20 **Abstract**

21 We have constructed a 3-D shear-wave velocity (V_s) model for the crust and uppermost mantle
22 beneath the Middle East using Rayleigh wave records obtained from ambient-noise cross-
23 correlations and regional earthquakes. We combined one decade of data collected from 852
24 permanent and temporary broadband stations in the region to calculate group-velocity dispersion
25 curves. A compilation of >54000 ray paths provides reliable group-velocity measurements for
26 periods between 2 and 150 s. Path-averaged group velocities calculated at different periods were
27 inverted for 2-D group-velocity maps. To overcome the problem of heterogeneous ray coverage,
28 we used an adaptive grid parametrization for the group-velocity tomographic inversion. We then
29 sample the period-dependent group-velocity field at each cell of a predefined grid to generate 1-D
30 group-velocity dispersion curves, which are subsequently inverted for 1-D V_s models beneath each
31 cell and combined to approximate the 3-D V_s structure of the area. The V_s model shows low
32 velocities at shallow depths (5-10 km) beneath the Mesopotamian foredeep, South Caspian Basin,
33 eastern Mediterranean and the Black Sea, in coincidence with deep sedimentary basins. Shallow

1 high-velocity anomalies are observed in regions such as the Arabian Shield, Anatolian Plateau and
2 Central Iran, which are dominated by widespread magmatic exposures. In the 10-20 km depth
3 range, we find evidence for a band of high velocities (> 4.0 km/s) along the southern Red Sea and
4 Arabian Shield, indicating the presence of upper mantle rocks. Our 3-D velocity model exhibits
5 high velocities in the depth range of 30-50 km beneath western Arabia, eastern Mediterranean,
6 Central Iranian Block, South Caspian Basin and the Black Sea, possibly indicating a relatively thin
7 crust. In contrast, the Zagros mountain range, the Sanandaj-Sirjan metamorphic zone in western
8 central Iran, the easternmost Anatolian plateau and Lesser Caucasus are characterized by low
9 velocities at these depths. Some of these anomalies may be related to thick crustal roots that support
10 the high topography of these regions. In the upper mantle depth range, high-velocity anomalies are
11 obtained beneath the Arabian Platform, southern Zagros, Persian Gulf and the eastern
12 Mediterranean, in contrast to low velocities beneath the Red Sea, Arabian Shield, Afar depression,
13 eastern Turkey and Lut Block in eastern Iran. Our Vs model may be used as a new reference crustal
14 model for the Middle East in a broad range of future studies.

20 **1. Introduction**

21 The current tectonic setting of the Middle East was mainly formed during the latest collisional
22 stage of the Alpine tectonic cycle associated with the Arabia-Eurasia collision (e.g. Allen et al.,
23 2004). The continued convergence between the Arabian and Eurasian plates is currently
24 accommodated by thrusting and folding in the sediments, thrust faulting in the basement and
25 thickening of the lower crust in mountain belts, principally Zagros, Alborz, Koppeh Dagh and
26 Greater and Lesser Caucasus, as well as by strike-slip motions across the Anatolian and Iranian
27 Plateaus. Part of the shortening in the Zagros is also accommodated by lithosphere thickening
28 (Priestley et al., 2012). As the result, the modern tectonic framework of the Middle East is defined
29 by an assembly of different plate boundary types (Allen et al., 2004; Le Pichon and Kreemer,
30 2010; Reilinger and McClusky, 2011). These include: 1) active subduction zones along the
31 Hellenic and Cyprus trenches in the west and Makran in the east, 2) continental collision zones:
32 Zagros-Bitlis, Alborz, Koppeh Dagh and Lesser and Greater Caucasus, 3) lithosphere-scale strike-

1 slip faults such as the Northern and Eastern Anatolian Fault zones and the Dead-Sea continental
2 transform fault, and systems of strike-slip faults in eastern Iran, and 4) spreading centers in the Red
3 Sea and the Gulf of Aden (Figure 1).

4 The presence of such a broad variety of plate boundaries and tectonic settings provides an ideal
5 opportunity to investigate the dynamic interaction between these tectonic systems. To this end, a
6 comprehensive knowledge of the lithospheric structure of the region is essential.

7 Numerous regional tomography studies have provided information on upper mantle structures
8 beneath different regions of the Middle East (e.g. Kaviani et al., 2007; Biryol et al., 2011; Salaün
9 et al., 2012; Simmons et al., 2015; Portner et al., 2018; Tang et al., 2016, 2018, 2019). However,
10 because of data access limitations, these studies have often been limited by political boundaries. In
11 the past few years, crustal structure has been studied in different parts of the Middle-East region
12 using receiver function analysis and surface-wave tomography (e.g. Zor et al., 2003; Paul et al.,
13 2006, 2010; Hammond et al., 2011; Vanacore et al., 2013; Delph et al, 2015; Tang et al., 2018,
14 2019; Rastgoo et al., 2018; Karabulut et al., 2019). Warren et al. (2013) and Delph et al (2015)
15 investigated the crustal structure of the Turkish-Anatolian Plateau using ambient-noise
16 tomography, but their models do not have adequate resolution along the outer limits of the study
17 area because they only used stations located inside Turkey. Motaghi et al. (2013) carried out the
18 first ambient-noise tomography of the crustal structure of the Iranian plateau using data from a
19 sparse array. Their images display large-scale tectonic features of the Iranian Plateau, but with low
20 resolution due to poor ray coverage. Recently, Movaghari and Doloei (2019) conducted a Rayleigh-
21 wave phase-velocity tomography based on ambient-noise analysis to investigate the crustal and
22 upper-mantle structure beneath the Iranian Plateau and Zagros. Their shear-wave velocity model
23 provides evidence for crustal thickening beneath the Zagros and high-velocity upper mantle
24 beneath the SE Zagros. However, due to the data coverage limit, their model does not have
25 sufficient resolution at the boundary regions. Pilia et al. (2020) used a relatively dense and new
26 passive seismic network in the United Arab Emirates, together with a number of stations in south-
27 central Iran. By using a sophisticated inversion scheme applied to seismic noise they were able to
28 image the crust beneath the southeastern Zagros, providing evidence for underthrusting of the
29 Arabian basement beneath central Iran and 3-D variations in the sediment cover of the Zagros
30 mountains. Priestley and McKenzie (2013) used long-period surface waves to provide seismic
31 images of the upper mantle beneath the broader Middle-East region, but their resolution was not
32 sufficient to delineate features at scales smaller than a few hundred km, particularly in the crust.

1 Kaviani et al. (2015) used an integrated Lg waveform data set to map attenuation and velocity
2 structure in the crust across the Middle East. However, due to the nature of the Lg wave, the average
3 crustal models have no depth resolution.

4 In this study, we aim at providing the first high-resolution crustal shear-wave velocity (V_s) model
5 of the broader Middle-East region computed with a robust method and homogeneous parameters.
6 The computed velocity model has potential for a variety of purposes including geological
7 interpretation, seismic hazard assessment, earthquake location and geodynamic modelling. Due to
8 the broad extent of the V_s model, we cannot discuss all its outcomes here. Therefore, we focus our
9 comments on a few regions to either outline differences with other models in well-studied areas
10 (Anatolia), or discuss the main features of less well-studied areas (Iran and Arabia).

11 Furthermore, an important missing piece of information about the lithospheric structure in the
12 Middle East is a comprehensive map of the crustal thickness. Knowledge of crustal thickness
13 variations is essential for a vast field of studies including seismic hazard assessment and numerical
14 simulation of lithospheric deformation. A major objective of our study is to provide such an
15 integrated crustal thickness map for the entire Middle East.

16

17 **2. Data and methodology**

18 **2.1 Data**

19 We conducted surface-wave tomography and inversion for shear-wave velocity to image the crustal
20 and uppermost mantle structure of the entire Middle-East region. The majority of the surface-wave
21 dispersion data was obtained by analysis of continuous seismic ambient noise (AN) collected from
22 709 broadband stations (blue triangles in Figure 2) operated in the Middle East over the last two
23 decades. Cross-correlations of long-term background noise records at simultaneously recording
24 stations yield an estimate of the empirical Green's function between station pairs (Lobkis and
25 Weaver, 2001; Campillo and Paul, 2003; Shapiro and Campillo, 2004; Campillo and Roux, 2014;
26 Boschi and Weemstra, 2015). The analysis and subsequent tomographic inversion of surface-wave
27 dispersion data derived from ambient-noise cross-correlation provide a high-resolution image of
28 the lithospheric structure beneath a dense network of seismometers (Sabra et al. 2005; Shapiro et
29 al. 2005; Bensen et al. 2007). In this study, the interstation distance for AN analysis varies between
30 20 and 5000 km. Our raw data covers the years 1994-2000 and 2007-2015. We follow the standard
31 procedure described by Bensen et al. (2007) and modified by Boué et al. (2014) to compute the
32 vertical component cross-correlation functions (CCF) between all station pairs (for more

1 information see the Supplementary Information). A gather of computed CCF is shown in
2 Supplementary Figure S1. The final CCF are exploited as Rayleigh wave records between stations
3 and standard frequency-time analysis (FTAN) is applied to extract group-velocity dispersion
4 curves. Examples of this analysis are shown in Supplementary Figure S2.

5 In regions where continuous seismic noise records were not available, such as Saudi Arabia, we
6 incorporated dispersion curve data from previous studies to improve ray coverage. We used the
7 dispersion measurements by Tang et al. (2018, 2019) for Rayleigh waves (periods 8-75s) observed
8 at 143 permanent broadband stations of the Saudi National Seismic Network (SNSN) (green
9 triangles in Figure 2) for regional earthquakes (EQ) located inside our study area. The inclusion of
10 these EQ-based dispersion data dramatically improves the ray coverage across Arabia (Figure S3).
11 The two sets of dispersion curves (from AN and EQ) overlap in the period range 8-75s for paths
12 crossing Saudi Arabia. To avoid biasing the group-velocity maps by multiple measurements along
13 paths close to each other and to assess the consistency of path-averaged measurements, we
14 followed a clustering procedure in which all similar paths are clustered to make a single path. This
15 procedure is explained in detail in the Supplementary Information.

16

17 **2.2 Surface wave tomography**

18 In order to constrain group-velocity variations at different periods, we construct 2-D group-velocity
19 maps from our path-averaged measurements. Our algorithm is based on that of Boschi and
20 Dziewonski (1999). The inversion algorithm is discussed in detail by Lu et al. (2018). As shown
21 by the examples in Supplementary Figure S3, we are dealing with heterogeneous ray coverage
22 across the study area. Following previous studies (Schaefer et al., 2011; Auer et al., 2014; and Lu
23 et al., 2018) we employed the adaptive-cell version of Boschi and Dziewonski's (1999) algorithm.
24 In this approach, the cell size in each part of the model space is adjusted according to the ray
25 density. This helps secure an optimal resolution for each part of the inverted model depending on
26 ray coverage. After several preliminary tests based on visual inspection, we selected varying cell
27 sizes of 0.25°, 0.5°, and 1.0°; a few examples of the adaptive cell size maps are shown in
28 Supplementary Figure S4.

29 We perform tomographic inversion for periods between 2 and 150 s. At each period, the inversion
30 is carried out in two steps. We first invert all measured group traveltimes using a high damping
31 value to detect incoherent measurements. Then we discard all paths with traveltime residual
32 (difference between observed traveltime and traveltime predicted from the over-damped model)

1 higher than 3 times the mean travelttime residual of all paths. Following this procedure, about 30%
2 of ray paths are discarded as outliers at each period. The second round of group-velocity
3 tomography is then carried out using the remaining paths. The average group velocity of all paths
4 at each period is used as the starting model for inversion. In the inversion algorithm, the trade-off
5 between data fitting and model resolution is controlled by a damping parameter and a roughness
6 coefficient whose values (0.3 and 0.1) are chosen based on an L-curve test (Hansen, 2001).

