ABSTRACT

Hepatitis C virus (HCV) is a major cause of liver disease including metabolic disease, fibrosis, cirrhosis and hepatocellular carcinoma (HCC). HCV induces and promotes liver disease progression by perturbing a range of survival, proliferative and metabolic pathways within the proinflammatory cellular microenvironment. The recent breakthrough in antiviral therapy using direct-acting antivirals (DAAs) can cure >90% of HCV patients. However, viral cure cannot fully eliminate the HCC risk, especially in patients with advanced liver disease or co-morbidities. HCV induces an epigenetic viral footprint that promotes a pro-oncogenic hepatic signature, which persists after DAA cure. In this review, we summarize the main signaling pathways deregulated by HCV infection, with potential impact on liver pathogenesis. HCV-induced persistent signaling pattern may serve as biomarkers for the stratification of HCV-cured patients at high risk of developing HCC. Moreover, these signaling pathways are potential targets for novel chemo-preventive strategies.
INTRODUCTION

Hepatitis C virus (HCV) is a main cause of chronic liver disease world-wide. Chronic HCV infection causes chronic hepatic inflammation, steatosis and fibrosis, which progresses to cirrhosis and hepatocellular carcinoma (HCC) (Polaris Observatory 2017). HCC is the most common type of liver cancer and the second leading cause of cancer-related death on the globe (Baumert and Hoshida 2019). The liver is an extraordinary resistant organ with an unique regeneration capacity, but the persistent stress induced by chronic inflammation and deregulation of signaling and metabolism culminate in a >10 fold increased HCC risk in HCV-infected patients compared to HCV-negative subjects in cross-sectional and case-control studies (El-Serag 2012). The rate of HCC among HCV-infected persons ranges from 1–3% and the interval from infection to HCC has been estimated to be ~30 years (Thrift et al. 2017). It is believed that a combination of direct (viral proteins) and indirect (chronic inflammation, deregulated signaling) factors are responsible for HCV-induced liver disease development and progression. Due to the absence of a latent phase in the viral life cycle or any DNA integration event, HCV must ensure an optimal condition to maintain its replication (Lupberger et al. 2019) and to escape from the host innate immune response (Gale and Foy 2005). In this review we summarize the main pathways that are deregulated during chronic HCV infection, which are relevant for the development and progression of HCV-induced liver disease and HCC. Some of these pathways remain deregulated in HCV-cured patients, serving as potential biomarkers for the identification of risk patients and novel drug targets for chemo-preventive clinical strategies.

