Abstract :

Within the development of future nuclear reactors, wet chemistry routes have been investigated for the fabrication of advanced oxide fuels. In this frame, a multi-parametric study focused on the hydrothermal conversion of uranium(IV) oxalate $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ into uranium oxides was undertaken in order to unravel the effects of temperature, pH and kinetics. For $\text{pH} \leq 1$, the lowest temperatures explored (typically from 180 to 200°C) led to stabilize $\text{UO}_{2+x}/\text{U}_4\text{O}_9$ mixtures exhibiting a global O/U ratio evaluated to 2.38 ± 0.10 from U M₄-edge HERFD-XANES experiments. Higher temperatures (220-250°C) led the oxide stoichiometry to decrease down to 2.13 ± 0.04 which corresponds to a lower fraction of U_4O_9 in the mixture. Additionally, increasing the temperature of the hydrothermal treatment efficiently improved the elimination of residual carbon species and water. Hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ also led to a drastic modification of the powders morphology. With this aim, pH tuning could be used to shift from bipyramidal aggregates (up to $\text{pH} = 1$), microspheres ($2 \leq \text{pH} \leq 5$) then to nanometric powders ($\text{pH} > 5$). Finally, a kinetics study showed that uranium oxides can be obtained from the hydrothermal decomposition of oxalate within only few hours. If the samples early collected during the treatment always presented the characteristic XRD lines of $\text{UO}_{2+x}/\text{U}_4\text{O}_9$ fluorite-type structure, they were found to be strongly oxidized ($\text{O/U} = 2.65 \pm 0.14$) which suggested the existence of a U(VI)-bearing amorphous secondary phase. This latter further tended to reduce through time. Hydrothermal conversion then probably proceeds as a two-step mechanism composed by the oxidative decomposition of uranium(IV) oxalate followed by the reduction of uranium by organic moieties and its hydrolysis. It appears as an easy and efficient way to yield highly pure uranium oxide samples in solution.

1. Introduction

Uranium dioxide (UO_2) is the most used nuclear fuel in Light Water Reactors (LWR). Additionally, some countries also employ actinide mixed oxides (MOx) such as $(\text{U,Pu})\text{O}_2$ in a number of LWR-type nuclear reactors and they still appear to be reference components for several future Generation IV designs, including Sodium-cooled Fast Reactor (SFR)¹. Such concepts not only aim to increase the reactor safety but also to save uranium resources. As these objectives can be achieved by the means of a closed cycle, it is compulsory to set up fuel reprocessing and subsequent refabrication processes. In this frame, the use of wet chemistry methods is foreseen to replace powder metallurgy, with the aim to improve the homogeneity in the cations distribution within the final oxides^{2,3}, and to reduce the amount of residual highly radioactive powder produced during fuel processing. Among the routes explored, the oxalic precipitation is certainly one of the most studied as revealed in a recent review⁴. Indeed, it provides quick, quantitative and homogenous precipitation of cations from aqueous mixtures and offer the possibility to incorporate simultaneously actinides with various oxidation states⁵.⁶. Moreover, the corresponding oxides are easily obtained through a heating conversion step^{7,8}.

Despite these advantages, the resulting oxide powders suffer from some drawbacks which can impact their ability to form dense ceramic material during sintering process. First, the precipitation of An(IV) oxalates generally yields platelet-shape agglomerates. This morphology is further retained upon heating due to the isomorphic character of the oxalate-oxide conversion⁹, and can lower the flowability of the final powder. Also, oxides coming from oxalate precursors were systematically found to present residual traces of carbon, typically from around 100 ppm when calcined under air¹⁰ up to several thousands of ppm for thermal conversion performed under inert or reducing atmospheres⁹. Unfortunately, such residual carbon content was frequently associated to de-densification processes observed during the sintering step^{11,12}.