7 To assess the resolution power of the data set and inversion approach, we performed several
8 synthetic tests using the same raypath configuration as the observational data set. The results of
9 synthetic tests at several periods are shown in Supplementary Figure S5. These tests reveal that
10 features as small as 1° can be resolved in most parts of the study area at periods from 10 to 36s,
11 while features of size 2° are resolved fairly well in the entire period range throughout the study
12 area. A more detailed description of results of the synthetic tests is given in the Supplementary
13 material.

14 In Figure 3, we present group-velocity maps at few selected periods. These maps delineate many
15 features related to the crustal structure. However, in order to provide more geologically meaningful
16 interpretations, we invert these group-velocity maps for 3-D shear-wave velocity (V_s) model. The
17 V_s model is described and discussed in detail in the next sections.

18 Since we combine two data sets (dispersion curves from ambient-noise (AN) and earthquakes
19 (EQ)), one important issue about the results shown in Figure 3 is how the inclusion of the EQ-
20 based dispersion data affects our results. In order to verify this, we show in Figure S6 group velocity
21 maps (at the same periods shown in Figure 3), which are obtained only using AN-based dispersion
22 data. The comparison between the group velocity maps shown in Figures 3 and S6 reveals that no
23 significant difference between the results are observed at period range less than 25 sec. The main
24 difference is observed at periods 36-46 sec for the region of the Arabian Shield, where the inclusion
25 of the EQ-based dispersion data tends to shift the group velocities to higher values. Since the ray
26 coverage in the case of the combined data set is much better than solely the AN-based data, we
27 conclude that the inclusion of the EQ-based data helps to suppress the effects of the low-velocity
28 outliers in these period ranges.

29

30 **2.3 Inversion for shear-wave velocity**

31 We adopted a modified version of the algorithm of Lu et al. (2018) to invert group-velocity
32 dispersion data for depth-dependent models of shear-wave speed (V_s), by extracting dispersion

1 curves at 0.25° intervals from the group-velocity maps (Figure 3). As shown by the resolution tests
2 (Supplementary Figure S5), resolution is best at 18 s period. We therefore select a cell for inversion
3 if the number of rays crossing the cell at 18 s is larger than 50. In addition, the number of crossing
4 rays at all other periods should be larger than 10.

5 The 1-D inversion of dispersion curves for V_s was performed in two steps. Examples of this two-
6 step inversion approach are shown in Supplementary Figure S7 for two cells in Iran and Arabia.
7 We first followed a Bayesian algorithm to find an optimum 1-D model, which was then used as
8 starting model for a linearized inversion. Our probabilistic inversion is based on the Bayesian
9 algorithm introduced by Bodin et al. (2012) and modified by Lu et al. (2018). It is summarized in
10 the Supplementary Information. In this approach, we first created a library of more than 14 million
11 random models and computed their dispersion curves. The random models have 5 layers (4 crustal
12 layers over a half space). Shear-wave velocity and thickness of each layer were randomly changed
13 to generate the set of initial models. The plausible range of variation of velocity and thickness of
14 each layer was defined using the reference model CRUST1.0 (Laske et al., 2013) and *a priori*
15 information from previous studies (e.g. Paul et al., 2006, 2010; Delph et al., 2015). The P-wave
16 velocity (V_p) and density of each layer were calculated using the empirical relationships (1) and
17 (9) of Brocher (2005). We use equations (9) and (1) of Brocher (2005) to calculate, respectively,
18 the V_p (from V_s) and density (from V_p). The ranges of thickness and V_s variations are given in
19 Table 1. The velocity of the bottom half space was calculated by random variation around the
20 uppermost mantle velocity of the standard Earth model IASP91 (Kennett and Engdahl, 1991). The
21 Bayesian inversion was performed for a maximum period of 100 s.

22 In the second step, we computed, for each cell, the average of the 1-D models resulted from the
23 Bayesian inversion and used it as the starting model for the linearized inversion (Herrmann, 2013).
24 The whole range of periods up to 150s was used in the linear inversion. As shown by
25 Supplementary Figure S7, the lower (mantle) part of the input velocity model is modified by the
26 linear inversion while the upper (crustal) part changes much less. Finally, the 1-D models obtained
27 from the two-step inversion of all cells are combined in a quasi-3-D final V_s model.

28

29 **3. Results**

30 In this section we present depth slices of our final 3-D V_s model on the scale of the entire study
31 area (Figure 4). The group-velocity maps shown in Figure 3 correspond to periods that are mostly
32 sensitive to V_s at the depths shown in Figure 4, in order to outline the correspondence between the

1 original group-velocity maps and the final V_s model (see sensitivity kernels of the linear inversion
2 in Supplementary Figure S8).

3

4 **3.1. Shear wave velocity maps**

5 Our V_s model exhibits slow velocities at shallow depths (down to 15 km) in the regions of thick
6 sedimentary basins such as the Mesopotamian Foredeep, Persian Gulf, Eastern Mediterranean, and
7 the Black Sea (Figure 4). High-velocity regions are observed in the shallow crust beneath the
8 Arabian Shield, the Afar depression, central Iran and parts of the Anatolian Plateau where
9 magmatic crystalline rocks are present at shallow depths and/or the crust is relatively thin. The
10 southern Red Sea and Arabian Shield exhibit upper mantle velocities ($V_s > 4.1$ km/s) at a depth of
11 15 km indicative of a very thin crust. These features also appear in the group velocity maps at
12 periods of 10-18 s (Figure 3).

13 At depths around 25 km (corresponding to a period of 25 s, Figure 3), the V_s map shows upper and
14 mid crustal velocities beneath the Iranian and Anatolian Plateaus, and upper mantle velocities
15 beneath Afar, the Red Sea, the Gulf of Aden, and the Aegean Sea. A strong low-velocity anomaly
16 is mapped in the easternmost Mediterranean Sea both in Figure 3 at 8-25 s and Figure 4 at 10-25
17 km. It could be due to the presence of a very thick sedimentary basin; however, the resolution in
18 that area is not sufficient to guarantee the reliability of this anomaly.

19 In the depth range of 35-45 km, we observe upper mantle velocities ($V_s > 4.1$ km/s) beneath the
20 western and northern Arabian Plate and the Dead Sea, the Aegean Sea, the Black Sea, the Caspian
21 Sea and Turan Plate. Crustal velocities ($V_s < 4.0$ km/s) are mapped beneath the mountain belts in
22 Iran and Eastern Turkey, due to their thick crust. The high-velocity region of the Eastern
23 Mediterranean and northern Arabia has a sharp northern boundary that coincides with the surface
24 trace of the Cyprus trench and Zagros-Bitlis suture zone. Low velocities are also found in SW
25 Turkey within the Isparta Angle that could be related to the assumed slab tear.

26 At depths > 45 km most regions are characterized by upper mantle velocities. A NW-SE elongated
27 low-velocity strip is mapped at 55 and 70 km depth beneath the Iranian-Turkish plateaus that may
28 be due to crustal thickening. The maps at 45 and 55 km depth reveal that the southern Red Sea has
29 relatively low upper mantle velocities while the northern Red Sea has a faster upper mantle. The
30 Afar region is characterized by low mantle velocities (3.9-4.0 km/s) surrounded by regions of low
31 velocities beneath the SE Red Sea, SW Yemen and the westernmost Gulf of Aden. Cyprus is also
32 characterized by low velocities at 45-55 km, probably due to its thicker crust than the surrounding

1 Eastern Mediterranean Sea. At depths ≥ 70 km (Figure 4), our V_s model exhibits features that are
2 comparable with the regional tomography models (e.g. Hansen et al., 2012; Priestley and
3 McKenzie, 2013; Simmons et al., 2015). A wide region of slow-velocity upper mantle is mapped
4 beneath the Afar depression, southern Red Sea and SW Arabia that possibly indicates ascending
5 hot material and/or partial melting. Several high-velocity anomalies are mapped beneath the SE
6 Zagros and Persian Gulf and the stable cratonic regions of the Eurasian plate. The features mapped
7 at large depths also appear on the group velocity maps of Figure 3 though long period group
8 velocities are sensitive to a wide depth range. We will discuss specific parts of our 3-D V_s model
9 in more detail in section 4.

10

11 **3.2. Moho Map**

12 We extracted a Moho depth map based on the inversion processes for V_s models. We first extracted
13 a preliminary Moho map during the Bayesian probabilistic inversion. At each cell, we used the
14 probability for having an interface and searched for the shallowest interface between 10 and 70 km
15 where V_s increases from crustal ($V_s \leq 3.5$ km/s) to upper mantle velocity ($V_s \geq 4.1$ km/s). The
16 resulting depth map was then visually checked by examining its lateral continuity and consistency
17 with the velocity boundaries in the final 3-D V_s model. The Moho depth at each cell was manually
18 corrected if required. In Figure 5, we compare the resulting Moho map with that from the global
19 reference model CRUST1.0 (Laske et al., 2013). The grid spacing in CRUST1.0 is 1.0° , while it
20 varies between 0.25° and 1.0° in our study. Our Moho map shown in Figure 5a is resampled at
21 0.5° . At first glance, the two maps exhibit similarities in large-scale features such as thick crust
22 beneath mountain belts and easternmost Turkey, and relatively thin crust beneath the Red Sea,
23 Mediterranean Sea and Black Sea. However, our high-resolution Moho map exhibits several
24 features that differ significantly from the reference map. For example, a wide area of thick crust is
25 located beneath the Zagros suture in the CRUST1.0 model. Our model, however, shows that the
26 crust beneath the Zagros is less than 45 km thick and that crustal thickening actually occurs within
27 a relatively narrow strip located NE of the suture, in better agreement with receiver function studies
28 (Paul et al., 2006, 2010). Another contrasting feature is the thinner crust beneath the South Caspian
29 Basin (SCB) and Turan plate (< 35 km), which is more than 40 km in CRUST1.0. Furthermore,
30 CRUST1.0 features a relatively smooth Moho beneath the Anatolian Plateau while our Moho map
31 has significant local topography and larger depth values. The thickest crust across the Turkish-
32 Anatolian Plateau is detected beneath the East Anatolian Accretionary Complex (EAAC) and

1 eastern Caucasus. The Moho in the Dead Sea region has an average depth of ~30 km, in agreement
2 with previous receiver function analysis (e.g. Mohsen et al., 2011). The Arabian Plate has relatively
3 thin crust (< 35 km in average) except in the SE part. The relatively thin crust of the Arabian plate
4 contrasts with the thicker crust beneath the deforming front of the Platform in the Zagros-Bitlis
5 fold-and-thrust belt. The thinnest crust is observed along the Red Sea in both models. Our model,
6 however, suggests that a thin (possibly oceanic?) crust has developed beneath the SE part of the
7 Red Sea while the NW part is still underlain by a regular continental-type crust. We discuss this
8 observation in more detail in the following section.

9

10 **4. Discussion**

11 It is beyond the scope of this paper to discuss in detail the crustal structure of each sub-region.
12 Therefore, we chose to focus on three sub-regions and discuss the results with respect to the tectonic
13 setting and in comparison with previous geophysical studies. Since extensive studies have already
14 been conducted on the crustal and mantle structure of the Turkish-Anatolian Plateau, we briefly
15 discuss the results in this area by comparison with previous studies. We then discuss in more detail
16 our results on the crustal structure of the Iranian Plateau and Zagros, and the Arabian Plate.

17

18 ***4.1 Turkish-Anatolian Plateau***

19 The low velocity at the 8-km depth slice (Figure 4) suggests a relatively thick sedimentary fill in
20 the Black Sea and a very thick sedimentary basin in the eastern Mediterranean. Apart from a few
21 small-size sedimentary basins, crystalline rocks constitute most of the shallow upper crust beneath
22 the Anatolian Plateau. A wide region of low velocities appears in western Anatolia at depths 15-
23 25 km that suggests a low-velocity mid-lower crust. Figure 4 also shows that eastern Turkey is
24 overall characterized by a low V_s crustal and uppermost mantle relative to Central Anatolia in
25 agreement with previous regional seismic tomography (e.g. Biryol et al., 2011; Salaün et al., 2012;
26 Portner et al., 2018). This can be explained by syn- and post-collisional volcanism (Keskin, 2003).
27 The crust in western Anatolia is much slower than in any other region in Turkey, which is likely a
28 consequence of the extensional tectonics in the region, as it was also suggested by previous studies
29 (e.g. Delph et al, 2015).

