Abstract

The synthesis and characterization of a preparation of the $[\text{Fe}\{(\text{SePPh}_2)_2\text{N}\}_2]\text{]_2$ complex (1$_{\text{Fe}}$) is described. X-ray crystallography shows that this system contains a tetrahedral $\text{FeSe}_4$ coordination sphere. The structural features of 1$_{\text{Fe}}$ are compared with those of similar first row transition metal complexes, including a recently reported preparation of $[\text{Fe}\{(\text{SePPh}_2)_2\text{N}\}_2]\text{]_2$ (1$_{\text{Fe}}$) exhibiting a highly unusual square planar $\text{FeSe}_4$ coordination sphere. The electronic structure of 1$_{\text{Fe}}$ was elucidated by magnetometry, high-frequency EPR, and Mössbauer spectroscopic studies, which reveal zero-field splitting (ZFS) parameters typical of high spin $S = 2$ tetrahedral $\text{Fe}^{IV}$ sites. Accurate ZFS parameters ($D = +8.22$ cm$^{-1}$, $E/D = 0.104$) were obtained by analysis of the EPR spectra and compared with those of the analogous $[\text{Fe}\{(\text{SPPh}_2)_2\text{N}\}_2]$ complex. The findings of this work call for a thorough structural and physicochemical characterization of the literature $\text{FeL}_2$ system.

Introduction

Selenium exhibits a rich and intensively investigated biological chemistry. [1] In that respect, the bioinorganic chemistry of selenium, mainly expressed via coordination of either selenocystein (Se-Cys) or selenide (Se$^2-$) to transition metals in metalloproteins or synthetic analogues, has been extensively explored. More specifically, X-ray crystallography has revealed the coordination of Se-Cys to nickel in the Ni-Se-Se hydrogenase, [2] as well as to molybdenum in the active site of formate dehydrogenase [3] and nicotinate dehydrogenase. [4] The analogues, has been extensively explored. More specifically, X-ray crystallography has revealed the coordination of Se -Cys to nickel in P$_2$P(E)NHP(E) backbone, has afforded the following structurally characterized homoleptic transition metal ions, like the [4Fe-4S] cluster of [FeFe] -hydrogenase, [12] the iron protein of nitrogenase, [13] the photosystem I polypeptide PsaC, [14] aconitase, [15] high potential iron-sulfur protein, [16] as well as [2Fe-2S] [17] and 2[4Fe-4S] ferredoxins. [18] As far as synthetic bioinorganic chemistry of selenium is concerned, a range of multinuclear clusters containing iron coordinated to Se$^2-$ and various thiols, [19] as well as tungsten-iron-sulfur/seelenium clusters, [20] have been investigated by Holm and co-workers. The coordination of selenium to transition metals has been also explored by employing the so called dithalogenodiimidodiphosphinato ligands, $R_2P(E)NHPP(E')R'_2$ (E, E' = O, S, Se, Te; R, R' = alkyl or aryl groups). [21] Among this family of chelating ligands, $L = [\text{Ph}_2P(\text{Se})\text{N}(\text{Se})\text{Ph}_2]^{-}$, [22] containing E = E' = Se as donor atoms, and R = R' = Ph as peripheral groups bonded to the P atoms of the P–N–P backbone, has afforded the following structurally characterized homoletic complexes with first series transition metal ions (structures deposited in the Cambridge Structural Database, CSD [23]): octahedral $M^{IV}L_3$, $M = V$, [24] Cr, [24] tetrahedral $M^{IV}L_2$, $M = Mn$, [25] Co, [26] Zn, [27] square planar $Ni^{II}L_2$, [28] and tetranuclear $[\text{Cu}_2L_2]BF_6$. [29]
With respect to the coordination of $[\text{Ph}_2P(\text{Se})\text{N}(\text{Se})\text{Ph}_2]$ to $\text{Fe}^{III}$, it should first be noted that the following literature complexes have been shown, by X-ray crystallography, to unequivocally contain a tetrahedral $\text{FeSe}_4$ coordination sphere: $[\text{Ni}(\text{CH}_3\text{CH}_2)_2][\text{Fe}(\text{SePh})_4]$, [30] $[\text{Fe}(1,10-\text{phen})][\text{Fe}(\text{SePh})_4]$, [31] $[\text{Fe}((\text{SePPh}_2)_2\text{N})_2]\text{]_2}$, $[\text{Ni}(\text{CH}_3\text{CH}_2)_2][\text{Fe}(\text{SeCICH}_3)_4]$, [32] $[\text{bis}(1,3\text{-di-t-butyl-1H-imidazol-3-ium})][\text{Fe}(\text{SePh})_4]$, [33] $[\text{Fe}\{(\text{SePPr}_2)_2\text{N}\}_2]$ [34] and $[\text{Fe}(\text{dmise})_4][\text{BF}_4]_2$. dmise = N,N'-dimethylimidazol selone. [35] In addition, on the basis of spectroscopic and room temperature magnetometry studies, the $[\text{Fe}(\text{SePh}_2)\text{CH}_2]$ complex, bearing a ligand which is similar to L, has been proposed to also contain a tetrahedral $\text{FeSe}_4$ core. [36] Based on the above, the recently reported crystal structure of a preparation of $\text{FeL}_2$ containing a square planar $\text{FeSe}_4$ coordination sphere ($\text{I}_{\text{Fe}}$), $[\text{N}(\text{CH}_3\text{CH}_2)_2][\text{Fe}(\text{SePh})_4]$, [37] and $[\text{Fe}(\text{dmise})_4][\text{BF}_4]_2$. dmise = N,N'-dimethylimidazol selone. [38]
X-ray crystallography revealed that our preparation of FeL₂ (1Td), presented herein, exhibits clearly a tetrahedral FeSe₄ coordination sphere. The magnetic and spectroscopic properties of 1Td were investigated by magnetometry, as well as by IR, high-frequency EPR and Mössbauer spectroscopies. Comparisons are being made with the properties of 1SP, [25] Fe{(SePPPr₂)₂N}²⁺ and [Fe{(SePPh₂)₂N}]²⁻ complexes. Recent high-frequency EPR studies of the latter have revealed distinct S = 2 Fe²⁺ sites, the spin-Hamiltonian parameters of which have been accurately determined. [29] This complex is a synthetic analogue of the reduced form of the iron-sulfur protein rubredoxin, which contains a [Fe{(S-Cys)}₂] active site. [24] To our best knowledge, replacement of the iron-coordinating Cys residues of rubredoxin by Se-Cys has not yet been reported.