In order to avoid these potential issues and to get the rid of the thermal conversion step, several studies recently investigated the use of hydrothermal conditions to directly achieve actinide oxide precipitation in solution. In such methods, the precipitation of the cations is ensured by the use of an organic complexing agent, which is further degraded *in situ* by the combined action of temperature and pressure. Simultaneously, actinides are hydrolyzed to form hydroxo- or oxohydroxo- species that finally age into oxides¹³. If some authors reported on the formation of spherical particles at the microscopic scale using aspartic acid or urea as

complexing agents ¹⁴⁻¹⁷, the use of oxalates was mostly related to the preparation of nanometric particles ¹⁸. Also, the studies frequently focused on the morphology of the powders obtained and generally lacked from a complete chemical characterization. As a matter of example, the accurate stoichiometry of uranium(IV) oxides prepared through hydrothermal conversion of hydrothermal precursors was rarely assessed, although the authors aimed at preventing oxidation through the use of anti-nitrous agents ¹⁹ or by working under inert atmosphere ²⁰.

On this basis, this paper is focused on the hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ oxalate precursor into uranium oxides. A multi-parametric study was undertaken in order to unravel the effects of temperature, pH and kinetics and get advanced insights on the hydrothermal conversion mechanism. For all the samples prepared, a complete characterization was achieved at the structural, morphological and chemical levels. The variation of the crystallographic data correlatively to that of the O/U ratio within the oxides as well as the presence of residual amounts of carbon and/or water was particularly investigated in order to finally suggest optimal conditions allowing the direct precipitation of pure uranium dioxides as close as possible from the stoichiometry.

2. Experimental

2.1. Preparation of the samples

All the reagents used were of analytical-grade and supplied by Sigma-Aldrich, except uranium metal chips that were kindly supplied by CETAMA. The preparation of uranium (IV) chloride solution was performed by dissolving uranium metal scraps in concentrated hydrochloric acid. The metal pieces were first rinsed with dichloromethane, acetone and water, washed in 2M HCl in order to eliminate possible traces of uranium oxide formed at the surface, then finally dissolved in 6M HCl. Such a high hydrochloric acid concentration allowed us to maintain the tetravalent oxidation state of uranium in solution for several months ²¹. The uranium concentration of the final solution was measured to 0.68 ± 0.01 M from ICP-AES measurements.

All the samples studied in this work were prepared from the precipitation of uranium(IV) oxalate and its subsequent conversion into oxide samples under mild hydrothermal conditions. The initial precipitation was obtained by mixing about 0.5 mmol of tetravalent uranium in hydrochloric solution with a 50 mol.% excess of 0.5M oxalic acid. Mixture of the

reagents rapidly led to the formation of a greenish precipitate. Afterwards, both the solid phase and the supernatant were transferred in a Teflon-lined autoclave (Parr). Whatever the operating conditions tested, the volume of the solution was adjusted to 15 mL by adding 0.5 M HCl to avoid any bias due to autogenous pressure during the thermal treatment. The pH of the resulting solution was generally below 0.5 and was further adjusted by addition of diluted NH_4OH and hydrochloric solution.

The reactor was finally sealed then heated between 130 to 250°C for 1 to 48 hours. As a matter of example, the pressure was close to 80 bars at 250°C²². The autoclave was cooled down naturally before collection of the final precipitate. This latter was separated by centrifugation at 14000 rpm, washed twice with deionized water and twice with ethanol then finally dried overnight at 90°C in an oven.

In parallel, the supernatant was analyzed by Photo-Electron Rejecting Alpha Liquid Scintillation (PERALS) to determine the residual uranium concentration and to calculate the precipitation yield. The extraction protocol described in our previous works²³ was considered, using Alphaex® as the extracting phase (containing HDEHP, as the extractive molecule).