30 In Figures 6 and S9, we present several vertical slices through the 3-D velocity model across
31 Anatolia. We also show Moho profiles from our study (solid black lines) in comparison with that
32 from CRUST1.0 model (dashed black lines) and the recent receiver functions study (solid white

1 lines) of Karabulut et al. (2019). In Supplementary Figure S10 we present vertical slices through
2 the 3-D probability density model for the depth of interfaces along the same profiles as in Figures
3 6 and S9. The deepest high-probability interfaces imaged along the profiles indicate the trace of
4 the Moho.

5 Recent ambient-noise tomography studies (Warren et al., 2013; Delph et al, 2015) showed that the
6 Turkish-Anatolian Plateau is characterized by lateral seismic velocity variations that correlate with
7 the geological boundaries and suture zones. Our tomography is in general agreement with these
8 studies, though it provides more details on the deep crust and the Moho topography. In contrast
9 with Delph et al. (2015), our extensive regional ray coverage allows us to map the shear-wave
10 velocity beneath the Turkish-Anatolian Plateau and its adjacent areas, such as Black Sea and the
11 Caucasus in the north, Eastern Mediterranean Sea and Arabian Plate in the south, and Iranian
12 Plateau and Zagros in the east. For example, the boundary between the Anatolian block and the
13 Arabian plate that corresponds to the Bitlis suture and the East Anatolian Fault on the surface
14 (Figure 1) is clearly marked by a sharp velocity change beneath the suture at different depth levels
15 (Figures 4, 6 and S9). In their inversion of ambient-noise dispersion data to Vs, Delph et al (2015)
16 used a priori constraints on the crustal thickness from the receiver function study by Vanacore et
17 al. (2013). Our Bayesian approach, however, allows constraining the Moho depth directly from
18 dispersion data, independently of any other model.

19 Our inversion method and uniform data coverage reveal strong lateral changes of the velocity in
20 the lower crust of the Anatolian Plateau and a rough Moho topography. These strong lateral
21 variations in Moho depth are visible in the interface probability function (Supplementary Figure
22 S10). Our Moho map (Figure 5) and vertical slices (Figures 6, S9 and S10) confirm the general
23 west-to-east deepening of the Moho documented by previous studies (e.g. Zor et al., 2003;
24 Vanacore et al., 2013; Karabulut et al., 2019), but with stronger small-scale topography. Karabulut
25 et al. (2019) showed that the crust thickens very regularly from west to east beneath the Anatolian
26 Plateau, which led them to propose that an initially rough Moho topography may have been
27 smoothed out by viscous flow in the lower crust. By contrast, our Moho model is rather irregular.

28

29 ***4.2 Iranian Plateau and Zagros***

30 The Iranian Plateau and Zagros encompass several main structural units including the mountain
31 belts of Zagros, Alborz and Kopeh Dagh, the Central Iranian block, the Sanandaj-Sirjan
32 metamorphic zone (SSZ), the Urumieh-Dokhtar magmatic arc (UDMA) and the Makran

1 subduction zone (Figure 1). The Zagros Fold-and-Thrust Belt (ZFTB) marks the deformational
2 front on the passive margin of the Arabian Plate. In the ZFTB, 8-13 km thick Phanerozoic
3 sedimentary sequences cover the underlying pre-Cambrian basement of the Arabian platform (see
4 Allen et al., 2013 and references therein). The SSZ represents a tectono-magmatic and
5 metamorphic zone that extends from the Bitlis area in Turkey to the western boundary of the
6 Makran active subduction zone in SE Iran and is made up mainly of sedimentary and metamorphic
7 rocks of Paleozoic to Cretaceous age (Stöcklin, 1968; Agard et al., 2011). The most accepted
8 hypothesis is that the SSZ delineates the former active margin of an Iranian microplate (Berberian
9 and King, 1981). The Main Zagros Thrust (MZT) that separates ZFTB and SSZ is regarded as the
10 suture zone between the former Arabian passive margin and central Iran (e.g. Agard et al., 2011,
11 Paul et al., 2006, 2010). The UDMA situated between the SSZ and Central Iran is a zone of
12 extensive Tertiary magmatic activity, with a record of peak activity in the Middle Eocene
13 (Berberian and King, 1981).

14 A strip of low velocity region is mapped at depths ≥ 35 km parallel to the Zagros belt that shifts
15 toward the NE beneath the SSZ and UDMA at depths ~ 55 km (Figure 4). This is an indication for
16 a progressive thickening of the crust toward the NE at the suture between the Arabian Plate and the
17 Iranian-Turkish plateau. The Moho map of Figure 5 also documents a thick crust (≥ 45 km) beneath
18 the mountain belts (Zagros, Alborz and Kopeh Dagh) and thinner crust (25-35 km) in northern
19 Central Iran and southern Caspian Sea.

20 In Figure 7, we present vertical slices through the 3-D velocity model across the Zagros belt and
21 the Iranian Plateau, with comparisons of our Moho depth estimates (solid black lines) with
22 CRUST1.0 model (dashed black lines). Figure 8 shows the same vertical slices through the
23 interface probability density model. Our model exhibits small-scale Moho topography unresolved
24 in CRUST1.0. The crustal thickening to the NE of the MZT (profiles I1 to I5) supports the
25 hypothesis of underthrusting of the Arabian crust beneath Central Iran as proposed by previous
26 studies (Paul et al., 2006, 2010; Motaghi et al., 2017a; Mahmoodabadi et al., 2019). Two interfaces
27 at the base of the sediments and at ~ 20 km depth are clearly identified in the velocity and interface
28 probability density slices (Figures 7 and 8). The middle and lower crust beneath the Zagros exhibit
29 relatively lower velocities than Central Iran and the undeformed parts of the Arabian Platform.
30 This difference may result from stronger deformation of the Zagros crust due to continental
31 collision, although a compositional difference cannot be ruled out.

1 In the depth range of 35-45 km (Figure 4), upper mantle velocities appear beneath the
2 Mesopotamian Foredeep, indicative of a relatively thin crust. Vertical cross-sections I2-I4 (Figures
3 7 and 8) also display this Moho uplift beneath the Mesopotamian Foredeep and Persian Gulf that
4 contrasts with the NE deepening of the Moho beneath the Zagros and SSZ. This large-scale
5 undulation of the Moho may support the flexural bending model proposed by Pirouz et al. (2017).
6 The uppermost mantle beneath the SSZ, UDMA, Central Iran and Alborz is overall marked by
7 lower velocities than Zagros and Turan plate (Figure 4). Previous studies (e.g. Kaviani et al., 2007,
8 Motaghi et al., 2015; Mahmoodabadi et al., 2019) suggest that this velocity contrast can be
9 observed down to a depth of 250 km. A high-velocity uppermost mantle is mapped beneath the
10 southern Zagros and Persian Gulf (slices 70-90 km in Figure 4; profiles I4 and I5, Figure 7). Maggi
11 and Priestley (2005) and Kaviani et al. (2007) also imaged a high-velocity region in the upper
12 mantle beneath the Central Zagros that was later defined as the “Zagros Core” by Priestley et al.
13 (2012). Our images suggest that this high velocity anomaly is likely located only beneath the
14 Persian Gulf and southern Zagros.

15 To the north, our velocity maps (Figure 4) and vertical cross-sections (C1, I1, I2, Figures 7 and 8)
16 suggest that the crust beneath the Alborz is on average thinner than 45 km. The Alborz mountain
17 belt separates the relatively stable South Caspian Basin (SCB) in the north from the Central Iranian
18 Block in the south (Allen et al., 2004). Despite its high relief, the Alborz mountain belt shows no
19 evidence for a thick crustal root. Our velocity model also suggests that the SCB has a relatively
20 thin (less than 40 km) and relatively low-velocity crust that lies over a high-velocity upper mantle
21 (Figure 4 and profile C in Figure 7). The SCB is taken as an aseismic and possibly rigid block
22 surrounded by actively deforming belts (Jackson et al., 2002; Allen et al., 2003; 2004). In a broader
23 prospect, the SCB also comprises the Kura basin to the west and the western Turkmenian
24 depression to the east. Figure 4 shows that the velocity anomalies of the SCB crust extend beneath
25 the Kura basin to the west and Turkmenian depression to the east, but they have sharp lateral
26 boundaries with the Alborz and Talesh at all depths. The values of the absolute shear velocities
27 suggest that the top few kilometers of the SCB crust are likely formed by unconsolidated
28 Quaternary sediments that merge to more consolidated and crystalline rocks at a depth of ~20 km.
29 The lower crust beneath the SCB exhibits low velocities probably indicating a felsic (granitic)
30 composition. Previous studies (Zonenshain and Le Pichon, 1986; Mangino and Priestley, 1998;
31 Knapp, et al., 2004) suggest that a “basaltic” layer could be present beneath the proposed “granitic”

1 layer. If this “basaltic” layer exists, it is probably too thin to be detected by the surface waves used
2 in this study.

3 Farther to the NE, the vertical cross-sections I3, I4 and I6 (Figures 7 and 8) show that the crust is
4 relatively thin (<40 km) beneath north Central Iran and that it thickens northward to ~45 km over
5 a wide region beneath the Kopeh Dagh and Binalud mountains. Farther NE, the crust becomes as
6 thin as 30 km beneath the Turan Plate. Interestingly, the sharp NE limit of the Kopeh Dagh
7 Mountains on the surface coincides with the steep gradient in Moho depth (Figures 5, 7 and 8). The
8 Kopeh Dagh Mountains in NE Iran form an NW-SE trending fold-and-thrust belt between Central
9 Iran and the stable Turan (Turkmenistan) Platform of Eurasia (Shabanian et al., 2009). Structurally,
10 the crust of the Kopeh Dagh belongs to the Turan platform (Alavi 1996). The Binalud Mountains
11 to the south of Kopeh Dagh mark the northeastern margin of Central Iran and the suture with Kopeh
12 Dagh (Eurasia; Alavi 1992, 1996). Our Vs model suggests that the present-day lithosphere structure
13 beneath the Kopeh Dagh is distinct from the Turan plate and exhibits more similarities with the
14 central Iranian lithosphere.

15 Our velocity maps and vertical slices (Figure 4; profiles I5 and I6 in Figure 7) show a low-velocity
16 uppermost mantle ($V_s \leq 4.1$ km/s) beneath the Lut block in eastern Iran. The Lut block acts as a
17 rigid block bounded by strike-slip fault systems (Jackson and McKenzie, 1984; Berberian, 2005;
18 Jackson et al., 2006; Javadi et al., 2015). The location of velocity contrasts coincide with the surface
19 expression of the major strike-slip faults such as Doruneh fault that marks the boundary between
20 the Lut Block and northern Central Iran and Kopeh Dagh (Javadi et al., 2015). The rather low
21 velocities immediately beneath the crust in our images may also suggest that the upper mantle
22 beneath the Lut Block is overall hotter than the surrounding regions.

23 The Makran Subduction Zone (MSZ) , which extends from southeast Iran to southern Pakistan,
24 includes an accretionary wedge where the Tethys oceanic lithosphere connected to the Arabian
25 plate is subducting beneath the Eurasian Plate (e.g. Farhoudi and Karig 1977; Şengör et al. 1988;
26 Byrne et al. 1992). In the crustal depth range (<40 km), our model suggests very low velocities to
27 20 km depth beneath the Makran, which are likely related to thick Cenozoic turbidites and younger
28 Quaternary detrital sediments filling the accretionary wedge (Burg, 2018). The Moho depth is ~40
29 km beneath the coast line increasing northward to ~50 km beneath the Lut block (profiles I6 and
30 I7, Figure 7). Our model does not have sufficient resolution to constrain the geometry of the
31 subducting slab in the Makran.