In the following, the interplay between literature tetrahedral and square planar FeII complexes, including their spin states and Mössbauer spectroscopic signatures, is analyzed. Moreover, the effects on the D (axial) and E (thombic) zero-field splitting (ZFS) components of Fe⁡II coordination to [Ph₂P(Se)NP(Se)Ph₂]⁻, as opposed to [Ph₂P(NP)(Se)Ph₂]⁻, in a similar tetrahedral S = 2 Fe²⁺ site, E = S, Se, are also discussed.

Results and Discussion

Chemical Synthesis. Complex 1Td was synthesized by mixing FeCl₂ and the [[(SePPh₂)₂N]²⁻] ligand, under anaerobic conditions, in order to minimize the formation of byproduct Fe³⁺ species. A different preparation of the same complex (1SP) has been recently reported. [34] The proposed crystal structure of 1SP, containing a square planar FeSe₄ coordination sphere, will be compared, in the following, with that of the present complex 1Td.

X-ray crystallography and IR spectroscopy. The molecular structure of 1Td is shown in Fig. 1. The crystal data, as well as the refinement statistics, of the structure of 1Td are listed in Table S1 (Supporting Information). Selected bond lengths and angles of 1Td are listed in Tables S2 and S3, respectively.

The FeSe₄ core of complex 1Td exhibits a distorted tetrahedral geometry, as reflected by the magnitude of the Se-Fe-Se angles which lie between 101.7(1)° and 115.7(1)° (Table S2). The two endocyclic Se-Fe-Se bite angles amount to 115.7(1)° and are similar to those of the [Fe{(SePPPr₂)₂N}]²⁺ and [M{Se(PPPr₂)₂N}]²⁻, M = Mn, Co, Zn [27] complexes listed in Table 1. The dihedral angle between the planes defined by the endocyclic Se-Fe-Se angles of complex 1Td is 86.7°, comparable to those of the [M{(SePPh₂)₂N}]²⁻, M = Mn, Co, Zn, complexes (Table 1). The significantly smaller values, 81.3° and 82.4°, respectively, for the sites 1 and 2 of the recently reported [Fe{(SePPPr₂)₂N}] complexes reveal a more profound deviation from the value (90.0°) of the ideal tetrahedral structure, apparently imposed by the Π peripheral groups of the ligand. In addition, the latter structure exhibits a different space group compared with the rest of those listed in Table 1. The FeSePNPSe rings in the structure of 1Td adopt a pseudo-boat conformation, with the P and Se atoms at the apices, in agreement with the structure of the analogous Mn, Co, Zn complexes (Table 1).