2.2. Characterization of the samples

PXRD. Powder X-Ray Diffraction (PXRD) patterns were obtained by the means of a Bruker D8 diffractometer equipped with a Lynxeye detector adopting the reflection geometry with Göbel mirror and using $\text{Cu K}\alpha_{1,2}$ radiation ($\lambda_{\text{average}} = 1.54184 \text{ \AA}$). PXRD patterns were recorded at room temperature in the $5 - 100^\circ$ range (2θ), a step size of $\Delta(2\theta) = 0.01^\circ$ and a total counting time of about 3 hours per sample. Powders were placed in a dedicated sample holder to avoid any radioactive contamination. This dome-shaped container equipped with an anti-scattering blade can lead to enhanced background in the $10\text{-}20^\circ$ 2θ range as well as small variations in peaks intensities. Pure silicon was collected as a standard and used to extract the instrumental function. All the PXRD patterns were refined by the Rietveld method using the Cox-Hastings pseudo-Voigt profile function²⁴ implemented in the Fullprof_suite program²⁵. During the refinements, the conventional profile/structure parameters (zero shift, unit cell parameters, scale factors, global thermal displacement and asymmetric parameters) were allowed to vary. Moreover, the modelling of the intrinsic microstructure parameters was performed by applying both an anisotropic size and strain model in agreement with the m-3m Laue class.

X-ray absorption spectroscopy (XAS). X-ray absorption near edge structure (XANES) data were measured at the MARS beamline of the SOLEIL synchrotron (Saint-Aubin, France)^{26, 27}. The storage ring was operating in top-up mode at an electron current of 500 mA, 2.5 GeV. The beam size on sample was 150 μm \times 150 μm FWHM (H \times V). High-energy resolution fluorescence detected XANES (HERFD-XANES) was measured at the U M₄-edge (3.7 keV) using the double-crystal monochromator (DCM) with a pair of Si(111) crystals. Higher harmonics rejection and vertical focusing was achieved using the Si strip of each mirror inserted before and after the DCM with a 4 mrad incidence angle. The incident energy was calibrated using the absorption K-edge of potassium of a KBr pellet (3.6 keV). The incident X-ray flux on the sample position was 1.9×10^9 ph/s at 3.5 keV. HERFD-XANES was measured using the crystal-analyzer x-ray spectrometer in the Rowland geometry and a KETEK single element silicon solid state detector. The M β emission line (3.339 keV) was analyzed using the 220 reflection of a Si(220) bent diced crystal analyzer with a curvature radius of 1m. The samples were oriented at 45° with respect to the incident beam. A He-filled chamber was used to reduce the scattering of the incident and emitted x-rays by the air between the sample and the crystal analyzer and the detector. The overall energy resolution of the emission spectrometer was 1.1 eV as determined from the FWHM of the elastic scattering peak at the double energy. Samples were prepared as pellets for each compound diluted in boron nitride. Thanks to the Athena Software, all spectra collected were normalized at the maximum of absorption, then they were fitted as a linear combination of different references to quantify the contribution of U(IV), U(V) and U(VI). All fits were obtained with a quality factor of $X^2 < 0.04$. A UO₂ single crystal provided by JRC Karlsruhe was chosen as pure U(IV) standard, while a U₄O₉ spectrum previously collected at the ESRF-ID26 beamline was used as a mixed standard for U(IV)/U(V) with a 1/1 ratio²⁸. This latter sample was obtained by solid-state chemistry from a mixture of UO₂ and U₃O₈. Its homogeneity and stoichiometry were checked by neutron diffraction in similar conditions than our experiments (i.e. at room temperature and ambient pressure)²⁹. Additionally, a U₃O₈ sample obtained by calcination of studtite (UO₄.4H₂O) under air at 800°C for 5 hours was taken as a mixed standard for U(V)/U(VI) with a 2/1 ratio²⁸ while UO₂(NO₃)₂.5H₂O supplied by Prolabo was selected as pure U(VI) standard.

SEM observations. Before their observation, the samples were systematically deposited on carbon adhesive tape. Scanning Electron Microscope (SEM) micrographs were then directly recorded from the as-deposited powders without any additional preparation such as metallization. A FEI Quanta 200 scanning electron microscope, equipped with an Everhart-

Thornley Detector (ETD) and a Back-Scattered Electron Detector (BSED) was used to record images with an acceleration voltage of 30 kV under high vacuum conditions.