HCV-induced chronic inflammation, fibrosis and cirrhosis

Inflammation is a life-preserving process to maintain cellular homeostasis. It is mostly activated in response to pathogens or tissue injury and is part of a physiological recovery response. The liver harbors a large spectrum of immune cells distributed within the hepatic compartments (Freitas-Lopes et al. 2017). This organ is constantly exposed to external signaling from commensal molecules and produces a series of neo-antigens derived by its metabolic activities. This leads to the development of a constant and physiological immunotolerance state in the organ (Jenne and Kubes 2013), which was first recognized by Calne and co-workers in 1969 (Calne et al. 1969). The relative immunotolerance in the liver is necessary to avoid over-activation of the immune system but it also facilitates the adaptation and persistence of different liver pathogens, such as malaria, hepatitis B virus (HBV) and HCV (Horst et al. 2016). HCV has developed several strategies to evade the innate and adaptive antiviral responses to infection (Gale and Foy 2005; Rosen 2013). Consequently, failure of viral clearance promotes a chronically inflamed liver that leads to scarification (fibrosis), cirrhosis, and ultimately
provokes the development of HCC. According to the World Health Organization (www.who.int), most of the HCV-infected patients do not achieve viral clearance and 60-80% develop chronic hepatic inflammation. In these patients, the risk of developing cirrhosis is around 15-35% after 20-30 years of infection (Thrift et al. 2017). The virus directly accelerates the inflammatory response through a large range of interconnected mechanisms, including pathogen pattern recognition, host-viral proteins interactions, activation of inflammasomes and reactive oxygen species (ROS) production (Gale and Foy 2005; Horner and Gale 2013; Negash et al. 2019). Liver diseases and fibrosis associated to HCV infection evolve in the context of a strong oxidative microenvironment. HCV core, E1, E2, NS3, NS4B and NSSA are known to encourage the production of ROS (Bureau et al. 2001; Pal et al. 2010; Ivanov et al. 2011). The antioxidant defense machine involves different ROS scavenging enzymes and their synthesis depends on many genes commonly regulated by the transcription factor NF-E2-related factor 2 (Nrf2) (Bureau et al. 2001). Nrf2 expression is inversely correlated with the severity of liver injury in chronic HCV patients and is impaired in end-stage liver disease (Kurzawski et al. 2012; Jiang et al. 2015). In HCV-positive cells, free Nrf2 is trapped at the replicon complexes and is therefore prevented from its entry into the nucleus (Medvedev et al. 2017). This observation is in line with impaired expression levels of anti-oxidative enzymes like catalase (Lupberger et al. 2019) and superoxide dismutase SOD1 (Levent et al. 2006; Diamond et al. 2012) in infected hepatocytes, which further promote oxidative stress damaging host proteins, lipids and DNA. This coincides with a perturbed endogenous DNA repair by HCV infection (Nguyen et al. 2018; Lupberger et al. 2019) further contributing to the development of HCC in HCV patients. Since ROS-induced lipid peroxidation hampers viral membrane fusion, HCV has developed strategies to divert oxidative stress, for example by the modulation of phospholipid hydroperoxide glutathione peroxidase (GPx4) (Brault et al. 2016). Importantly, ROS levels strongly promote liver fibrosis, characterized by an excessive production of extracellular matrix (ECM) and scarring of the tissue (Luangmonkong et al. 2018). At the same time, ROS stimulates pro-oncogenic signaling pathways, promoting cell survival, proliferation and angiogenesis (Zhang et al. 2016). Chronic inflammation is accompanied by elevated plasma level of pro-inflammatory cytokines, such as tumor necrosis factor alpha (TNF-α), which are further induced by HCV proteins NS3, NS4 and NS5 (Hosomura et al. 2011; Alhettheel et al. 2016). The levels of liver and blood cytokines are associated with HCV microenvironment and liver fibrosis (de Souza-Cruz et al. 2016). In particular, Interleukin-1 alpha (IL-1α) is increased in HCV patients and correlates with liver cirrhosis and HCC (Tawfik et al. 2018). Therefore, HCV-induced cytokine signaling increases the oncogenic pressure within the host cell and contributes to a recalibration of hepatocyte functions (Figure 1).
HCV sustains Hedgehog signaling pathway and promotes fibrogenesis

The Hedgehog (Hh) pathway regulates liver development and differentiation and is a critical modulator of adult liver repair (Ingham and McMahon 2001; Machado and Diehl 2018). Interestingly, stimulation of Hh pathway results in increased permissiveness for HCV replication in cell culture (Choi et al. 2011). HCV activates Hh signaling during fibrogenic repair of liver damage and increases the production of Hh ligands in HCV-infected cells (Pereira Tde et al. 2010). Complementary studies confirm that HCV derived from the sera of HCV-infected patients stimulates Hh signaling in human primary fibroblasts via activation of zinc finger protein GLI2 transcription factor. Especially, GLI2 inhibits autophagy in fibroblasts and thus forcing their conversion into myofibroblasts, which promotes fibrogenesis (Granato et al. 2016). The increase in Hh ligands may additionally be sustained by the accumulation of liver damage markers, such as epithelial growth factor (EGF), transforming growth factor-beta (TGF-β) and platelet-derived growth factor (PDGF) (Stepan et al. 2005; Jung et al. 2008; Omenetti et al. 2008), creating a persistent proliferative and anti-apoptotic environment in the infected liver.