The averaged P–Se and P–N bond lengths of Ph₂P(Se)NHP(Se)Ph₂ and 1Td are listed in Table 2. Close inspection reveals that the average P–Se bond length of 1Td is increased compared with that of the ligand, whereas the opposite trend is observed for the average P–N bond length. These observations are in agreement with the findings based on the IR spectra of Ph₂P(Se)NHP(Se)Ph₂ and complex 1Ted. The IR spectrum of the former contains characteristic bands, which are attributed to ν(SeSe) (595, 546) and νₐ(PNP) (937, 926, 918) stretching vibrations, respectively. [23] On the other hand, in the IR spectrum of complex 1Td the bands observed at 534 and 1203 cm⁻¹ are assigned to ν(SePSe) and νₐ(PNP) stretching vibrations, respectively. The aforementioned IR data are compatible with an increase of the P–N bond order and a decrease of the P–Se bond order, upon coordination of the ligand to Fe. This trend has been observed before for similar metal complexes and is thought to be caused by the delocalization of π-electron density over the ligand framework upon its coordination to the metal center. [24-25] The bond-order shifts suggested by the above IR data, confirm the structural differences between Ph₂P(Se)NHP(Se)Ph₂ and complex 1Td observed by X-ray crystallography (vide supra). It should be noted that similar ν(PSe) and νₐ(PNP) stretching vibrations, respectively, have been reported for tetrahedral [M{(SePPPr₂)₂N}]²⁻, M = Mn (536, 1205), [23] Co (545, 1199) [26].

The average value of the four non-equivalent Fe–Se bond lengths of complex 1Td is 2.48 Å (Table 2), which is within the corresponding values observed for tetrahedral FeSe₄-containing complexes identified in the CSD [21], [N(CH₃)₂]Fe{(SePPh₂)₄} (2.46 Å), [Fe(1,10-phen)₂]Fe{(SePPPr₂)₂N} (2.46 Å), [PPPr₂N]Fe{(SePPPr₂)₂N} (2.45 / 2.43 Å), [N(CH₃)₂]Fe{(SeP(CH₃)₂)₂N} (2.47 Å) [31] [bis(1,3-di-t-butyl-1H-imidazol-3-ium)]₂[Fe{(SePPPr₂)₂N}]²⁻ (2.45 Å), Fe{(SePPPr₂)₂N}]²⁻ (2.47 Å) [35] and Fe{(dmise)₂N}]²⁻, dmise = N,N'-dimethylimidazolone selone (2.46 Å). [36] The recently reported structure of 1SP surprisingly contains a square planar FeSe₄ coordination sphere. [39] This structure exhibits significantly larger average Fe–Se bond lengths (2.65 and 2.66 Å for its two sites, Table 2), compared with those of complex 1Td and the above tetrahedral FeSe₄-containing complexes. These larger bond lengths are very similar to those of the initially suggested square planar [Sn{(SePPPr₂)₂N}]²⁻ complex (S.P. SnSe₄, CSD code ZOPGEQ), [22] as well as to structurally characterized [Se{(SePPPr₂)₂N}]²⁻ (CSD GEFHUK) [27] (Table 2). In addition, the unit cell parameters of the FOMWIP, ZOPGEQ and GEFHUK structures, listed in Table S4, are rather similar. It should be stressed that an earlier report that the [Sn{(SePPPr₂)₂N}]²⁻ complex contains a square planar SnSe₄ coordination sphere [27] has been extensively discussed, with suggestions that the reported crystal structure is due to crystals of [Se{(SePPPr₂)₂N}]²⁻, presumably formed as a side-product during the synthesis of the Sn⁴⁺ complex. [43] Attention should also be given to the fact that the cif file of the 1SP FOMWIP structure, [38] deposited in the CSD, [23] reports large calculated positive residual density on the Fe₂ atom, which could be attributed to occupation of metal of the site by the heavier Se atom.