TG-MS Analyses. Thermogravimetric analyses coupled with mass spectrometry were undertaken thanks to a Setaram Setsys Evolution equipped with a type S thermocouple (Pt / Pt-10% Rh). After recording a baseline using an empty crucible (100 μ L), weight loss was measured with a μ g precision during a heat treatment up to 1000°C with a rate of 5°C.min⁻¹ under Ar atmosphere. Moreover, the gaseous species emitted during the heat treatment were analyzed by the means of Hiden Analytical QGA analyzer using mass spectrometry.

Carbon Analyses. The amount of residual carbon in the oxide powders was determined thanks to a LECO CS230 Carbon/Sulfur Determinator. In order to remove all adsorbed atmospheric CO₂, the samples were first dried overnight at 90°C in an oven. Their complete combustion was then immediately performed under oxygen atmosphere and the concentration of CO₂ was further determined by IR absorption. In order to recover quantitative values, a blank and a series of standards (steels containing 0.0013 to 5.02 wt.% of carbon) were analyzed prior our samples.

3. Results and discussion

3.1. Effect of temperature

The effect of the hydrothermal treatment temperature on the physico-chemical properties of the powders prepared was first investigated between 130 and 250°C range. With this aim, the duration of the hydrothermal treatment was arbitrarily set to 24 hours whereas the pH of the reacting media remained uncontrolled and was then systematically found to be strongly acidic (*i.e.* pH < 1). Additionally, a sample that did not undergo any hydrothermal treatment was prepared and considered as a reference obtained at room temperature.

The samples obtained after hydrothermal treatment between 130 and 250°C were first characterized by PXRD (**Figure 1**). The reference sample prepared without any hydrothermal treatment confirmed the precipitation of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ from the mixture of U(IV) hydrochloric solution and oxalic acid. Indeed, the PXRD diagram collected presented all the XRD lines characteristic of the monoclinic structure (C2/c space group) reported by Clavier *et al.*³⁰ (see the stick pattern in **Figure 1a**). Also, although one should have expected the formation of the hexahydrate compound $\text{U}(\text{C}_2\text{O}_4)_2 \cdot 6\text{H}_2\text{O}$ ³¹, the hydration rate was in our case lowered by the drying step operated at 90°C^{32, 33}. $\text{U}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ was further maintained when applying hydrothermal treatments up to 160°C. A slight modification of the PXRD diagram was noted at 170°C, with the appearance of additional XRD lines near to 17, 29 and 34°. Such transformation was likely to be due to the partial dehydration of the oxalate. As no data was reported in the literature for $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ compounds with $n < 2$, the identification of the patterns was made from the work of Dash *et al.* on the thorium analogues³⁴. It led to assign the supplementary phase to $\text{U}(\text{C}_2\text{O}_4)_2 \cdot \text{H}_2\text{O}$.

Figure 1. XRD diagrams obtained after hydrothermal treatment of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ at various temperatures during 24h : a) RT - 170°C, b) 180°C - 250°C. Stick pattern in figure a) is taken from PDF data file #01-078-7197. * : signal assigned to the sample holder.

In contrast, all the PXRD patterns recorded for samples prepared for temperatures higher than 180°C were found to present all the characteristic XRD lines of UO_{2+x} (fluorite-type structure)³⁵. The hydrothermal conversion of the oxalate species then occurred on a very narrow temperature range. This observation was backed up by the determination of the uranium(IV) precipitation yield (**Figure 2**). Indeed, for the lowest temperatures investigated (i.e. up to 130°C), the precipitation yield remained close to the value determined for the oxalate obtained at RT and can be considered as almost quantitative, in good agreement with the

abundant literature dedicated to uranium oxalates ^{36, 37}. The synthesis yield was then found to drastically decrease down to only 15% at around 170°C, which marked the transition from oxalate to oxide. This temperature was in good agreement with the literature, since Crossey reported the decomposition of aqueous oxalate species in the 180-230°C range ³⁸. Oxalates were found to evolve to formic acid species following a first-order kinetic law, the reaction rate being increased for low pH values and high temperatures.