32

1 ***4.3 Arabian Plate, the Red Sea and Afar depression***

2 The Arabian Plate consists of two major domains: the Arabian Shield in the west and the Arabian
3 Platform in the east. The boundary at the surface is locally identified along the remnants of the Late
4 Proterozoic orogen (Stoeser & Camp 1985). The crust of the Arabian Shield is composed primarily
5 of several tectonostratigraphic terranes that were accreted during the Neoproterozoic (Stoeser &
6 Camp 1985; Camp & Roobol, 1992; Johnson and Woldehaimanot, 2003). The Precambrian
7 basement rocks are exposed at the surface in the Arabian Shield with virtually no sedimentary
8 cover. The crust of the Arabian Shield was also affected by Cenozoic volcanism and uplift. The
9 Cenozoic volcanism is mostly flood basalts, which likely have a causal link to the rifting processes
10 in the Red Sea and Afar (Coleman and McGuire, 1988). In the Arabian Platform, however, a thick
11 succession of Phanerozoic sedimentary rocks covers the Precambrian basement. The sedimentary
12 cover in the Arabian Platform gradually thickens eastward and reaches more than 10 km thickness
13 beneath the Mesopotamian Foredeep and Persian Gulf (Seber 1997).

14 Our velocity maps and vertical slices (Figures 4, 9 and S11) suggest that on average the Arabian
15 Shield has higher crustal seismic velocities than the Arabian Platform, in agreement with previous
16 studies (Hansen et al., 2007, 2008; Chang and Van der Lee, 2011; Tang et al., 2016, 2018, 2019).
17 The velocity map at 8-km depth (Figure 4) exhibits high velocities beneath the Arabian Shield and
18 Afar depression where magmatic crystalline rocks are exposed at shallow depths. At ~15 km, a
19 wide region of very high velocities ($V_s > 4.0$ km/s) is mapped beneath the southeastern Red Sea, the
20 western Arabian Shield and the Gulf of Aden, which may indicate the presence of mantle rocks at
21 shallow depths. This high-velocity layer is imaged from a high-velocity peak in the group-velocity
22 dispersion curves (see example shown in Figure S7). Our verification with the AN-based and EQ-
23 based dispersion data (Figures 3 and S6) indicates that this layer is a robust feature in our model.
24 We suggest that the presence of such a shallow high-velocity layer beneath the Arabian Shield is
25 the result of lateral spreading of mantle material coming up beneath the Red Sea. At 25-km depth,
26 the high velocity anomaly is confined to the SE Red Sea, while the other regions of western Arabia
27 and northwest Red Sea exhibit low velocities ($3.5 < V_s < 4$ km/s). Our velocity model generally
28 suggests that northern and western Arabia and the Dead Sea region have structural similarities with
29 the Arabian Shield. For example, the 35-km depth map (Figure 4) shows that all these regions
30 exhibit mantle velocities at this depth, while further east the Arabian Platform has crustal velocities
31 ($V_s < 4.0$ km/s). The northern boundary of the Arabian Plate with the Turkish-Anatolian Plateau
32 across the Bitlis suture zone is marked by strong velocity contrasts at all depths (depths slices 15-

1 70 km, Figure 4). In addition, our model shows that the crustal structure beneath the Arabian Shield
2 and Red Sea is more complex than previously thought. Previous seismic imaging studies (e.g.
3 Rodgers et al., 1999; Tkalčić et al., 2006; Park et al., 2007, 2008; Hansen et al., 2007, 2008; Chang
4 and Van der Lee, 2011; Tang et al., 2016, 2018, 2019) suggested that the crust thickens rapidly
5 eastward from less than 25 km beneath the western Arabian Shield and Red Sea to 40-45 km
6 beneath the central region of the Arabian Shield. In contrast, our Vs model reveals a very complex
7 crustal structure beneath the Red Sea and Arabian Shield, so that the Moho can hardly be identified
8 (Figures 9, S11 and S12).

9

10 ***4.3.1 Widespread regional mantle flow beneath Afar, Red Sea, W. Arabia***

11 At depths ≥ 55 km (Figure 4), a low-velocity anomaly is mapped beneath the SE Red Sea that
12 extends laterally at 70-km depth to cover the Afar depression, Red Sea, south and SW Arabia. At
13 greater depths (90 km), this widespread low-velocity region extends northward and likely connects
14 to the low-velocity region beneath eastern Turkey. Previous global and regional seismic
15 tomography studies (e.g. Ritsema and Allen, 2003; Bastow et al., 2008; Hansen et al., 2012;
16 Hammond et al., 2013) suggest that the broad low-velocity region in the upper mantle beneath
17 eastern Africa, Afar, and western Arabia likely results from shallow decompression melting and
18 northeastward flow of the African superplume material. Our model also shows a broad low-velocity
19 region in the uppermost mantle beneath the southern Red Sea and Arabia Shield that might be
20 related to the wider mantle upwelling beneath Afar. Our model also favors the hypothesis of a
21 northward channeled flow in the uppermost mantle beneath the western Arabian Shield that was
22 also proposed by previous studies (e.g. Park et al., 2007, 2008; Hansen et al., 2007, 2008, 2012;
23 Chang and Van der Lee, 2011; Tang et al., 2016, 2018, 2019; Kaviani et al. 2018). Petrological
24 studies of Cenozoic rocks in the Arabian Shield (Duncan et al., 2016; Downs et al., 2018) also
25 support the hypothesis of a northward mantle flow. This possible northward flow of the upwelled
26 material affects not only the upper mantle but also the crustal structure beneath the Red Sea and
27 Arabian Shield. One important question that seismic tomography studies have attempted to address
28 is the mechanism of emplacement of Cenozoic volcanism in the Arabian Shield (Hansen et al.,
29 2007, 2008; Chang and Van der Lee, 2011; Koulakov et al., 2016; Yao et al., 2017; Tang et al.,
30 2016, 2018, 2019). Tang et al., (2019) and Koulakov et al., (2015) argue that the crustal low-velocity
31 zones imaged beneath the western Arabian Shield may reflect weakened zones in the crust caused
32 by magma ascent rather than significant partial melt or steady-state crustal reservoir. We also

1 propose that instead of being from large-scale crustal magma chambers, the magma intrusion
2 beneath the Arabian shield is mainly sourced from the large-scale mantle flow as suggested above.

3

4 ***4.3.2 Different structures in northern and southern Red Sea?***

5 The velocity maps of Figure 4 reveal that the southern (12°N-21°N) and northern (> 21°N) parts
6 of the Red Sea exhibit very different characteristics in terms of crustal and upper mantle structure.
7 At shallow depths (10-20 km), the southern Red Sea shows higher Vs than the northern Red Sea.
8 The shallow high-velocity layer of the southern Red Sea extends eastward beneath the Arabian
9 Shield rather than along the Red Sea. At depths below ~35 km, the situation is opposite, with lower
10 velocities beneath the southern Red Sea than beneath the northern Red Sea (Figures 4, 9 and S11).
11 The upper boundary of the low-velocity zone is marked by a negative velocity gradient as indicated
12 by red color in the interface probability sections (Supplementary Figure S12). Our Vs model
13 suggests a transition from a mostly continental crust in the northern Red Sea to an oceanic crust in
14 the southern Red Sea. Recent geophysical and offshore drilling data also highlight this structural
15 difference between the northern and southern segments of the Red Sea (Mitchell and Park, 2014;
16 Bonatti et al., 2015). These observations suggest that the crust beneath the northern Red Sea is
17 likely undergoing late stages of continental rifting, while southern Red Sea is in a stage of sea floor
18 spreading.

19 The driving force for the rifting and sea floor spreading in the Red Sea has long been a subject of
20 debate. Two end-member mechanisms are proposed: passive and active rifting. In passive rifting
21 model, spreading is driven by far-field forces such as slab pull from Zagros subduction (Koulakov
22 et al., 2016; Yao et al., 2017). In active rifting model, spreading is driven by local mantle upwelling
23 (e.g. Hansen et al., 2007). Koulakov et al. (2016) suggested passive rifting because they observed
24 a high P-wave velocity anomaly in the upper mantle beneath the Red Sea. Their velocity anomaly
25 is mainly located beneath the central part of the Red Sea. A thick low-velocity zone is mapped in
26 our images beneath southwestern Yemen (NE of the Bab el Mandeb Strait) that extends down to a
27 depth of ~60 km, where is likely the location of active partial melting and magma generation. In
28 connection to the wider mantle flow at greater depths, it seems that active mantle upwelling is
29 confined to the southern Red Sea. Based on these observations, we hypothesize that active mantle
30 upwelling is the main contributor to sea floor spreading in the southern Red Sea. GPS observations
31 (e.g. ArRajehi et al., 2010) also suggest a faster extension rate in the southern than in the northern
32 Red Sea, in support of an active rifting in the southern Red Sea. In the northern Red Sea, passive

1 rifting appears to be the dominant mechanism and mantle upwelling has a secondary role. The rift
2 axis in the NW seems to be shifted to the eastern flank of the Red Sea and beneath the western
3 margin of the Arabian Shield rather than centered at the Red Sea ridge as was also suggested by
4 Chang et al. (2013).

5

6 **5. Conclusions**

7 We used an integrated data set and a robust inversion approach to construct a 3-D shear-wave
8 velocity (V_s) model for the broader region of the Middle East. Our tomographic images of crustal
9 and upper mantle velocity structure cover the region from western Turkey to eastern Iran in the
10 EW direction and from Afar depression to Caucasus Mountains in the NS direction. Our model
11 provides relatively high-resolution images of various tectonic units constituting the crustal
12 structure of the Middle East and reveals the transitions, both laterally and vertically, between these
13 crustal units.

14 The crustal and uppermost mantle structure beneath the Anatolian Plateau and eastern Turkey
15 concurs with the main features shown by previous studies. The extent of the low-velocity crust
16 beneath the western Anatolian Plateau, likely related to the extensional tectonics of the region, and
17 the low-velocity uppermost mantle beneath eastern Turkey are very well resolved in our model.
18 The Moho exhibits local-scale topography beneath western Anatolia; a point that should be taken
19 into consideration in future studies.

20 Our velocity model provides relatively high-resolution images of the crustal and uppermost mantle
21 structure beneath the Iranian Plateau and Zagros. It delineates along-strike variation of the crustal
22 structure beneath the Zagros, which can be indicative of different stages of crustal thickening.
23 Furthermore, we observe evidence for under-thrusting of the Arabian crust beneath Central Iran,
24 with varying structure along the suture line. The crust beneath Central Iran is relatively thin (less
25 than 40 km). Our velocity model also suggests that a crustal root is lacking beneath the Alborz
26 mountains in northern Iran. In eastern Iran, we image a relatively low-velocity uppermost mantle
27 beneath the Lut Block, which could indicate a hot upper mantle but it requires higher resolution
28 imaging to be confirmed.

29 The velocity model also provides relatively high-resolution images of the crustal structure beneath
30 the Arabian Platform and Shield, Red Sea and Afar. These images suggest that while the crust
31 beneath the SE Red Sea exhibits oceanic characteristics, the crust beneath the NW part seems to
32 have a continental affinity. A relatively high-velocity layer is present extensively at the mid-crustal

1 depths beneath the Arabian Shield that likely originates from the mantle material upwelling beneath
2 the central ridge of the Red Sea and spreading to the east and NE beneath the Shield. The Cenozoic
3 magmatic activity in the Arabian Shield may be sourced from the hot material flowing beneath the
4 Shield at different depth levels.

5 Our integrated 3-D Vs model and crustal thickness map of the Middle East provide a foundation
6 for future studies in different disciplines including local crustal studies, earthquakes location and
7 seismic hazard assessment, and first order constraints for geodynamic modeling. The digital Moho
8 map is provided as Supplementary material for future references. The 3-D Vs model is made
9 available online through the IRIS (Incorporated Research Institutions for Seismology) Earth Model
10 Collaboration (IRIS DMC, 2011) (<http://ds.iris.edu/ds/products/emc-earthmodels/>) with the label
11 Midd_East_Crust_1.

13 **Acknowledgment**

14 The authors would like to thank three anonymous reviewers for providing valuable comments and
15 suggestions that improved the initial and revised versions of the manuscript.