HCV modulates activation of the TGF-β pathway

TGF-β has a key role in fibrogenesis and it is involved in all the stages of liver disease progression (Dooley and ten Dijke 2012; Fabregat et al. 2016). The TGF-β superfamily includes pleiotropic growth factors that are essential for embryonic development and organ homeostasis. TGF-β is responsible for cell proliferation, differentiation and migration during embryogenesis, while it is involved in tissue regeneration, cell growth control and remodeling throughout adulthood. Under certain conditions TGF-β1 is also involved in the induction of apoptotic cell death in the liver (Oberhammer et al. 1992). The TGF-β cytokine is physiologically sequestered in the ECM as part of latent complexes and it is released in response to different environmental perturbations (Xu et al. 2018). This cytokine triggers downstream signaling through the activation of canonical and non-canonical pathways. First, TGF-β mediates the formation of a heterotrimeric complex of type I and type II serine/threonine kinase receptors, which phosphorylate receptor-associated SMAD (R-SMADs) proteins. The trimeric complex formed by R-SMADs (Smad2 and Smad3) and Smad4 enters the nucleus and regulates gene expression (Miyazawa et al. 2002). Secondly, TGF-β triggers other signaling pathways, such as mitogen-activated protein kinase (MAPK) and transforming protein RhoA cascades, even in absence of SMADs activation (Yu et al. 2002; Derynck and Zhang 2003). In addition, both canonical and non-canonical signaling pathways can be modulated by TGF-β in order to tightly control epithelial to mesenchymal transition (EMT) (Bhowmick et al. 2001; Katsuno et al. 2019), which is a physio-pathological program implicated in liver disease progression (Thiery and Sleeman 2006). TGF-β1 triggers hepatic fibrosis and cirrhosis in both animal models and human hepatic disorders (Castilla et al. 1991; Bedossa et al. 1995;
Sanderson et al. 1995), and thus most evidently also play an important role during HCV pathogenesis. Several studies and clinical observations highlighted a clear correlation between TGF-β and chronic HCV infection (Nelson et al. 1997; Grungreiff et al. 1999; Ray et al. 2003; Chen et al. 2017). TGF-β plasma levels are associated with high degree of hepatic fibrosis in patients with chronic HCV (Tsushima et al. 1999; Flisiak et al. 2002). Notably, HCV core protein seems to upregulate the transcription of TGF-β (Taniguchi et al. 2004). HCV induces TGF-β1 via endoplasmic reticulum stress activation and the unfolded protein response (UPR) (Chusri et al. 2016). Additionally, in vitro studies demonstrated that HCV-induced oxidative stress indirectly regulates TGF-β1 expression through p38 MAPK, c-jun N-terminal kinase (JNK), and extracellular signal-regulated kinase (ERK) via nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) signaling (Erhardt et al. 2002; Lin et al. 2010). More recent studies observed decreased TGF-β1 levels in the serum of chronic HCV-infected patients that achieved sustained virologic response (SVR) after antiviral treatment (Janczewska-Kazek et al. 2006; Kotsiri et al. 2016). Therefore, uncovering the role of HCV proteins in TGF-β signaling pathway may contribute to understand the mechanisms involved in HCV-induced HCC. Indeed, HCV core and NS3 have been shown to interact with Smad3 in vitro and in vivo (Cheng et al. 2004). Interestingly, some HCV core variants isolated from HCC tissue interact with Smad3 and inhibit TGF-β signaling. According to this study, a possible selection of viral variants during chronic HCV infection gradually promotes anti-apoptotic effects in the liver that overcome the initial antiproliferative functions of TGF-β (Cheng et al. 2004). Hence, although TGF-β may have pro-apoptotic effects during the early stage of chronic liver disease, it probably acquires pro-cancerogenic responses afterwards HCV core variants selection (Pavio et al. 2005; Battaglia et al. 2009).

**HCV-induced IL-6/STAT3 signaling**

Signal transducer and activator of transcription 3 (STAT3) is involved in tissue repair mechanisms by the regulation of proliferative and pro-survival cellular programs. In this context, activation of STAT3 can be induced by a vast number of different cytokines, including Interleukin-6 (IL-6), which sensitizes hepatocytes to regenerative signals (Michalopoulos 2007). Beyond its physiological role, persistent activation of STAT3 induces chronic inflammation and fibrosis, increasing the risk to develop severe pathological conditions (Yu et al. 2014; Kasembeli et al. 2018). HCV requires IL-6/STAT3 signaling to maintain infection (Lupberger et al. 2013; McCartney et al. 2013), therefore it induces its activation by several mechanisms. HCV core directly binds and sustains STAT3 activation (Yoshida et al. 2002), while the expression of NS5A, E1 and NS3 promotes STAT3 signaling indirectly via ROS production (Gong et al. 2001; Machida et al. 2006). The activation of STAT3 is not limited to HCV-infected hepatocytes. miR-19a secreted in endosomes from HCV-infected hepatocytes impairs suppressor of cytokine signaling 3 (SOCS3) in hepatic stellate cells (HSCs). As a negative regulator of STAT3, impaired SOCS3
levels cause a subsequent activation of TGF-β in HSCs (Devhare et al. 2017). Therefore, considering the pro-fibrotic role of STAT3 signaling and its strong cooperation with the TGF-β pathway, it has been suggested as a potential target for anti-fibrotic therapies (Chakraborty et al. 2017).