For higher temperatures, the synthesis yield increased progressively between 180 and 200°C then stabilized up to 250°C to reach about 70%. U(IV) was then partly precipitated in these conditions, which could be explained by the very low pH of the solution (i.e. pH < 1). Indeed, after the initial decomposition of the oxalate moieties, the formation of the oxide was likely to occur through the formation of hydroxides, which further rapidly aged to form $\text{UO}_{2+x} \cdot n\text{H}_2\text{O}$. This mechanism was already depicted by several authors ^{14, 39}. Rai *et al.* already reported that such reaction operated at room temperature for pH > 2 ⁴⁰, while the solubility of amorphous UO_2 did not sustain important variation up to 300°C ¹³. The formation of $\text{U}(\text{OH})_4$ (i.e. total hydrolysis of U^{4+}) was then incomplete in our experimental conditions, which tended to lower the precipitation yield. As the starting pH of the solution appeared as a very important parameter to consider, a detailed study will be presented in the next section of this paper.

Figure 2. Variation of the U(IV) precipitation yield as a function of hydrothermal treatment temperature (pH < 1, t = 24 hours), determined from PERALS analyses of the supernatant.

In order to complete the structural characterization of the uranium oxide samples, Rietveld refinements of the PXRD patterns were performed in order to extract unit cell volumes and average crystallite sizes (**Figure 3**). It is to note that in some cases, duplicates coming from distinct synthesis batches were analyzed in order to check the reliability of our results. As shown in the review from McEachern and Taylor, at temperatures below 400°C, oxidation of uranium only led to limited over-stoichiometry in the fluorite structure of uranium dioxide (typically up to $x = 0.05$) and then quickly yielded complex mixtures of UO_{2+x} , U_4O_9 and even U_3O_7 ⁴¹. Nevertheless, typical features of U_3O_7 XRD pattern (such as the splitting of diffraction lines located around 32.5 and 47°) ^{42, 43} were never observed in our samples. Conversely, the presence of U_4O_9 , which crystallizes in a superlattice derived from the fluorite-type structure, cannot be discarded using a classical laboratory PXRD apparatus⁴²⁻⁴⁴. In this structure, additional oxygen atoms are accommodated in cuboctahedral clusters that depend on the stabilized form (i.e. α , β or γ)^{29, 45}. Hence, the similarity of UO_{2+x} and U_4O_9 XRD patterns, combined with the limited resolution of our XRD data, precludes any phase quantification in the hypothesis of a UO_{2+x} / U_4O_9 mixture. As a preliminary approach, only one fluorite-type structure, corresponding to a single UO_{2+x} phase, was then considered in the fitting procedure. Therefore, the derived lattice parameter is merely a qualitative indicator of the oxide stoichiometry, i.e. of uranium oxidation state.

Whatever the temperature considered for the conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ in the 180-250°C range, the unit cell volume was systematically found to be lower than the reference value recently reported by Leinders *et al.* for $\text{UO}_{2.00}$ ⁴⁶ (163.781 Å³). This clearly indicated the formation of hyper-stoichiometric oxides, as the unit cell volume of UO_{2+x} was reported for long to vary from 163.5-163.8 Å³ for $\text{UO}_{2.00}$ ^{47, 48} to around 161.0 Å³ for O/U ratios close to 2.25 ⁴⁹⁻⁵¹, which constitute the upper limit of the fluorite-type structure ($\text{UO}_{2.25}$ being indexed in the R3c or the I-43d space group depending on the temperature considered ²⁹). Thus, two ranges of temperatures can be distinguished depending on the value of the unit cell volume.

From 180 to 210°C, all the hydrothermal synthesis performed led to unit cell volumes below the limit value of 161.0 Å³, which could be interpreted as a strong increase of the O/U ratio in the samples. On this basis, one must envisaged that the use of hydrothermal conditions, combined with the submicrometric size of the powders (see below) might stabilize a fluorite-derived structure towards higher values of O/M ratio. Indeed, cubic UO_{2+x} with $x = 0.24 - 0.5$ was already reported after oxidation of ultra-fine $\text{UO}_{2.00}$ under air at room temperature ^{43, 52}. In the 220-250°C range, the unit cell volume of the samples prepared was further found to increase, which could be seen as a decrease of the O/U ratio in hyper-stoichiometric UO_{2+x}

samples, or of the U_4O_9 amount in UO_{2+x} / U_4O_9 mixtures. However, the direct correlation of the lattice parameters with an accurate value of x remains difficult in such a complex multiphase system.