16 This study was possible thanks to the availability of continuous daily record of seismic noise from
17 permanent and temporary stations operating in the region. Data was provided by different
18 seismological networks and data centers. The Iranian Seismological Center (Institute of
19 Geophysics, University of Tehran) and International Institute of Earthquake Engineering and
20 Seismology (IIEES) gratefully provided the daily noise record from the permanent broadband
21 stations in Iran. Continuous records from Kandilli Observatory Digital Broadband Seismic
22 Network (doi: 10.7914/SN/KO, Kandilli Observatory and Earthquake Research Institute,
23 Bosphorus Univ. (2001)) and Israeli Broadband Seismological Network (GII-Net, network code
24 IS) were downloaded from the European Integrated Data Archive (EIDA). The facilities of IRIS
25 Data Services and specifically the IRIS Data Management Center were used to access data of
26 temporary stations and global permanent stations used in this study. IRIS Data Services are funded
27 through the Seismological Facilities for the Advancement of Geoscience and EarthScope (SAGE)
28 Proposal of the National Science Foundation under cooperative agreement EAR1261681. The
29 seismological networks providing data to us via the IRIS data service are listed in the
30 Supplementary Information.

31 Rayleigh wave group-velocity dispersion data from the Saudi National Seismic Network (SNSN)
32 operated by the Saudi Geological Survey was taken from previous studies (Tang et al., 2018, 2019)

1 of the seismology group (PMM and ZT) from the King Abdullah University of Science and
2 Technology (KAUST). PMM and ZT were supported by grant BAS/1/1339-01-01 funded by the
3 KAUST.

4 We adopted the algorithm introduced by Boué et al. (2014) and used the WHISPER software
5 package (Briand et al., 2013) to preprocess individual daily vertical-component records. Seismic
6 analysis was conducted using the routines implemented in the Python package ObsPy (Beyreuther
7 et al, 2010).

8 The maps shown in the paper were created using the Generic Mapping Tools (Wessel et al., 2013).
9 S.P. acknowledges support from Natural Environmental Research Council (NERC) grant
10 NE/R013500/1 and from the European Union's Horizon 2020 research and innovation program
11 under Marie Skłodowska-Curie grant agreement 790203. S.P. is grateful to the NCM for providing
12 continuous passive seismic data used in this study.

Computation of vertical component cross-correlation functions and extraction of Group-velocity dispersion curves

We follow a standard approach based on algorithms suggested by Bensen et al. (2007) and Boué et al. (2014) to compute the two-station cross-correlation functions from daily noise records. The initial step includes removing mean and trend, decimating to 2 samples per second and removing the instrument responses. The main steps of preprocessing of instrumentally corrected daily records are: (1) applying a Butterworth filter (2s-200s); (2) cutting each daily trace into 4-hour segments; (3) zeroing 4-hour segments suspicious of being contaminated by energy of large earthquakes; (4) dividing each 4-hour segment into three sub-segments and clipping the large amplitudes in order to minimize the effect of local earthquakes; (5) whitening of Fourier amplitude spectra to achieve uniform spectra of the ambient-noise records (a requirement to achieve equipartitioning); (6) merging the 4-hour segments to make daily preprocessed traces.

We then cross-correlate the preprocessed daily records for all possible pairs of stations. The daily cross-correlations for each station pair are finally stacked using the time-frequency phase-weighted stacking algorithm of Ventosa et al. (2017). Some examples of the stacked cross-correlation traces are shown in Figure S1. The stacked cross-correlation function (CCF) for each station pair represents the Green's function between the two stations and is dominated by the fundamental-mode Rayleigh waves. We therefore apply frequency-time analysis (FTAN) (Levshin et al. 1989; Bensen et al. 2007) on the stacked cross-correlations to extract Rayleigh wave Group-velocity dispersion curves for each interstation path. We apply a phase-matched filter to suppress possible contamination by higher modes and to enhance the signal-to-noise ratio (SNR). The FTAN analysis is applied separately on the causal and acausal parts of each cross-correlation function. The SNR of the filtered signal at each central frequency is evaluated for each side of the cross-correlation function. The SNR is defined by dividing the peak amplitude in the time window of the Rayleigh wave by the standard deviation of noise outside of the Rayleigh wave window. The estimated group velocities from causal and acausal sides of the CCF are then compared at each period. In the end, the average of the measurements from the two sides of the CCF is taken as the Group-velocity at target periods. If the standard deviation of the measurement from the two sides is larger than 0.22 km/s, the measurement at the corresponding period is discarded. We also verify each individual dispersion curve for its continuity along the whole range of observable periods. In the case of large gaps or jumps, the dispersion curve is not used for the subsequent tomography analysis. The longest period for each path depends on the interstation distance. By assuming that the interstation distance is larger than three wavelengths and taking an average Group-velocity of 3.3 km/s, the longest period measurable for each path is assumed to be $\sim 1/10$ of the interstation distance. The difference between the causal and acausal measurements is taken as the uncertainty of the Group-velocity measurement at each period. In Figure S2, we show a few representative examples of the FTAN analysis and extraction of Group-velocity dispersion curves.

Clustering of group-velocity paths

In order to avoid biasing the Group-velocity maps by multiple measurements along close paths, we use the following clustering approach. The endpoint coordinates and Group-velocity value of the new path are the mean values computed from the individual paths forming the cluster. If the

Group-velocity measurement of a path among a cluster falls beyond two standard deviations relative to the mean value of the cluster, it is considered an outlier and discarded. Paths with no nearby paths are treated as unique paths. This clustering procedure is particularly helpful in our case because we merge different data sets and measurements (from noise correlations and earthquakes). Following this clustering procedure, we obtain more than 54000 ray paths giving reliable Group-velocity measurements at periods between 5 and 150 s. In Figure S3, we show ray paths at several selected periods. The paths are color-coded according to their associated group velocities.

Synthetic tests for group-velocity tomography

To assess the resolution power of the data set and inversion approach, we performed several synthetic tests using the same ray configuration as the real data set. At each period, we calculated theoretical travel times from the synthetic models and added random noise with standard deviation 0.15 s. The synthetic data set was inverted using the same regulation parameters as the real data inversion. The results of synthetic tests at several periods are shown in Figure S5. Figures S5a-b show results for checkerboard tests with anomaly size 1° and 2° , respectively. In Figure S5c, the input model is made up of spikes with random locations and sizes. These tests reveal that at short periods (8 s), features as small as 1° are well resolved in Turkey, across the Zagros, and in Afar, while some smearing can be observed in other regions. At periods 18-36 s, the 1° anomalies are fairly well resolved in all regions with some minor smearing across the Arabian Plate and Eastern Iran. At 46 s, the resolution power of small-size anomalies is fair in Northern Middle East and Afar but relatively low in other regions. At periods ≥ 55 s, 1° anomalies are well resolved in Turkey but not in other regions where ray coverage is lower. Larger features with size up to 2° are well resolved at all periods throughout the entire study region. Interestingly, the resolution of the model with an arbitrary distribution of anomalies (Figure S5c) is much better than that of the checkerboard models. This test implies that the resolution in a real case might be better than what is estimated by checkerboard tests. For example, the checkerboard tests (Figs S5a and S5b) show strong smearing along the Red Sea, whereas the synthetic model with irregular distribution of velocity anomalies (Fig. S5c) indicates that this type of anomalies in the Red Sea can be resolved with our data coverage.

Inversion for shear-wave velocity

For each cell, a depth-dependent probability function is calculated that defines the probability distribution of Vs and the probability of occurrence of a layer boundary at each depth. The probability function is defined as follows:

$$p(d_{obs}|m) = \frac{1}{\sigma^N} e^{-\frac{(g(m)-d_{obs})^2}{2\sigma^2}}$$

The term $(g(m) - d_{obs})^2$ is the root mean squared misfit between the observed and calculated dispersion curves. This term is calculated for all input random models. The uncertainty parameter σ varies between 0.02 and 0.2. N is the number of observed periods of the dispersion curves. In our case, $N = 42$ (for periods 2, 3, 4, 5, 6, 7, 8, 10, 12, 14, 15, 16, 18, 20, 22, 24, 25, 30, 36, 40, 46, 50, 55, 60, 65, 70, 75, 80, 85, 90, 95, 100, 105, 110, 115, 120, 125, 130, 135, 140, 145 and 150 s). At each grid, the probability value of each random model is calculated as stated above, in a sense that the sum of all probability values is 1. The optimal values for σ are also found through this search. Then, the 10 most probable models are selected to create the final 1-D model. A 2-D (depth-velocity) probability function is generated by summing up the 1-D depth-velocity profiles of the best random models. In this summation, each model is weighted by the corresponding probability value. The 2-D probability function for each cell presents the range of most probable velocities at each depth.

As the initial random models consist of four crustal layers separated by velocity boundaries, the probability of occurrence of a layer boundary at each depth is also calculated by assigning the probability value of each random model to the corresponding layer boundaries and summing up the values among the best models. The result is a 1-D depth-probability function that shows the weighted probability values at each depth. At the end, in order to take into account the velocity contrast at each layer boundary, the interface occurrence probability is modulated by the velocity-depth gradient value at each depth to give a normalized 1-D depth-probability function. In the case of a low velocity layer, the velocity gradient at the upper boundary of the layer is negative, which therefore gives a negative the normalized probability value. By combining the normalized 1-D depth-probability function at each cell, a 3-D probability function is obtained that gives the probability of occurrence of velocity interfaces.

In the second step, the average 1-D model obtained by the Bayesian inversion at each cell is used as the starting model for the linearized inversion (Herrmann, 2013). The 1-D models are discretized for the linear inversion as follows: 1 km interval for depths 0-60 km, 2 km interval for depths 60-80 km, 5 km interval for depths 80-100 km, and then every 10 km down to 150 km. Two examples of the two-step inversion of dispersion curves for 1-D Vs models at selected cells are shown in Figure S6. The final 1-D velocity models are merged to create the 3-D Vs model.

Supplementary Figures

Figure S1. Examples of stacked cross-correlations used in this study. The traces are sorted by interstation distance. For each distance range, a single high-quality trace is selected and displayed. Clear dispersive Rayleigh wave-trains are observed with group velocities between 2.1 km/s and 4.1 km/s.