It is of interest that square planar FeO₄ sites have been found in solid state structures, [34] including the rare mineral gillespite (BaFe₄Si₂O₈) [29] and a catalytically active Fe⁶⁺ zeolite site converting methane to methanol. On the other hand, only a handful of molecular Fe⁴⁺ systems contain square planar FeO₄ [46, 47] or Fe₈N₄Cl₄ [48] coordination spheres, which are qualified as highly unusual. The above systems have been shown to contain high spin, S = 2, sites, exhibiting unique Mössbauer spectroscopic signatures (vide infra).

Square planar complexes of Fe⁴⁺ containing intermediate spin, S = 1, sites, have also been reported (and references therein). In addition, Fe³⁺-porphyrins contain square-planar FeO₄ coordination spheres exhibiting various spin states. [39] Complex 1SP has not been studied by either magnetometry or by any spectroscopic method. On the other hand, the spin state (S = 2) and tetrahedral geometry of 1Td reported herein is strongly supported by magnetometry and high-frequency EPR / Mössbauer spectroscopy (vide infra).

Based on the above observations, the FOMWIP square planar FeSe₄ structure of 1SP needs to be re-examined, with respect to the possibility that it is due to crystals of [Se{(SePPPr₂)₂N}]²⁻ formed as a by-product under the reaction conditions employed for its
Although it is not possible to assess the validity of the deposited FOMWIP cif file, it is of interest that issues concerning the reliable validation of a CSD-deposited cif file have been recently raised. In addition, complex 1SP should also be investigated by magnetometry and spectroscopic methods, in order for its magnetic properties to be assessed in detail.

It is of interest that a case of stereoisomerism in a four-coordinate 3d metal complex has been observed for [Ni(SePiPr₂N)₂], which has been shown to afford discrete crystals containing tetrahedral and square planar Ni₄Se₄ coordination spheres. In this case, the square planar isomer exhibits shorter Ni−Se bond lengths, compared with those of the tetrahedral one, in agreement with expectations from ligand field theory for complexes containing a d⁸ metal center like Ni⁺. Similar arguments have been put forward for tetrahedral and square planar organometallic complexes of Fe⁺. The fact that 1SP exhibits significantly larger Fe−Se bond lengths than 1Td needs to be further discussed, once the spin state of 1SP has been unequivocally determined.

Magnetometry. The temperature dependence of the magnetic susceptibility $\chi_M$ of $1_{1Td}$, plotted as $\chi_M T$ vs $T$ recorded under a Direct Current (DC) field of 1 T, is shown in Fig. 2. At high temperatures, the value of $\chi_M T$ is 3.59 cm$^3$/mol K, which is consistent with an $S = 2$ species exhibiting $g > 2.0$. Upon cooling, the $\chi_M T$ product exhibits a very progressive and linear decrease down to 100 K. Upon further cooling, the decrease becomes more pronounced, reaching 1.19 cm$^3$/mol K at 2 K. We attribute this behavior to the combined effects of magnetization saturation under the influence of the magnetic field due to Zeeman interactions and to ZFS effects. To better study the ZFS contributions, we carried out isothermal magnetization studies at 2, 3 and 5 K, which we plot as $M$ vs $HT^{-1}$ in the inset of Figure 2.

Simultaneous fits were carried out on the $\chi_M T$ vs $T$ and the $M$ vs $HT^{-1}$ data, using the spin Hamiltonian in Equation (1)

$$H = D[S_z^2 - S(S+1)/3] + E(S_x^2 - S_y^2) + \beta g B$$

(1)

in which $D$ and $E$ are, respectively, the axial and rhombic components of ZFS, $\beta$ is the Bohr magneton and B is the external magnetic field. For the analysis of the magnetic data, the $g$-tensor is assumed isotropic.

Models considering $D > 0$ and $D < 0$, as well as $E = 0$ and $E \neq 0$, were examined, corresponding to four different solutions. Best-fit parameters were $g_{iso} = 2.14$, $D = +7.9$ cm$^{-1}$, $E = +1.1$ cm$^{-1}$, TIP (Temperature Independent Paramagnetism) = $5.5 \times 10^{-4}$ cm$^3$/mol K. It is noteworthy that magnetic susceptibility as well as isothermal magnetization data were sensitive to the sign of $D$. As can be seen from the various solutions presented in Figures S1 and S2, it is clear that acceptable fits were only derived for $D > 0$. Moreover, liberating the $E$ parameter in the case of $D > 0$, further improved these fits, yielding an $E/D$ value of 0.14.