Additionally, the variation of the crystallites size (**Figure 3b**) was also monitored. Even if the values obtained tend to be underestimated when considering a single fluorite-type structure instead of the real multiphase system, a general trend can be discussed. In the 180-210°C range, the crystallites size was first found to remain mostly constant and close to 30-40 nm. For higher temperatures of hydrothermal treatment, growth processes were activated and led to crystallites sizes up to 90 nm. Such a two-step behavior was usually observed during the thermal conversion of An(IV)-based oxalates⁵³ as well as for nanocrystals growth of AnO_2 ⁵⁴. Moreover, no clear correlation was established between the variation of the oxide stoichiometry and that of the crystallites size. The O/U ratio was then probably a second-order parameter compared to temperature regarding crystallites growth.

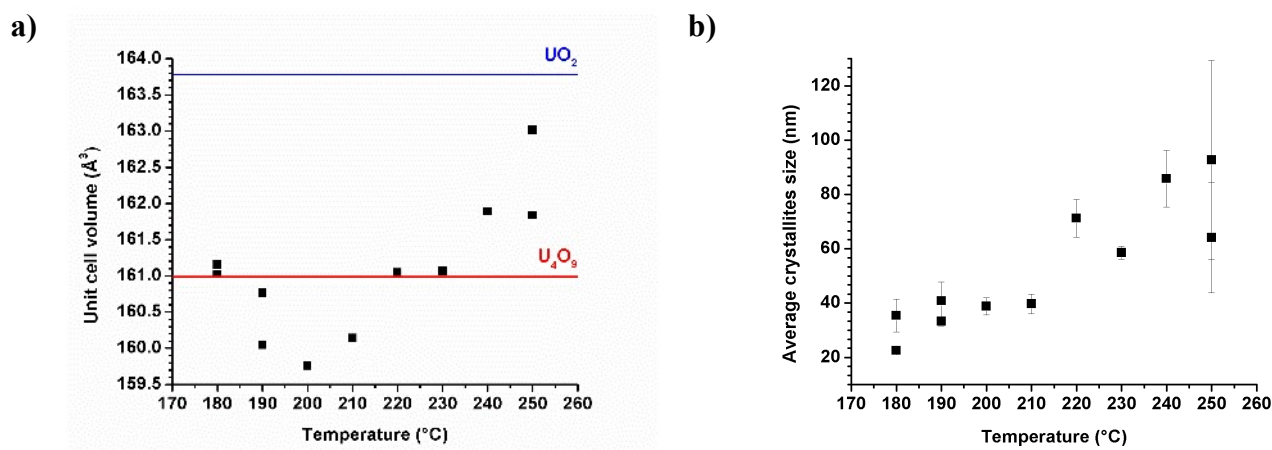

Figure 3. Variation of the unit cell volume (a) and of the average crystallites size (b) of uranium oxide (considered as a single fluorite-type structure) versus temperature of hydrothermal treatment (pH < 1, t = 24h). Reference values for UO_2 and U_4O_9 are taken from references⁴⁶ and⁴⁵, respectively.

In order to get further insights on the O/U stoichiometry of the oxide produced by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$, additional HERFD-XANES experiments at the uranium M_4 -edge²⁸ were undertaken on selected samples as well as on UO_2 , U_4O_9 and U_3O_8 references (**Figure 4**). As expected, UO_2 only presented one large peak corresponding to U(IV) whereas U_4O_9 exhibits two peaks with similar intensities corresponding to U(IV) and U(V) contributions. Comparatively, U_3O_8 presented a large signal located around 3727 eV that accounted for U(V) and U(VI). As already demonstrated by Leinders *et al.*⁵⁵, the different peaks

are well separated in energy with this technique, which allowed us to investigate accurately the oxidation state of uranium in our samples.