**HCV increases cancer risk by deregulation of oncogenic signaling pathways**

The liver is a key organ for the detoxification and metabolism of a wide range of potentially harmful substances. Therefore, liver regeneration is a tightly controlled process (Cordero-Espinoza and Huch 2018) that converge in the reconstruction of hepatocyte parenchyma in response to damage. The replacement of the damaged tissue occurs mainly through hepatocyte proliferation and to a lesser extent via an activation of ductal progenitor cells. During regeneration, the HSCs differentiate in myofibroblasts that release ECM within the space of Disse. Under normal conditions, the excess of ECM is promptly degraded by metalloproteinases (MMPs), which restore the original architecture and function of the tissue without scar formation (Kholodenko and Yarygin 2017). During chronic inflammation this balance is perturbed, which leads to a progressive deposition of ECM and the development of liver fibrosis. HCV infection causes oxidative stress, steatohepatitis and fibrosis, which create an hepatic pro-oncogenic environment. The oncogenic pressure on the diseased liver is further promoted by virus-induced growth factors and signaling pathways such as EGF, vascular endothelial growth factor (VEGF) and Wnt/β-catenin are strongly implicated in the cirrhotic remodeling of the tissue and hepatocarcinogenesis (Fuchs et al. 2014; Wang et al. 2018a; Moon et al. 2019). As a consequence, patients affected with HCV-associated cirrhosis present a 4-5% cumulative annual incidence of HCC (El-Serag 2012).

**HCV upregulates EGFR and stimulates MAPK signaling**

The growing knowledge on the interplay between HCV and epithelial growth factor receptor (EGFR) cascade has markedly contributed to explain the pathologic consequences of the viral infection, such as fibrosis development and HCC (Lupberger et al. 2011; Lupberger et al. 2013; Fuchs et al. 2014; Roca Suarez et al. 2018). It has been demonstrated that EGFR signaling promotes the formation of the cluster of differentiation 81 (CD81)/claudin1 (CLDN1) co-receptor complex, which is required for HCV entry (Harris et al. 2010; Krieger et al. 2010; Lupberger et al. 2011; Zona et al. 2013). Inhibition of EGFR kinase hampers the CD81/CLDN1 co-receptor association and thus prevents HCV particle entry (Lupberger et al. 2011). The physical link between EGFR kinase and CD81/CLDN1 interaction is mediated by GTPase HRas, activated downstream of the EGFR signaling (Zona et al. 2013). HCV has an interest in maintaining EGFR signaling and elevated EGFR signaling is observed in liver biopsies of HCV patients (Mailly et al. 2015). EGFR signaling is further prolonged by a NS5A-induced retention of
activated EGFR in the early endosomal compartment (Mankouri et al. 2008) and by an increasing level of Netrin-1, that impedes EGFR recycling (Plissonnier et al. 2016). Furthermore, NS3/4A protease mediates the downregulation of T-cell protein tyrosine phosphatase (TC-PTP), which is negative regulator of EGFR and MAPK signaling (Brenndorfer et al. 2009; Stanford et al. 2012). The activation of EGFR during HCV infection induces MAPK signaling (Hayashi et al. 2000; Burckstummer et al. 2006; Mankouri et al. 2008; Diao et al. 2012), an evolutionary-conserved mechanism of cellular transduction that regulates many vital cellular functions, such as proliferation, differentiation, survival and apoptosis (Zhang and Liu 2002; Dhillon et al. 2007). EGFR is overexpressed in ~50% of patients with chronic HCV and in most patients with cirrhosis and HCC. The extent of EGFR expression is even higher in the advanced stages of HCV-related fibrosis (Badawy et al. 2015). These observations have a potential clinical application since EGF is a major driver of liver disease progression and inhibition of EGFR signaling using clinical compounds in animal models attenuates the development of liver fibrosis and HCC nodules (Fuchs et al. 2014).