These results are in good agreement with high-frequency EPR measurements (vide infra). From the magnetometry data, it is already clear that complex $1_{1Td}$ exhibits a rather large and positive $D$ value. Therefore, as the $M_s = 0$ is the ground state of this $S = 2$ system, no significant slow relaxation of magnetization is expected. Indeed, Alternating Current (AC) magnetic susceptibility measurements, either in the absence or in the presence of a DC magnetic field, do not show a non-zero value of the imaginary part, $\chi''$, of the magnetic susceptibility that would indicate slow relaxation of the magnetization.
**High-frequency EPR spectroscopy.** The cw EPR spectrum of a powder sample of \( \text{I}_{\text{Td}} \) recorded at 275.7 GHz and 10 K is shown in Fig. 3. The spectrum comprises several resonances, with the most relevant for the \( S = 2 \) Fe\(^{II} \) site of \( \text{I}_{\text{Td}} \) being those at ca. 2.0, 4.7, 5.2 and 8.8 T. The signal around 9.8 T (\( g = 2 \)) may arise from a high spin, \( S = 5/2 \), Fe\(^{III} \) species, whereas the signal at 9.6 T is due to an impurity in the cavity. Finally, a rather weak signal is observed at ca. 0.7 T, superimposed on a relatively broad background. The origin of the above features is discussed below.

The magnetic measurements presented above were satisfactorily analyzed within the spin Hamiltonian (1), yielding spin Hamiltonian parameters \( g_{||} = 2.14, D = +3.9 \text{ cm}^{-1}, E = +1.1 \text{ cm}^{-1} (E/D = 0.14) \). A more reliable and accurate determination of these parameters is obtained by the analysis of the high-frequency EPR resonances. Fig. S3 depicts the dependence of the energy levels on the external magnetic field, for three orientations with respect to the principal axes of the ZFS tensor, assuming the ZFS values that reproduce the spectra. On the basis of these plots, the resonance at ~2.0 T is attributed to the transition between the lowest lying levels 1 and 2 for an orientation of the magnetic field parallel to the y-axis, whereas the resonance at ~4.6 T is attributed to the transition between the lowest-lying levels for an orientation parallel to the x-axis. Similarly, the resonances at 5.0 T and 8.5 T arise from the next two levels, 2-3, with the orientation parallel to x- and y-axes, respectively. A weak shoulder at 4.0 T can be attributed to the 2-3 transition for an orientation parallel to the z-axis. A survey over the parameter space indicates that all transitions can be simultaneously reproduced with a unique set of parameters \( D, E/D, g_{||}, \) and \( g_{\perp} \) in a relatively narrow range. In Fig. 3 are included simulations of the spectra obtained with the following set of spin Hamiltonian parameters: \( D = +8.22 \text{ cm}^{-1}, E/D = 0.104, g_{||} = 2.12 \) and \( g_{\perp} = 2.10 \). The contribution from each transition between the levels 1 - 2 and 2 - 3 is shown separately. The fine structure between 2 and 4 T is not noise from the acquisition, but changes, instead, when the sample tube is rotated. The extreme width of this shift (> 2 T) leads to incomplete powder averaging of randomly oriented microcrystals in the 20 nl sample volume.

![Figure 3](image-url)

**Figure 3.** Experimental and theoretical 275.7 GHz cw-EPR spectra of a powder sample of \( \text{I}_{\text{Td}} \) at 10 K. The theoretical spectra are obtained as described in the text. Experimental conditions: Modulation frequency: 1.8 kHz, modulation amplitude: 3 mT, microwave power: 5 \( \mu \text{W} \).

The spectra recorded at 10 and 25 K are compared in Fig. S4. We observe that upon increasing the temperature, the relative intensity of the 2-3 signals increase with respect to the intensity of 1-2, in agreement with the above assignment, further confirming the positive sign of \( D \). The signals at 9.6 T arise from an impurity species of the cavity, whereas the strong derivative feature at ~10 T can be attributed to half integer spin species, such as high spin, \( S = 5/2 \), Fe\(^{III} \) impurities. Less obvious is the origin of the signals in the low field (<1.0 T) part of the spectrum, which is enlarged in Fig. S5. A closer examination indicates that the relatively sharp peak at 0.7 T is superimposed on a rather broad background. We tentatively assign these signals to the existence of two additional \( S = 2 \), high spin Fe\(^{III} \) minor species (see the caption of Fig. S5). The origin of these minor species is at present unknown. In any case, quantification of these signals with respect to the major \( S = 2 \) Fe\(^{III} \) signals indicate that they represent a small fraction of total iron (~ 3.0 %) and are hardly discernible in the Mössbauer spectra (vide infra).