All the spectra recorded on oxides prepared after hydrothermal conversion of uranium(IV) oxalate between 200 and 250°C presented two distinct peaks, which accounted for a mixed U(IV) / U(V) valence in these compounds. Nevertheless, the intensity of the two peaks was systematically found to be uneven, which excluded the simple formation of U_4O_9 . Also, one must note that the presence of uranyl entities was discarded in these samples due to the absence of band around 3733 eV. Moreover, significant differences were noted between the sample obtained at 200°C, and those synthesized at higher temperatures. On the one hand, the sample prepared at 200°C displayed a U(V) contribution significantly higher than the U(IV) one. A very slight band around 3732 eV can also be distinguished and accounted for the presence of limited amount of U(VI) in the system. Conversely, the U(IV) was found to be predominant in samples prepared at 220°C, 240°C and 250°C.

Figure 4. Normalized HERFD-XANES spectra of reference samples and of oxide samples obtained after hydrothermal treatment of $U(C_2O_4)_2 \cdot nH_2O$ at various temperatures for 24 hours at $pH < 1$.

The contribution of U(IV), U(V) and U(VI) was then quantified by fitting the collected spectra as a linear combination of the three references (**Table 1**). For the sample prepared at 200°C, the spectrum was only correctly fitted by considering the three different oxidation states

of uranium. On the contrary, satisfactory fit was obtained by using only a combination of UO_2 and U_4O_9 for samples synthesized between 220 and 250°C. With these results, the global O/U ratio in the samples was estimated to 2.38 ± 0.10 at 200°C and close to 2.13 ± 0.04 in the 220-250°C range. Based on the U-O phase diagram reported by Guéneau *et al.*⁵⁶, the sample prepared at 200°C should then correspond to a mixture between U_3O_7 and U_3O_8 . Nevertheless, as mentioned previously, the presence of these phases was discarded from the XRD analysis. The use of hydrothermal conditions then allowed to stabilize the cubic structure of UO_{2+x} / U_4O_9 up to higher O/U ratios. On the contrary, the samples prepared at higher temperatures presented a stoichiometry corresponding to a mixture of approximately 60% $\text{UO}_{2.05}$ and 40% U_4O_9 , which is in good agreement with the XRD patterns recorded.

Table 1. Uranium oxidation state distribution obtained from the linear combination fitting of HERFD-XANES spectra.

Temperature (°C)	U(IV) (%)	U(V) (%)	U(VI) (%)	O/U ratio	Average U oxidation state
200	36.0 ± 1.8	52.5 ± 1.8	11.5 ± 0.6	2.38 ± 0.10	4.8
220	76.3 ± 1.5	23.7 ± 0.5	0	2.12 ± 0.04	4.2
240	73.8 ± 1.4	26.2 ± 0.4	0	2.13 ± 0.04	4.3
250	74.9 ± 1.1	25.1 ± 0.4	0	2.13 ± 0.03	4.3

The oxide samples prepared by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ between 180 and 250°C ($\text{pH} < 1$; $t = 24$ hours) were further characterized from the morphological and chemical points of view. With this aim, SEM images were collected for selected samples (**Figure 5**). While the oxalate samples retained their classical platelet-like habit up to 170°C, the conversion towards oxides marked a drastic modification in the powders morphology. Indeed, as soon as 180°C, the powders were found to be formed by bipyramid-shape aggregates of about 1 μm in length. These objects were composed by smaller crystallites of about 40 nm, as evidenced from PXRD data refinement, and then possessed a hierarchical microstructure, which was frequently observed in samples obtained through hydrothermal methods^{14, 15}. The use of hydrothermal conditions then allowed to get rid of the usual platelet-like morphology of An(IV) oxalates, which is expected to be poorly suitable for shaping and sintering and was always retained by using isomorphic thermal conversion. Also, it is worth noting that this morphology slightly differed from that reported by Balice *et al.* during the preparation of An-based oxides by hydrothermal conversion of oxalate precursors, which were mostly nanometric

powders ¹⁹. This difference probably arose from variations in the synthesis protocols. Indeed, Balice *et al.* first separated the initial oxalate precipitate from the supernatant then poured it into a mixture of deionized water and hydrazine to perform their final conversion. The concentrations of organic species in the reacting media, which were frequently depicted as shaping agents ¹⁶, were then lower than that obtained in this work. Consequently, the aggregation of the nanocrystallites was most probably disadvantaged.