**HCV upregulates VEGF and promotes angiogenesis**

Angiogenesis is a growth factor-dependent program responsible of the formation of new vessels from pre-existing ones. It is commonly induced in response to hypoxia-related and inflammatory mechanisms (Paternostro et al. 2010). Hepatic angiogenesis is triggered by HCV via the deregulation of multiple pathways (Hassan et al. 2009). Several studies have demonstrated an upregulation of VEGF in HCV-related HCC patient tissues (Llovet et al. 2012; Mukozu et al. 2013). The HCV core protein seems to sustain VEGF signaling by several mechanisms. It can lead to hypoxia inducible factor 1 (HIF-1α) stabilization, which consequently upregulates VEGF expression (Shimoda et al. 1999; Abe et al. 2012; Zhu et al. 2014). Additionally, HCV-mediated VEGF expression seems to engage also Janus kinase (JAK)/STAT signaling. Indeed, the inhibition of the JAK/STAT pathway in cell culture blocks the HCV core protein-mediated activation of the androgen receptor (AR) causing a downregulation of VEGF (Kanda et al. 2008). HCV core protein potentiates VEGF expression by the activation of activator protein 1 (AP-1) transcription factor, which is binding to the VEGF promoter region (Shao et al. 2017).

**HCV induces β-catenin accumulation and Wnt pathway activation**

Wnt pathway is crucial for embryonic development and cellular differentiation (Kielman et al. 2002; Reya and Clevers 2005; Grigoryan et al. 2008; Bone et al. 2011). When Wnt signaling is active, β-catenin phosphorylation is reduced via the inhibition of the β-catenin destruction complex (Behrens et al. 1998; Amit et al. 2002; Liu et al. 2002). The augmented unphosphorylated β-catenin migrates from the cytoplasm to the nucleus, where it binds to T cell factor (TCF) and promotes transcription of genes such as *Cyclin D1* (Tetsu and McCormick 1999), *c-MYC* (He et al. 1998), *Axin-2* (Jho et al. 2002), and *c-Jun*.
In cell culture, NS5A triggers the serine/threonine-protein kinase Akt, by interacting with phosphoinositide 3-kinases (PI3K). Consequently, this leads to an inhibition of glycogen synthase kinase-3 beta (GSK-3β), which is a key component of the destruction complex (Street et al. 2005). Moreover, NS5A stabilizes β-catenin in the cytoplasm and therefore promotes β-catenin signaling, which is also reflected in elevated β-catenin levels in livers of HCV patients (Park et al. 2009). This is very relevant for liver pathogenesis since β-catenin is most frequently activated in HCC pathogenesis (Khalaf et al. 2018). NS5A-induced stabilization of β-catenin transcription factor stimulates c-Myc expression in cell lines, human liver tissues and livers from FL-N/35 transgenic mice (Colman et al. 2013; Higgs et al. 2013). c-Myc is an essential regulator of liver regeneration and its perturbation is considered as an early event during HCC development (Colman et al. 2013). Moreover, HCV-induced c-Myc expression drives the metabolic shift from glucose to glutamine dependence, which is a hallmark of cancer cells (Levy et al. 2017).