The size of \( D \) for complex \( \text{I}_{\text{Td}} \) is typical for high-spin \( S = 2 \) Fe\(^{III} \) systems, including the most, relevant analogues \([\text{Fe}(\text{SPPh}_3\text{N})_2]_2\) complex.\(^{[39b (and references therein)]}\) This complex has been shown to adopt different structural conformations, the electronic structure of which exhibits subtle variations. More specifically, the corresponding ZFS parameters of two distinct conformations are \( D_{1} = +9.17 \text{ cm}^{-1}, E_{1}/D_{1} = 0.021 \) and \( D_{2} = +8.87 \text{ cm}^{-1}, E_{2}/D_{2} = 0.052 \). The \( D \) component of the ZFS of \( \text{I}_{\text{Td}} \) is comparable to those of each distinct site of \([\text{Fe}(\text{SPPH}_{3}\text{N})_2]_2\), while the value of \( E/D \) is slightly larger, suggesting that the nature of the ligand’s donor atom (S vs Se) has a small effect on the ZFS for the corresponding \( S = 2 \) Fe\(^{III} \) site, E = S, Se, tetrahedral sites. It should be stressed that recent magnetometry studies have provided evidence that the high spin \( S = 3/2 \) tetrahedral \([\text{Co}(\text{EPPr}_{2}\text{N})_2]_2\), E = S, Se, complexes also exhibit rather similar \( D \) values, i.e. the magnitude of \( D \) does not depend on the identity of the E donor atoms (S or Se) in these systems as well.\(^{[53]}\)

**Mössbauer spectroscopy.** Zero-field Mössbauer spectra of powder samples of \( \text{I}_{\text{Td}} \) were recorded in the 4.2 - 200 K temperature range. The spectra at 4.2 and 80 K are shown in Fig. 4. The spectra comprise one quadrupole doublet and the corresponding Mössbauer parameters are listed in Table S5. Spectra recorded at various other temperatures are shown in Fig. S6. The spectrum at 4.2 K comprises one symmetric doublet, exhibiting the following parameters: \( \delta = 0.79(1) \text{ mms}^{-1} \) and \( \Delta E_{Q} = 3.23(1) \text{ mms}^{-1} \). These parameters are fully consistent with a high spin \( S = 2 \) Fe\(^{III} \) site.\(^{[56]}\) In particular, the magnitude of the quadrupole splitting provides conclusive evidence that \( \text{I}_{\text{Td}} \) contains a tetrahedral coordination sphere. High-spin, \( S = 2 \), square-planar Fe\(^{III} \) sites are rather rare (vide supra). Among this family of Fe\(^{III} \) systems, those that have been studied by Mössbauer spectroscopy,\(^{[40b, 48, 50a, 57]}\) exhibit quadrupole doublets with remarkably low \( \Delta E_{Q} \) values (<<1.0 mms\(^{-1} \)). This trend, which has been also observed for \( S = 2 \), trigonal planar Fe\(^{III} \) sites with thiolate ligands,\(^{[58]}\) may be qualitatively understood on the basis of the symmetry of the square planar ligand environment. Under these conditions, the contribution of the ligand environment to the Electric Field Gradient (EFG) tensor cancels out the contribution of the valence, thus leading to unusually small, for \( S = 2 \) Fe\(^{III} \) sites, \( \Delta E_{Q} \) values.\(^{[59]}\) On the other hand, in tetrahedral ligand environments, the
ligand asymmetry contribution to the EFG tensor is much smaller and, therefore, the valence contribution prevails, leading to the usual large $|\Delta E_{Q}|$ values for such $S = 2$ Fe$^{II}$ sites. Most relevant to the case of complex $\text{I}_{\text{Td}}$ are the recently studied tetrahedral $[\text{Fe}((\text{SePiPr}_2\text{N})_2)_2]$, $E = \text{S, Se}$, complexes.$^{39}$ These complexes exhibit, within experimental error, $\delta$ and $|\Delta E_{Q}|$ values of the same order of magnitude with those of complex $\text{I}_{\text{Td}}$. The $|\Delta E_{Q}|$ parameter of complex $\text{I}_{\text{Td}}$ exhibits a non-profound temperature dependence, implying a well isolated orbital ground state.