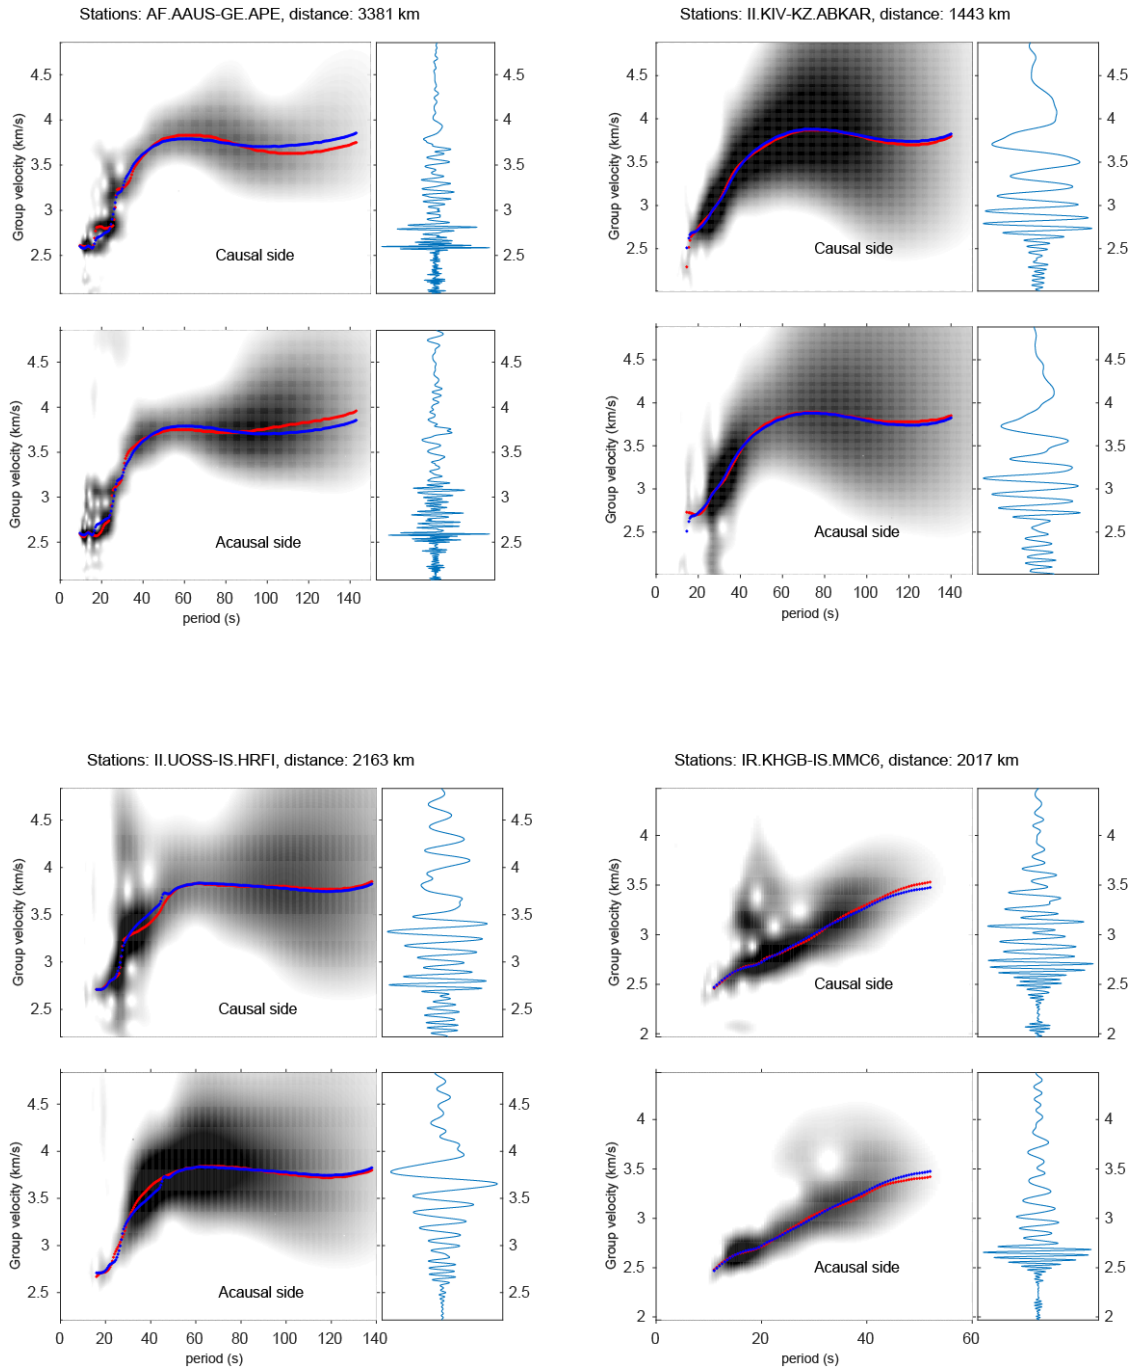

Figure S2. Examples of frequency-time analysis (FTAN) on cross-correlation waveforms used to compute group-velocity dispersion curves. The background grey color in the period-Group-velocity domain indicates envelope amplitude of the filtered trace around each central period. The trend of the maximum energy follows the Group-velocity of the dispersive surface wave train and helps extract the dispersion curve. The blue curve is the extracted dispersion curve from each side (causal and acausal) and the red one is the average final dispersion curve.

Figure S3. Examples of two-station ray paths color-coded according to their group velocities at each period. Note that the color scale changes with period.

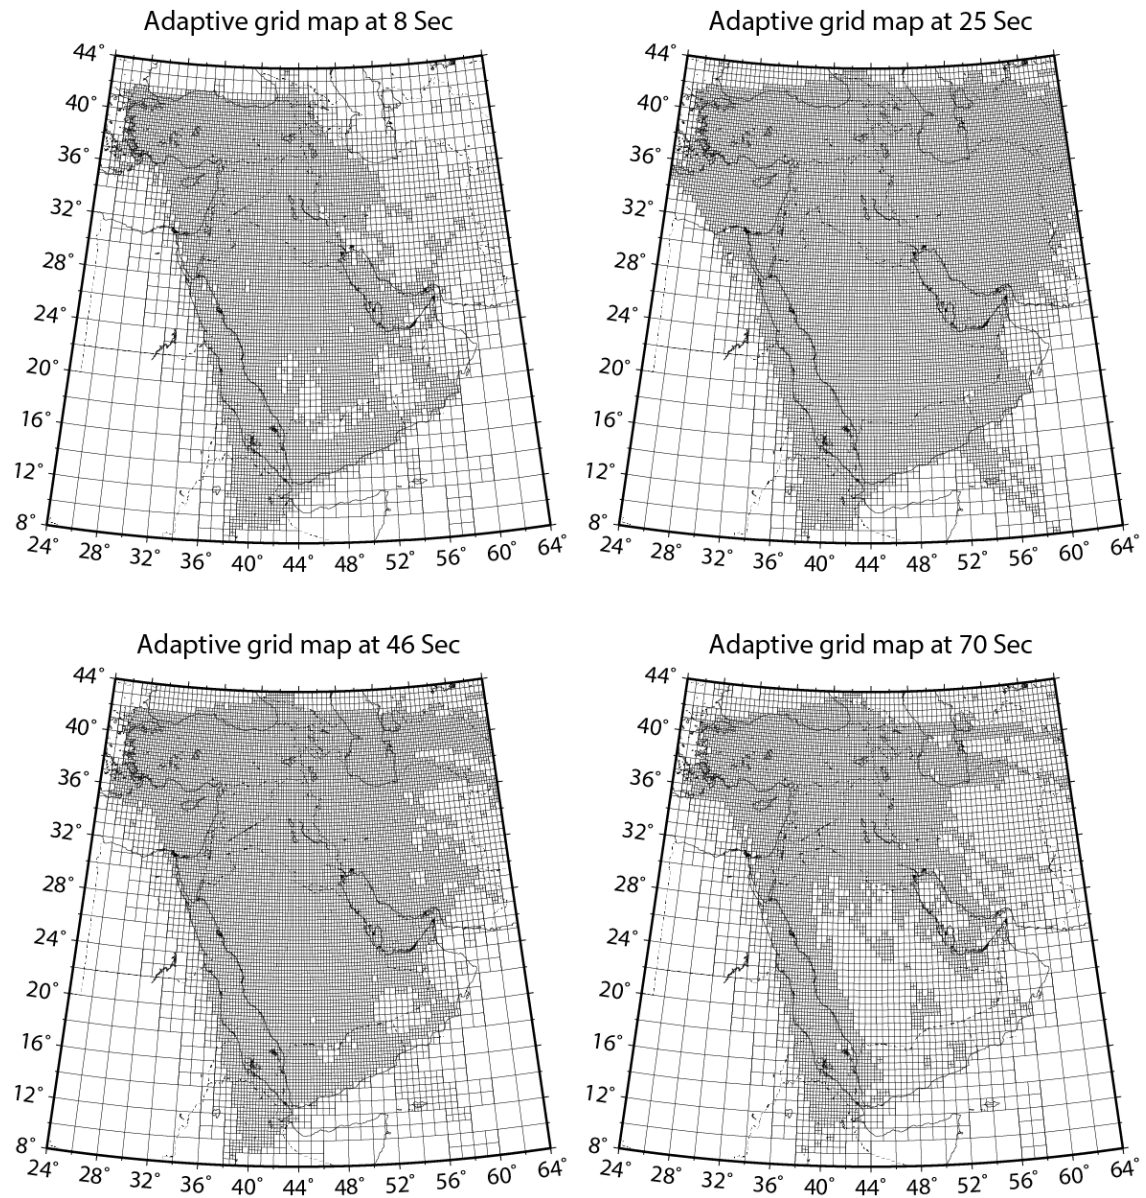

Figure S4. Maps showing examples of the adaptive cell parameterization for the 2-D group-velocity tomography. The smallest cells have a size of $0.25^\circ \times 0.25^\circ$

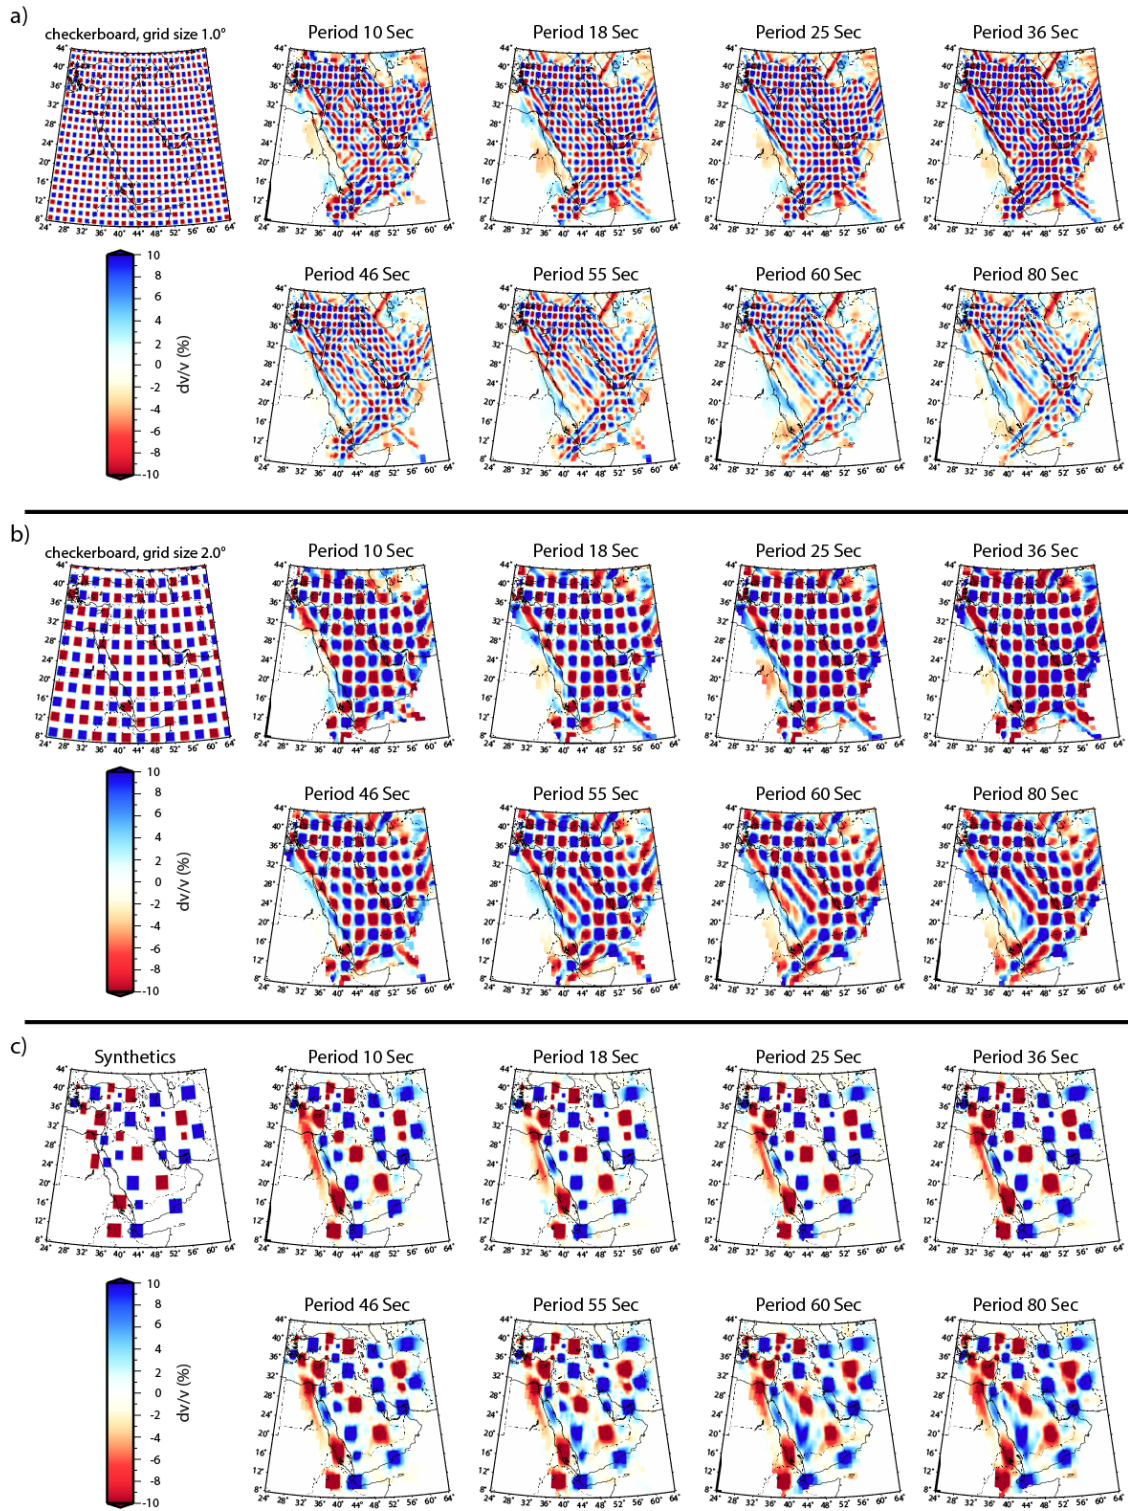

Figure S5. Synthetic tests to assess the resolution power of the inversion for Group-velocity. a) and b): Checkerboard tests with cell size of 1° and 2° , respectively. c): A random distribution of velocity anomalies with varying sizes. Input models shown in the upper left corner of each panel.