**HCV infection alters liver metabolism**

The liver plays an essential role in the metabolic regulation during both post-prandial period and fasting state. The energetic balance of the organism is finely maintained by a series of biochemical reactions involved in metabolism, storing and redistribution of carbohydrates, proteins and lipids (Bechmann et al. 2012). HCV circulates in the serum of patients as lipo-viro-particles and interacts with very low-density lipoprotein (VLDL) components of the host. The striking association between the HCV life cycle and the VLDL pathway is not only crucial for HCV entry, maturation and morphogenesis, but has also an impact on the immune escape capacity of the virus (Miyanari et al. 2007; Gondar et al. 2015). Importantly, the interplay between the virus and metabolic pathways contributes to the pathogenesis of liver disease via deregulation of the host lipid metabolism (Syed et al. 2010). HCV infection is strongly associated with hepatic steatosis and dysmetabolic syndromes, such as hypocholesterolemia, altered body fat distribution, insulin resistance (IR) and hyperuricemia (Kralj et al. 2016). Estimates suggest that around 55% of HCV-infected patients develop hepatic steatosis, which is defined as an excessive accumulation of triglycerides (TGs) within the hepatocyte cytoplasm (Lonardo et al. 2006; Vilgrain et al. 2013). Although this has been observed for several HCV genotypes, steatosis is most frequent and severe in patients infected with genotype 3 (Leandro et al. 2006), which correlates with the viral load (Rubbia-Brandt et al. 2001). HCV-induced steatosis is triggered by the interaction between HCV proteins and host factors and its development does not require the presence of visceral obesity (Adinolfi et al. 2001). HCV infection deregulates metabolic pathways via miR-146a-5p expression, probably dependent on NF-kB signaling (Bandiera et al. 2016). Beside this, it
has been suggested that HCV core protein expression may be sufficient to induce liver fat accumulation and steatosis (Moriya et al. 1997). In particular, core protein 3a induces the activation of miR-21-5p and thereby promoting HCV replication and steatosis (Clement et al. 2019). An important factor in lipid homeostasis is the beta-oxidation of fatty acids in mitochondria and the peroxisomal compartment. HCV infection suppresses peroxisomal beta-oxidation, which leads to the accumulation of very-long chain fatty acids (VLCFAs) in the infected hepatocytes (Lupberger et al. 2019). This is partially mediated by HCV-induced STAT3 signaling (Van Renne et al. 2018), suppressing the peroxisome proliferator-activated receptor alpha (PPARα) expression (Lupberger et al. 2019). These results are consistent with decreased hepatic PPARα levels in HCV infected patients (Dharancy et al. 2005). Importantly, HCV antiviral therapy can restore lipidic levels in serum (Batsaikhan et al. 2018; Doyle et al. 2019) and attenuate hepatic steatosis after viral clearance (Shimizu et al. 2018). However, many genes relevant for metabolism remain deregulated even after viral cure (Hamdane et al. 2019), including peroxisomal genes. Restoration of peroxisomal function may be therefore a clinical strategy to improve liver function in HCC risk patients. Notably, HCV genotype 3 infection is associated with the downregulation of phosphatase and tensin homolog deleted on chromosome 10 (PTEN) leading to decreased levels of insulin receptor substrate 1 (IRS1) and the formation of large lipid droplets (Clement et al. 2011). This is relevant for the viral life cycle and liver disease progression since PTEN overexpression has been shown to reduce HCV viral particle secretion (Peyrou et al. 2013) and it is one of the most important tumor suppressors frequently mutated in many tumors, including HCC (Schulze et al. 2015). PTEN is also an important regulator of insulin pathway and HCV infection perturbs the glucose homeostasis in the liver. Epidemiological studies suggest a link between chronic HCV infection and diabetes type 2 (Shintani et al. 2004; Gastaldi et al. 2017) and HCV core transgenic mice develop IR (Shintani et al. 2004). This is accompanied by a marked reduction in insulin-stimulated Akt phosphorylation without any alterations in MAPK activity in HCV-infected subjects (Aytug et al. 2003). HCV proteins upregulate the protein phosphatase 2 alpha (PP2A) catalytic subunit and alter signaling pathways controlling hepatic glucose homeostasis by inhibiting Akt and dephosphorylation of FoxO1 (Bernsmeier et al. 2008; Bernsmeier et al. 2014). Importantly, DAA treatment improves glycemic control and IR in livers, muscles and adipose tissues of HCV cured patients (Adinolfi et al. 2018; Lim et al. 2019).