At 4.2 K, the observed doublet of $\text{I}_{\text{Td}}$ is symmetric with Lorentzian lines. The linewidth (FWHM, $\Gamma = 0.25$ mm s$^{-1}$) is close to the lowest limit of our experimental setup. This indicates a well-defined and fairly homogeneous ligand environment of the Fe$^{II}$ center in complex $\text{I}_{\text{Td}}$. The inherent narrowness of the lines makes it possible to detect small, albeit reliable, changes as a function of temperature. As the temperature increases, the quadrupole doublet is getting asymmetric, with the lowest energy line becoming broader than the highest energy line. The largest asymmetry is observed at 80 K (Fig. 4). A similar behavior has been observed in other $S = 2$ Fe$^{II}$ systems$^{40}$ and it may be understood on the basis of relaxation effects.$^{41}$ High-frequency EPR and magnetometry studies show that the $D$ value of complex $\text{I}_{\text{Td}}$ is rather large and positive, of the order of $+8.0$ cm$^{-1}$ ($\text{vide supra}$). This corresponds to an $M_s = 0$ ground state, designated as $|0\rangle$, which is separated by $D \sim 8$ cm$^{-1}$ from the first excited $|\pm 1\rangle$ and $4D \sim 32$ cm$^{-1}$ from the second excited $|\pm 2\rangle$ non-Kramers doublet, respectively. At 4.2 K, the thermal population of the ground $|0\rangle$ state is $\sim 88.5 \%$. Therefore, no magnetic field is induced on the $^{57}$Fe nucleus and the spectrum gives rise to a doublet. The non-zero rhombic $E$ component of the ZFS revealed by the high-frequency EPR studies splits further the $|\pm 1\rangle$ first excited doublet ($\sim 11.5 \%$ population at 4.2 K) into two singlets, which do not induce effective magnetic fields at the nucleus either. The splitting of the $|\pm 2\rangle$ excited non-Kramers doublet is much smaller and, under favorable spin relaxation conditions, this state can give rise to magnetically split spectra. However, its thermal occupation at 4.2 K is negligible and does not affect the spectra. As the temperature increases, the occupation of the $|\pm 2\rangle$ doublet increases. If the spin-lattice-relaxation time is appropriate (of the order of $10^{-7}$ s), this doublet will affect the spectra, resulting in asymmetric broadening. At 80 K, the occupation of the $|\pm 2\rangle$ doublet is sufficiently large ($\sim 29 \%$) and the relaxation effects are observable through the asymmetric broadening of the doublet. At higher temperatures, the occupation of the $|\pm 2\rangle$ doublet reaches a saturation value and then the spin-relaxation time decreases. Under these conditions, the quadrupole doublet is becoming more symmetric again.

The zero-field Mössbauer spectra of complex $\text{I}_{\text{Td}}$ recorded at various temperatures (Table S5, Figure S6) are consistent with the findings of the magnetometry and high-frequency EPR studies, which indicate a large and positive ZFS axial component, $D$. The broadening of the low energy line, compared with the high energy line, indicates a negative value for $|\Delta E_{Q}|$, as expected for a $d_{z^2}$ ground orbital state.

**Conclusions**

In this work, the synthesis and characterization of a preparation of $[\text{Fe}((\text{SePPh}_2\text{N})_2)_2]$ ($\text{I}_{\text{Td}}$) is described. X-ray crystallography shows that this system contains a tetrahedral FeSe$_4$ coordination sphere. The electronic structure of $\text{I}_{\text{Td}}$ is elucidated by magnetometry, high-frequency EPR and Mössbauer spectroscopy studies, which provide spin Hamiltonian parameters typical of high spin, $S = 2$, tetrahedral Fe$^{II}$ sites. The magnitude of the $D$ parameter is similar to that of the corresponding $[\text{Fe}((\text{SPPh}_2\text{N})_2)_2]$ complex. The recently reported preparation of $[\text{Fe}((\text{SePPh}_2\text{N})_2)_2]$ ($\text{I}_{\text{SP}}$) exhibiting a square planar coordination sphere should be investigated in a similar manner, in order to establish magnetostructural correlations for this system.

