the suspensions before (left) and after (right) bioconjugation.

Prior to SEA immunosensing, the surface coverage of antibodies for each bioconjugate was indirectly estimated by measuring the unbound antibody quantity remaining in the supernatant using enzyme-linked immunosorbent assay (ELISA). This information is very important when comparing the efficiency of the bioconjugates for biosensing as it can be directly related to the amount and accessibility of the recognition sites. ELISA gave the actual concentrations of Ab in the supernatants *i.e.* 14.8  $\mu\text{g/mL}$  for Au@AgNPs and 19.4  $\mu\text{g/mL}$  for Ag@AuNPs (**Figure S6**). Surprisingly, these unbound Ab concentrations indicate a higher grafting of Ab on Au@AgNPs compared to Ag@AuNPs despite a lower shift of the LSPR band and smaller particle size. The reactivity of thiol groups towards silver and gold is also supposed to be similar, yet, we can expect slight differences, which may influence the coverage on the NPs. As stated above, the amount of citrate needed to stabilize Au@AgNPs is higher than that required for Ag@AuNPs. This may be at the origin of this difference in coverages. It is also important to note that ELISA was performed on the supernatants. This method has been shown to overestimate the amount of adsorbed Ab.<sup>64</sup>

**SEA immunosensing.** In this experiment, the position of the LSPR bands of the colloidal suspensions of Ab-Au@AgNPs and Ab-Ag@AuNPs was monitored over time upon addition of increasing amounts of SEA in the range 0 to 1000 ng/mL (**Figure 6A-C**). A progressive shift of the LSPR band was observed and a dose-response curve was established by plotting

the band shift  $\Delta\lambda$  measured after stabilization versus the concentration of analyte (**Figure 6B-D**). The detailed fit parameters showing the accuracy of the measurement ( $\chi^2$  and  $R^2$  values) are summarized in **Table S2**. Following the red-shift of LSPR bands to assess SEA recognition led to a large enhancement of the dynamic range compared to our previously published data.<sup>20</sup> Yet, at this step, no remarkable differences are observed between the responses of Au@AgNPs and Ag@AuNPs immunoprobes towards SEA. Indeed, addition of SEA led to red-shift of the LSPR band which reached a total shift of  $\Delta\lambda = 6.3$  nm and  $\Delta\lambda = 6.6$  nm at saturation for Au@AgNPs@SEA and Ag@AuNPs@SEA, respectively, upon exposure to 500 ng/mL SEA (**Figure 6**); no further shift is observed for higher SEA concentrations. Through the Langmuir fit on adsorption isotherm curves, both Ab-Au@AgNPs and Ab-Ag@AuNPs show a high affinity between anti-SEA and SEA while Ab-Ag@AuNPs exhibited a better affinity (**Figure 6B-D**). The dissociation constants for Au@AgNPs and Ag@AuNPs are  $168.8 \pm 35.3$  ng/mL ( $6.0 \pm 1.3$  nM) and  $134.6 \pm 27.1$  ng/mL ( $4.8 \pm 1.0$  nM), respectively and the limits of detection (LOD) of SEA are estimated to equal 5.4 ng/mL (0.2 nM) and 10.6 ng/mL (0.4 nM), respectively. These LOD results points toward a high analytical performance for both systems and are of the same orders of magnitude as for the Ab-AuNPs bioconjugate, reported in a previous work.<sup>20</sup>

**Figure 6.** (A) LSPR band position vs time and (B) dose-response curve established by plotting  $\Delta\lambda$  at stabilization vs [SEA] for Ab-Au@AgNPs immunoprobe. (C) LSPR band position vs time and (D) dose-response curve established by plotting  $\Delta\lambda$  at stabilization vs [SEA] for Ab-Ag@AuNPs immunoprobe. Langmuir fit was applied and the equation was added to the figure.