**HCV-induced liver disease - Is there a point of no return?**

Since the discovery of HCV in 1989, there has been a remarkable breakthrough in the antiviral therapy using DAAs. Meanwhile, >90% of patients can be cured by interferon-free treatments (Chung and Baumert 2014) (Arends et al. 2016). However, in patients with advanced liver disease the risk of mortality and HCC development cannot be fully eliminated (Carrat et al. 2019). It has been estimated
that HCV-induced HCC will remain one of the major health burdens for the next decades (Harris et al. 2014; Sievert et al. 2014; Petrick et al. 2016; Baumert et al. 2017). This also raises the question whether some of the HCV-induced pro-oncogenic signaling pathways remain deregulated after viral cure. Indeed, HCV infection causes epigenetic alterations which act as genetic circuits that influence gene expression pattern in the long term. DNA hyper-methylation has been observed in livers of patients with chronic HCV infection leading to a silencing of tumor suppressor gene expression (Wijetunga et al. 2017). In addition, HCV induces histone modifications which also result in persistently altered gene expression pattern (Hamdane et al. 2019; Perez and Gal-Tanamy 2019). Importantly, this epigenetic footprint is still detectable in livers of HCV-cured chimeric mice and patients (Hamdane et al. 2019) (Perez and Gal-Tanamy 2019). Associated with this viral footprint, the transcriptional signature reflecting many of the earlier mentioned HCV-induced pro-oncogenic signaling pathways remains deregulated after viral cure (Hamdane et al. 2019). This may partially account for the observed elevated HCC risk. Therefore, a detailed knowledge of these pathways will be potentially useful as biomarkers to identify patients at risk and highlight potential targets for future chemo-preventive strategies.

Clinical methods to predict HCV-related fibrosis and cirrhosis and its associated HCC risk are still limited. The clinical outcome also very much depends on co-morbidities like human immunodeficiency virus (HIV)/HBV co-infection or alcohol. Yujin Hoshida and co-workers developed a prognostic liver signature (PLS) from genome-wide transcriptomics of non-tumor liver tissues adjacent from HCCs, which correlates to the clinical outcome of the patients (Hoshida et al. 2008). This has been later extended to a composite prognostic model for HCC recurrence (Villanueva et al. 2011). The PLS consists of 186 genes representing a powerful tool to predict the risk for patients to progress to cirrhosis and HCC and help prioritizing those for regular follow up and HCC surveillance. Importantly, the PLS is induced also by HCV infection (Hoshida et al. 2013; King et al. 2015). PLS components are cytokines and signaling mediators that may be useful as targets for chemoprevention of their biological impact on liver disease development.