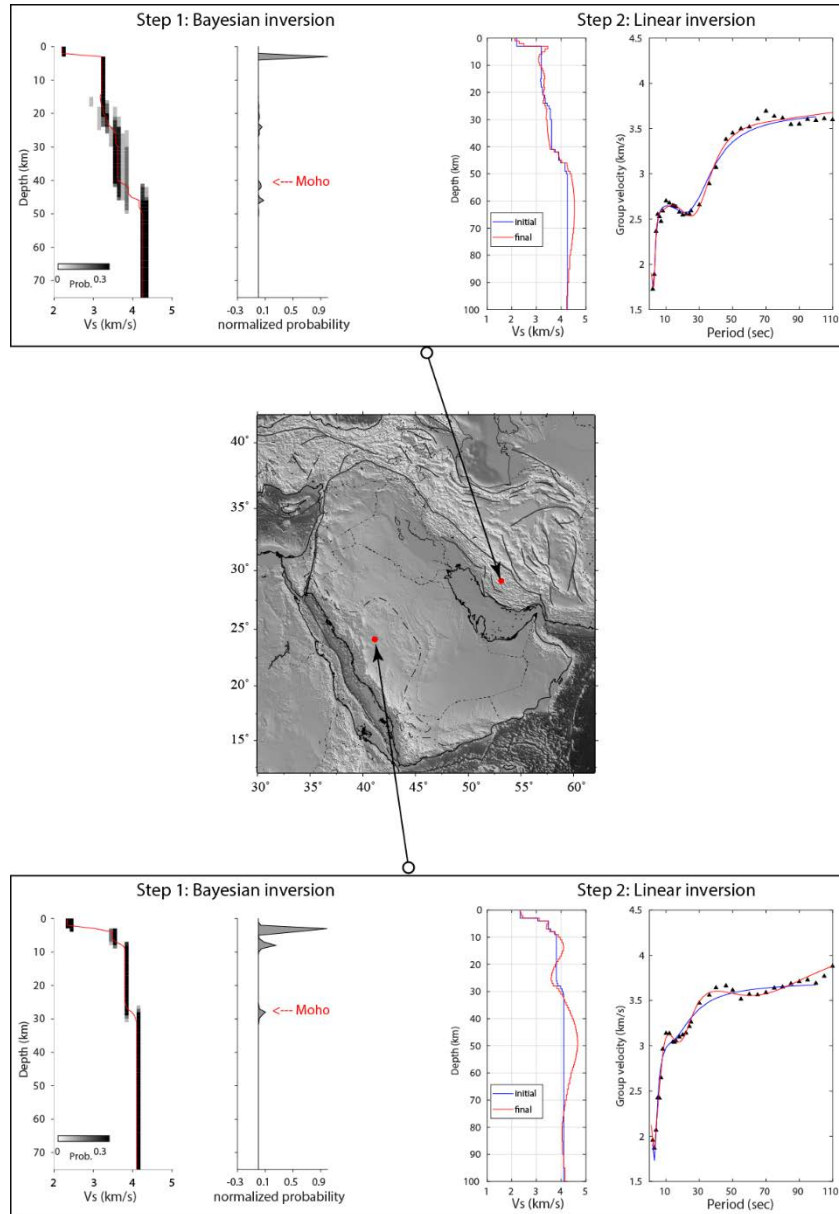

Figure S6. Examples of results of the two-step inversion for V_s for two selected cells in the Zagros and Arabian Shield. In each sub-figure, the left panel shows the results of the Bayesian inversion: velocity-depth probability function and the probability function for interface occurrence normalized by the associated velocity gradient. The red solid line in the velocity-depth figure (left) is the velocity-depth profile averaged from 10 best models. This model is used as the initial model for the linear inversion in step 2. The right panel shows the result of the final linear inversion. Left: Initial (blue) and final (red) velocity models; Right: group-velocity dispersion curves: black stars: observed data, blue and red curves: dispersion curves calculated for the initial and final velocity models.

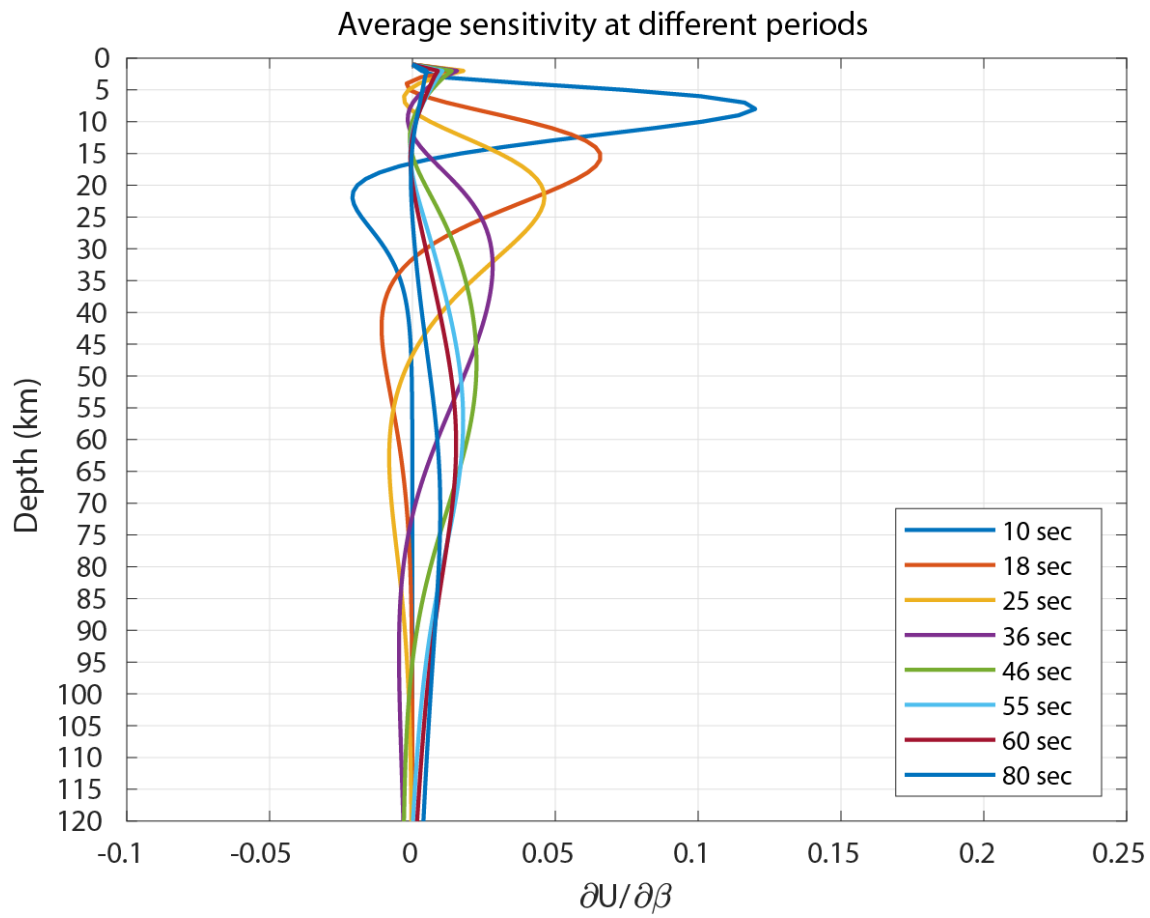

Figure S7. Sensitivity kernels showing the sensitivity of Rayleigh wave Group-velocity at different periods to the shear-wave velocity at different depths.

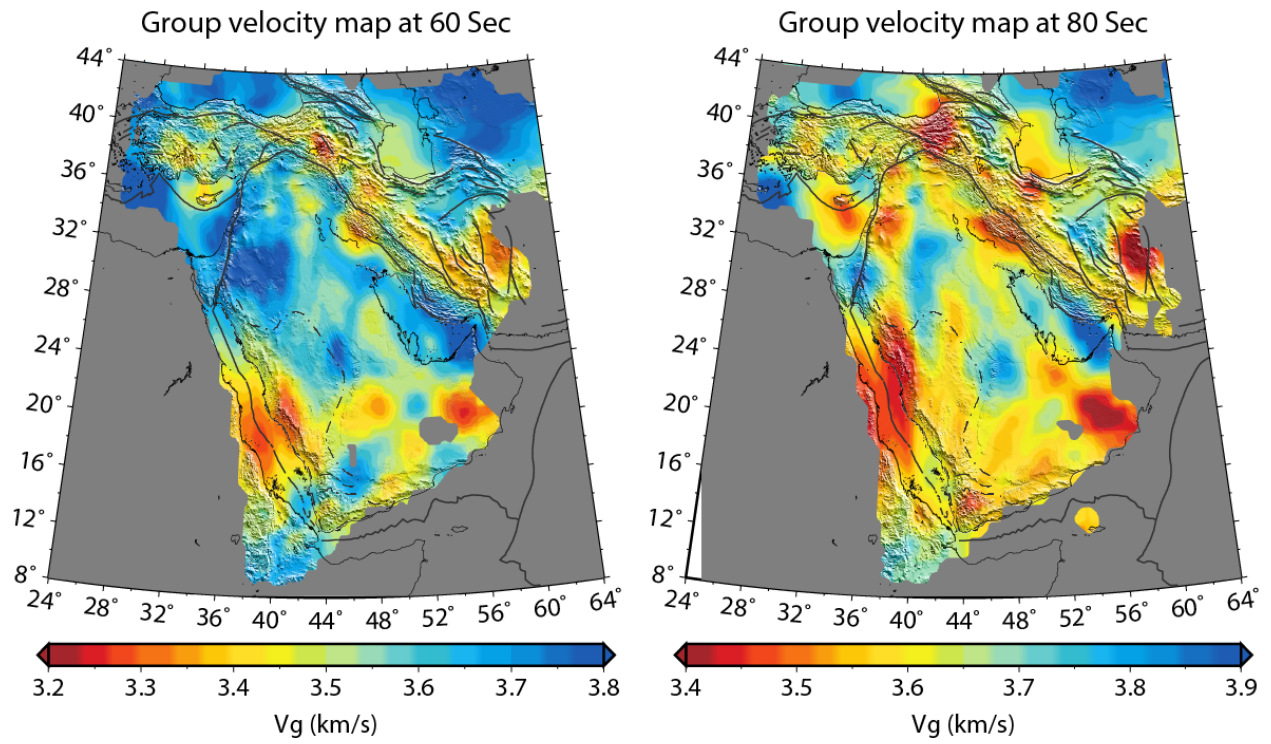

Figure S8. More examples of Group-velocity maps for periods 60 and 80 s. According to the sensitivity kernels of Figure S7, the Group-velocity at these periods is representative of V_s at depths 70 and 90 km, respectively.