Owing to the rich coordination chemistry of Se-containing ligands in both chemical and biological systems ($\text{vide supra}$), our research groups will continue exploring the electronic structure of transition metal complexes bearing Se-containing imidodiphosphinato type of ligands.

Experimental Section

Reagents and synthetic procedures: All manipulations were carried out under a pure Ar atmosphere, by employing Schlenk techniques. The Ph3P(Se)NHP(Se)Ph ligand was prepared according to published procedures.[23]

Complex 1Td. In a Schlenck-type flask, 0.032 g (0.25 mmol) FeCl2 were added to a solution of 0.29 g (0.50 mmol) K[(SePPh2)2N] in dry CH3OH (30 mL) affording a pale yellow solid. The mixture was stirred for 2 h at room temperature and after that the solvent was removed to dryness under vacuum. CH2Cl2 (10 mL) was then added, followed by filtration through Celite pad in order to remove KCl that is formed. Suitable dark yellow crystals for X-ray crystallography were obtained by slow mixing of n-hexane layer to the above CH2Cl2 filtrate. Elemental analysis: calc: C, 50.55; H, 3.54; N, 2.46; found: C, 50.25; H, 3.50; N, 2.46. Selected IR bands (cm−1): ν(PSe) 534, ν3(PNP) 1203.

X-ray crystallography. Diffraction data were collected at room temperature, by the 0-20 scanning method on a Syntex diffractometer equipped with Rigaku rotating anode and graphite monochromator (Cu Kα radiation (λ = 1.5418 Å). The cell dimensions were obtained by least-squares analysis of reflections in the range 20° < 2θ < 40°. Three standard reflections were monitored every 97 reflections, showing no decay in intensity during data collection. The data were corrected for Lorentz and polarization effects and a semiempirical absorption correction, based on the psi scans, was applied.[62] The structure was solved by direct methods and refined by full matrix least squares based on F2, using the program SHELXL97.[63] Anisotropic refinement was applied to all non-hydrogen atoms. Hydrogen atoms have been placed in idealized positions and refined by the riding model (UH = 1.20 UC). The crystal structure of complex 1Td has been deposited to the Cambridge Crystallographic Data Centre (CCDC 1574747). The corresponding Crystallographic Information File (CIF) can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html; or e-mail: deposit@ccdc.cam.ac.uk. The structure of 1Td shown in Figure 1 was visualized by employing the CSD Mercury software (https://www.ccdc.cam.ac.uk/solutions/csd-system/components/mercury/).

IR spectroscopy. IR spectra were run in the range 4000-200 cm−1 on a PERKIN-ELMER 883 IR spectrophotometer, as KBr discs.

Magnetometry. Magnetic susceptibility measurements were performed using an MPMS-5500 Quantum Design (for dc measurements) or a Quantum Design PPMS (for ac or dc measurements) magnetometers. Experimental data were corrected for the sample holder and for the diamagnetic contribution of the sample using Pascal’s constants. The PHIL program (v 3.1) was used for fitting the magnetic data.[64]

High-frequency EPR spectroscopy. Continuous-wave (cw) EPR spectra were recorded at 275.7 GHz using a home-built spectrometer at Leiden University.[65] using a probe specially developed to record the extremely broad spectra of high-spin Fe-systems in cw mode.[66] A TE011 resonator was used for detection of the EPR signal allowing a sample volume of 20 nL. Spectra of 1Td were recorded with a field-modulation amplitude of 3 mT, a modulation frequency of 1.8 kHz, and a microwave power of 5 μW.

Simulations of the EPR powder spectra were performed by numerical diagonalization of the spin Hamiltonian with the help of the EasySpin toolbox for Matlab[67] or with the program SpinCount, kindly provided to us by Prof. M.P. Hendrich, Carnegie Mellon University, Pittsburgh, PA, U.S.A.

Mössbauer spectroscopy. Mössbauer spectra were recorded by a constant-acceleration conventional spectrometer with a source of 57Co (Rh matrix). Spectra were obtained using a Janis or an Oxford cryostat. The spectra were analyzed by using home written routines. Isomer shift values (δ) are reported relative to iron foil at 293 K.

Supporting Information

Complex 1Td. Crystal data and crystallographic information files, selected bond lengths and angles, structural comparisons, magnetometry / EPR / Mössbauer data.