Small molecule inhibitors targeting signaling pathway have arrived in clinical practice long time ago, especially in cancer therapy. Some of these inhibitors target pathways that are potentially involved in an HCV-induced signaling pattern and have been tested or are currently in clinical trials for the treatment of liver disease progression. Human fibrosis and HSC activation are regulated by Wnt/β-catenin signaling (Berg et al. 2010; Ye et al. 2013; Lam et al. 2014), which therefore represents a promising target for the treatment of liver fibrosis (Cheng et al. 2008). Proof-of-concept has been provided targeting the interaction of CREB-binding protein (CBP) and β-catenin using the small molecule inhibitor PRI-724. The compound hampers HSCs activation and accelerated fibrosis
resolution, which seems to be accompanied by an increased expression of MMP-2, MMP-8 and MMP-9 in intrahepatic leukocytes (Osawa et al. 2015). Currently, the safety and tolerability of PRI-724 is being evaluated in patients with HCV or HBV-associated cirrhosis (NCT03620474). Hh pathway is involved in the development of cirrhosis and HCC. Sonidegib (LDE225), a specific inhibitor of Hh is currently being tested in a phase I clinical trial for toxicity in patients with cirrhosis and advanced/metastatic HCC, who are intolerant to sorafenib (NCT02151864). In the last years, a large number of non-specific and specific TGF-β inhibitors have been developed (Giannelli et al. 2011; de Gramont et al. 2017). Despite of that, Galunisertib (LY2157299), a selective ATP-mimetic inhibitor of TGFβRI/ALK5, is the only inhibitor of TGF-β signaling currently under clinical trials in HCC patients (NCT01246986). Moreover, it seems to downregulate the expression of stemness-related genes (such as CD44 and THY1) in HCC patients (Rani et al. 2018). Receptor tyrosine kinases (RTKs), such as EGFR and vascular endothelial growth factor receptor (VEGFR), have been shown to play crucial roles in fibrogenesis, cirrhosis and HCC development, highlighting the importance of their therapeutic inhibition (Komuves et al. 2000; Yoshiji et al. 2003; Fuchs et al. 2014; Badawy et al. 2015). Ramucirumab a VEGFR-2 inhibitor, was recently evaluated as a second-line treatment for HCC patients previously treated with sorafenib, showing an improved overall survival compared to placebo (Zhu et al. 2019) (NCT02435433). STAT3 signaling pathway has shown to be upregulated during HCV infection (Yoshida et al. 2002; McCartney et al. 2013; Van Renne et al. 2018) and strong data reveal its role in fibrosis development (Chakraborty et al. 2017). A large spectrum of clinical and preclinical data supports STAT3 as pharmacological target for different typings of cancers (Laudisi et al. 2018). This has prompted substantial efforts to design and test different types of STAT3 inhibitors. Some of the potential therapeutic opportunities to target STAT3 pathway are to be found upstream its activation, at STAT3 SH2 domain and at STAT3 DNA binding domain levels. AZD1480 (NCT01219543) and AG490 inhibitors belong to the first category and inhibits JAK2 kinase (Meydan et al. 1996; Hedvat et al. 2009). The safety and tolerability of AZD1480 have been tested in a phase I study in patients with solid tumors (including HCC). However, the unusual dose limit toxicity and the lack of clinical activity brought to discontinuation in its clinical development (Plimack et al. 2013). OPB-31121, a potent SH2 domain inhibitor exerting also JAK inhibitory activity (Kim et al. 2013; Brambilla et al. 2015), has demonstrated insufficient antitumoral activity and toxicity in patients with advanced HCC (Okusaka et al. 2015). S3I-201 (NSC 74859), discovered by structure-based virtual screening (Siddiquee et al. 2007), seems to suppress HSC activation and proliferation, as well as angiogenesis and fibrogenesis in fibrotic livers (Wang et al. 2018b). A promising therapeutic agent for liver fibrosis can be represented by HJC0123, which inhibits human HSC proliferation and STAT3 dimerization (Chen et al. 2013; Nunez Lopez et al. 2016). Recently, OPB-111077 (NCT01942083) has been shown to be well tolerated in patients with advanced HCC after failure of Sorafenib therapy (Yoo et al. 2019). However, the preliminary outcomes of the OPB-111077 treatment are still very limited
(Yoo et al. 2019) and further investigation of the role of the STAT3 signaling pathway in fibrosis and HCC are required.

CONCLUSION

Studying HCV-host interactions is not only important for the understanding of the viral life cycle but also to answer how the virus manages to tweak its host cell to ensure persistence with all its consequences for liver pathogenesis. The molecular circuits exploited and triggered by HCV resemble strikingly other liver disease etiologies like non-alcoholic fatty liver disease (NAFLD) following a very similar path of disease progression. Studying HCV with all the experimental tools that have been developed during the last 30 years serves here as a powerful model to understand the specific and common mechanisms of liver disease development. This is essential to develop new diagnostic biomarkers and chemo-preventive strategies in order to help HCV cured patients with advanced liver disease to tackle the epigenetic turnouts set by decades of chronic HCV infection. These tools will be potentially very useful also for other liver disease etiologies.

Figure 1: HCV infection alters signaling pathways relevant for liver disease. HCV-mediated activation of STAT3 causes VLCFAs accumulation in the infected hepatocytes via downregulation of PPAR-α expression. STAT3 activation sustains profibrotic gene expression via upregulation of TGF-β. Downregulation of PTEN by HCV decreases IRS1 expression and the formation of large lipid droplets favoring hepatic steatosis. HCV impairs NRF2 activity and enhances the accumulation of ROS. Activation of the Hh pathway via GLI2 inhibits autophagy in HSCs favoring their conversion into myofibroblasts and the development of fibrosis. HCV infection induces ER stress triggering TGF-β expression. EGFR is activated by several mechanisms and induces MAPK signaling and the expression of genes related to fibrosis and hepatocyte proliferation. Following HCV infection, the Wnt pathway is activated and inhibits the β-catenin destruction complex. As a consequence, β-catenin migrates to the nucleus and activates c-Myc oncogene. HCV sustains VEGF via the stabilization of HIF-1α which consequently upregulates VEGF signaling and increases angiogenesis. The percentage of infected patients developing steatosis, cirrhosis or the cumulative incidence of HCC is indicated.