Figure S9. Vertical sections in the 3-D Vs model along profiles T4-T8 across Eastern Turkey and the Anatolian Plateau. The solid and dashed black lines indicate the traces of Moho, from this study and CRUST1.0, respectively. Vertical exaggeration is 3.

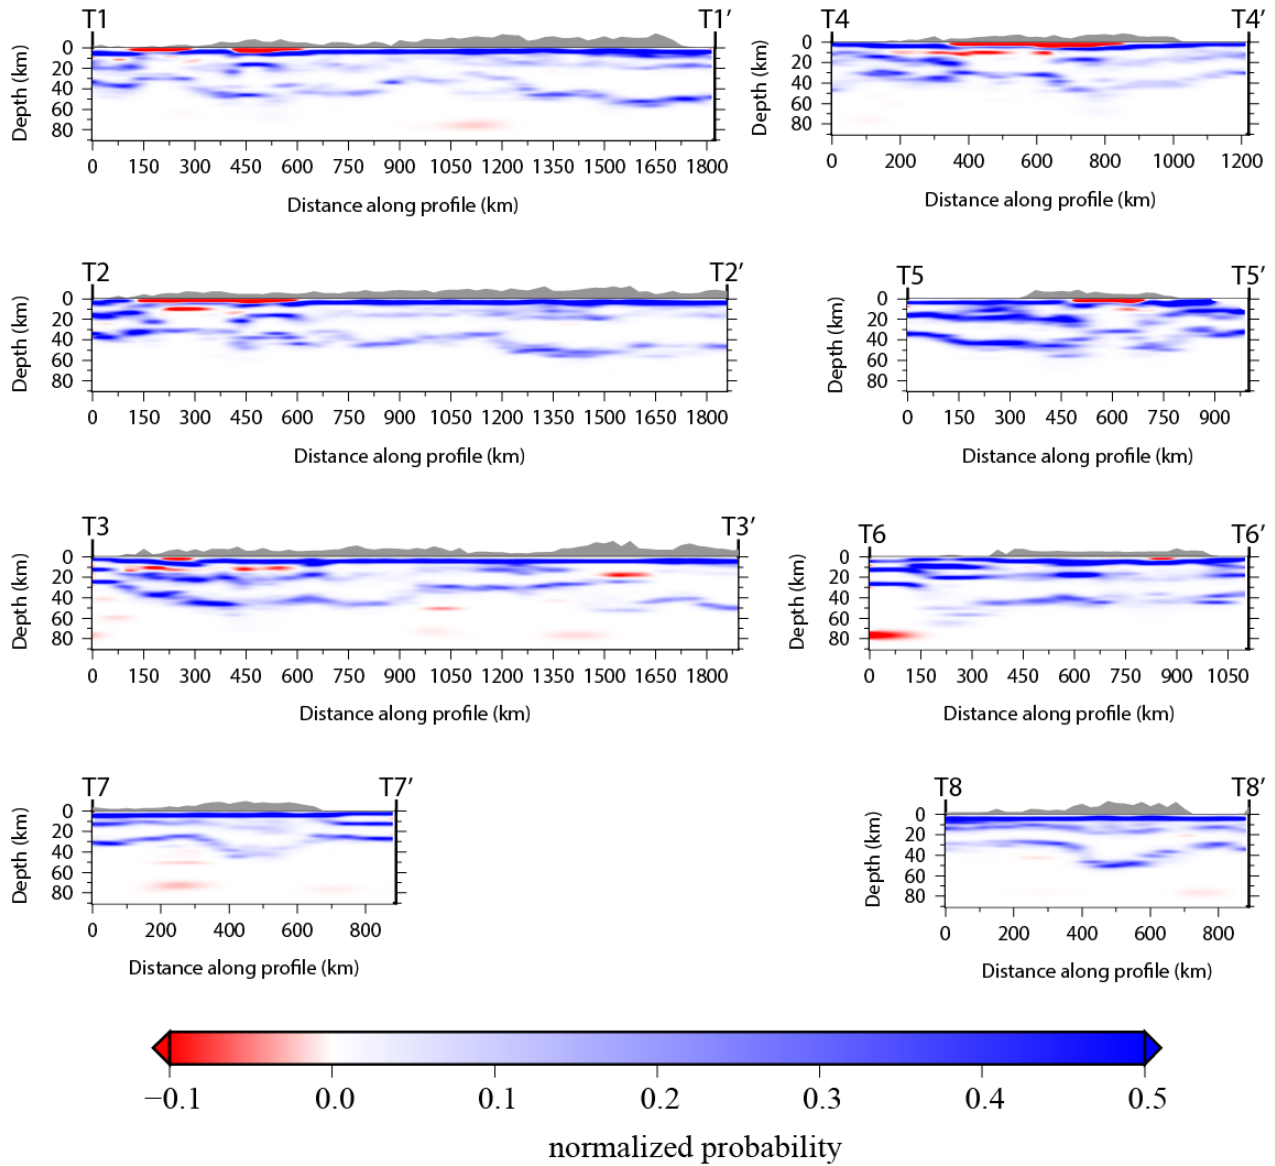

Figure S10. Vertical slices of interface probability function across Eastern Turkey and the Anatolian Plateau. The color scale of the vertical slices indicates the probability of occurrence of a layer boundary at a given depth. The blue color indicates boundaries of low-to-high velocity change with depth. The red color indicates boundaries with negative velocity gradient, which correspond to the top of low-velocity layers. Locations of cross-sections as in Fig. S9.

Figure S11. Same as Figure S9 for profiles A1, A3, A7 and A8 across the Arabian Plate, Red Sea and Afar.

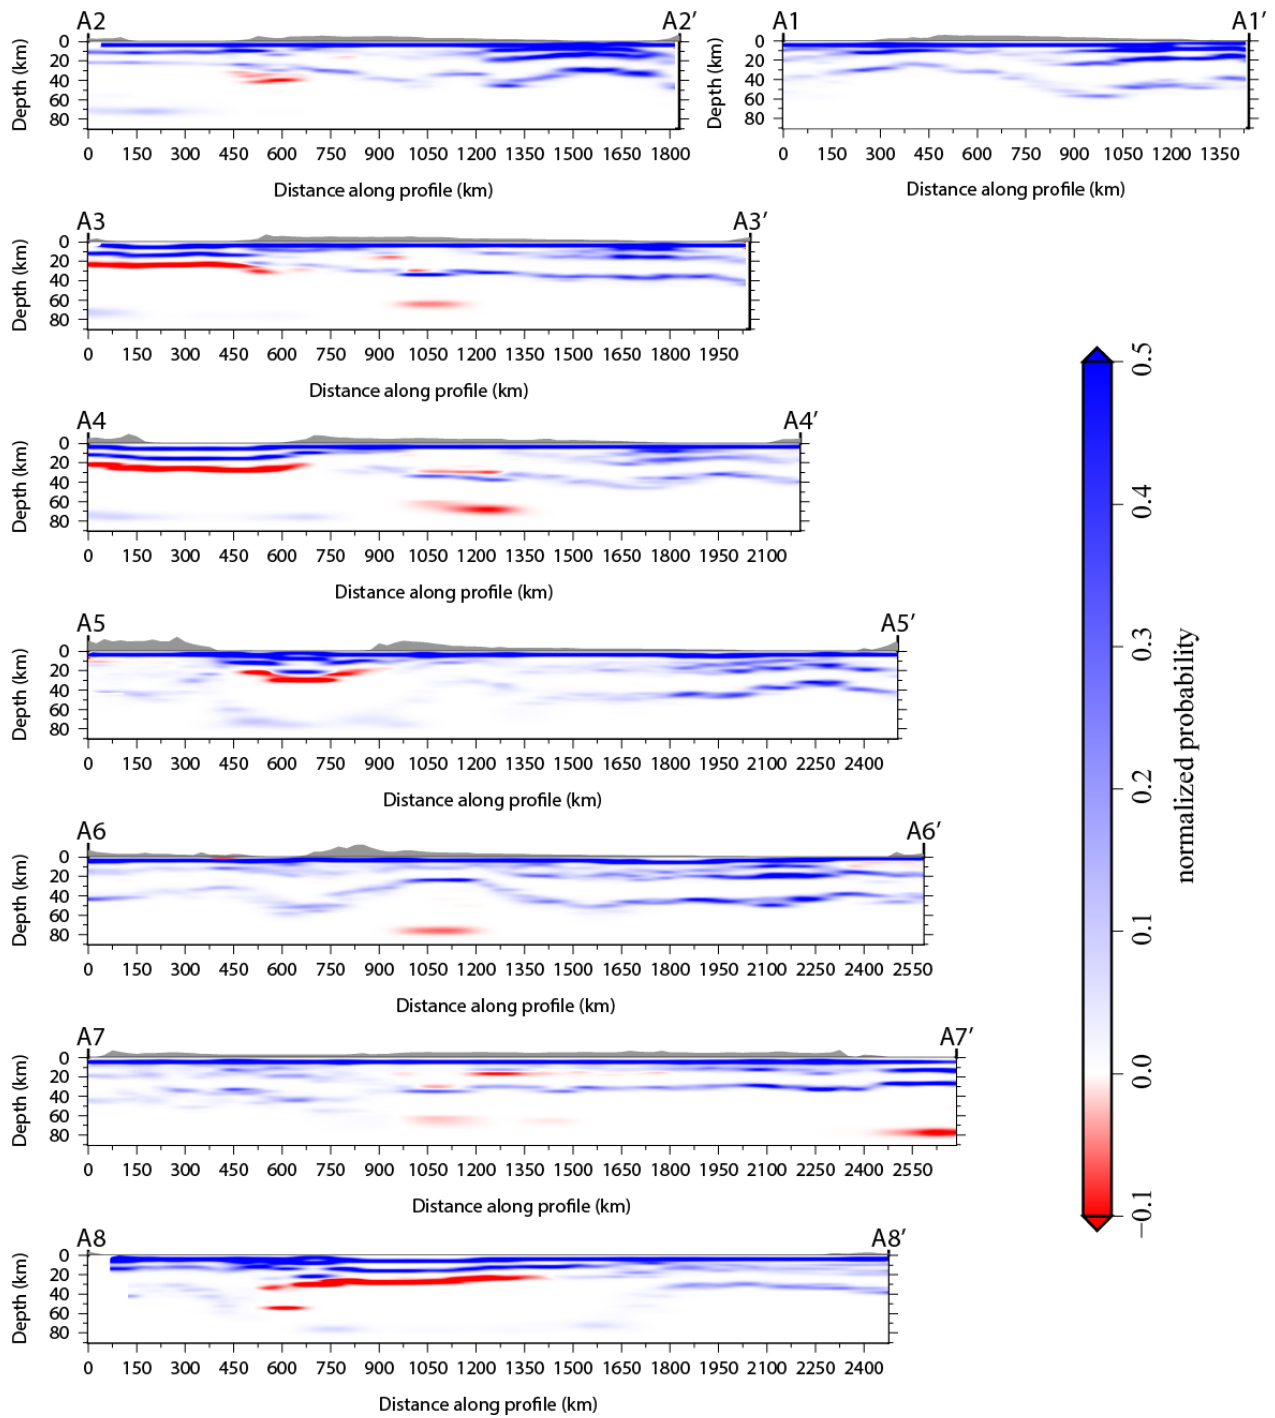

Figure S12. Vertical slices of interface probability function across the Arabian Plate, Red Sea and Afar. The color scale of the vertical slices indicates the probability of occurrence of a layer boundary at a given depth. The blue color indicates boundaries of low-to-high velocity from surface to depth. The red color presents the reverse-velocity gradient, which means the top of a low-velocity layer.