In addition, we were able to visualize the optical response of the immunosensors to SEA by naked-eye readout even for relatively small red-shifts (<7 nm) (see **Figure 6**). We observed a significant color change from orange to red for Ab-Ag@AuNPs suspension after addition of 200 ng/mL SEA, and remains unchanged when adding up to 500 ng/mL SEA as shown in **Figure 7A**. This confirms the predictions stated above that the LSPR band of the Ab-Ag@AuNPs was shifted in the optimal window ( $\sim 500$  nm) to yield an orange to red color change upon for naked-eye interrogation.<sup>45</sup> In the case of plasmonic Au@AgNPs, the LSPR band, after Ab grafting, was already outside the window targeted in this work. Nevertheless, SEA could be visually detected even if the color change was less evident: from red without SEA to pinkish tinge with SEA (**Figure 7B**). Thus, the elaboration of plasmonic Ag-Au core shell NPs, with well-controlled parameters (Ag@AuNPs), provide significantly better results for naked-eye toxin biosensing.

**Figure 7.** Photos of the suspensions, before and after adding SEA to Ag Au core-shell NP suspensions: the color change is visually detected from (A) orange without SEA to red with SEA for Ag@AuNPs and (B) from red without SEA to pinkish tinge with SEA for Au@AgNPs. Photos were taken after the last addition of SEA (500 ng/mL) due to the limit of *in-situ* device.

## CONCLUSIONS

Au-Ag core-shell NPs were engineered by growing a thin layer of Ag on citrate-capped AuNPs, while Ag-Au core-shell NPs were obtained by controlling the Ag reduction and deposition inside hollow gold nanoshells by nanoconfinement effect. Two immunoprobes (Ab-Au@AgNPs and Ab-Ag@AuNPs) were engineered by conjugating thiolated anti-SEA antibody to Au@AgNPs and Ag@AuNPs. These immunoprobes were applied to detect and quantify SEA by LSPR in real time using a UV-Vis spectrometer. The one step LSPR assays of SEA with Ab Au@AgNPs and Ab Ag@AuNPs bioconjugates afforded remarkable analytical performances at the ng/mL level and LOD were estimated spectroscopically to be 5.4 ng/mL (0.2 nM) and 10.6 ng/mL (0.4 nM), respectively. The benefit gained by combining Au and Ag noble metals in core-shell entities was two-fold: (1) the RI sensitivity of the NPs was shown to be higher, and (2) the wavelength window allowed visual detection of biomolecules binding by tuning the LSPR band of Au@AgNPs and Ag@AuNPs. Indeed, starting from the antibody conjugation step, the LSPR band of both core-shell NPs were markedly red-shifted. This led to the color change of the colloidal suspension, initially orange, that visually turned to red for Au@AgNPs and deep orange for Ag@AuNPs. Thus, grafting of Ab could be visualized by naked-eye. Yet, the extent of this red-shift moved the LSPR band of Au@AgNPs outside the ideal spectral window targeted in this work. Therefore, color change detectable by naked-eye was less obvious upon subsequent binding of SEA. In contrast, the LSPR band of Ab-Ag@AuNPs immunoprobe was still within the desired spectral window and the color of suspension changed from orange to red upon binding of SEA, even for similar red-shift of LSPR band. The one-step LSPR assays of SEA with Ab-Au@AgNPs and Ab-Ag@AuNPs bioconjugates afforded remarkable analytical performances at the ng/mL level and LOD were estimated to be 5.4 ng/mL (0.2 nM) and 10.6 ng/mL (0.4 nM), respectively. Finally, gold and silver core-shell NPs, and more particularly Ag@AuNPs synthesized from hollow gold nanoshells, appear to be an innovative tool in medical diagnostic and environmental monitoring, especially in situations where basic laboratory infrastructure is sparse or non-existent. Our ongoing work is to improve the specificity of these plasmonic nanoparticles in complex matrices as milk and then, expand the potential of these biosensors to other toxins/biomolecules.