The size and the shape of the aggregates obtained was further maintained up to 220°C, although the inner porosity substantially increased, thereby increasing the roughness. Such modification of the aggregates microstructure was correlated to the increase of the average crystallite size with temperature, as already evidenced by PXRD measurements. In contrast, the particles obtained at 250°C were found to be smaller with sizes typically between 200 and 500 nm. This feature was likely to be linked with the kinetics of oxalate degradation which was fastened by the rise of temperature and probably favored the nucleation of isolated particles.

Figure 5. SEM images of uranium dioxide synthesized by hydrothermal treatment of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($\text{pH} < 1$, $t = 24\text{h}$) at various temperatures and comparison with original oxalate precursor.

The presence of impurities coming from the hydrothermal degradation of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ was finally checked in the oxide samples. Indeed, previous works showed that the presence of residual carbon in the oxide powders could impact negatively the densification step^{9, 11, 12}. Powders were then first characterized thanks to a carbon analyzer (**Table 2**). After heating at 180°C, the residual carbon content within the oxide powders reached 0.82 ± 0.01 wt.%. Such a huge amount might indicate that the decomposition of oxalate species was still

incomplete, even if only fluorite-type oxides were detected by PXRD. Also, amorphous carbon or carbonate species could be trapped either within the oxide structure or between the crystallites forming the aggregates. Nevertheless, the carbon content was found to quickly drop down with temperature. Indeed, it was found to 0.12 ± 0.02 wt.% after heating at 200°C, which was lower than the value measured by Martinez *et al.* in UO_{2+x} oxides coming from direct conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot 2\text{H}_2\text{O}$ under reducing atmosphere at 1000°C (i.e. 0.2 wt.%)⁹. Beyond 220°C, the value became even lower and decreased by about one order of magnitude to reach 100-200 ppm. Such amount was close to that generally reported for oxides prepared through the calcination of oxalate precursors under oxidizing atmospheres^{9, 10, 57}, which strongly favors the elimination of carbon through the Boudouard equilibrium ($\text{C}/\text{CO}/\text{CO}_2$). Also, it satisfies to the ASTM C753 standard which state the upper limit (100 ppm) for C impurities in nuclear-grade sinterable uranium oxide powders⁵⁸. The use of mild hydrothermal conditions then appears as a powerful way to eliminate carbon residues from the samples and yields highly-pure uranium dioxide samples.

Table 2. Carbon content (expressed in wt.%) and water content (expressed in mol. per mole of oxide) obtained in uranium oxide samples resulting from hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ for various temperatures (pH < 1, t = 24h).

T (°C)	Total weight loss at 1000°C (%)	C (wt.%)	H ₂ O (wt.%)	H ₂ O (mol. per unit formula)
180	5.00 ± 0.05	0.82 ± 0.01	4.18 ± 0.05	0.66 ± 0.01
200	2.75 ± 0.05	0.12 ± 0.02	2.63 ± 0.05	0.41 ± 0.01
220	0.80 ± 0.05	0.01 ± 0.03	0.79 ± 0.06	0.12 ± 0.01
240	0.50 ± 0.05	0.02 ± 0.03	0.48 ± 0.06	0.07 ± 0.01
250	0.80 ± 0.05	< 0.01	0.80 ± 0.05	0.12 ± 0.01

Additionally, thermogravimetric experiments were undertaken under inert atmosphere (Ar) to monitor the elimination of residual carbon and to assess the water content in the prepared powders (**Figure 6**). As expected from the carbon analyses, the sample prepared at 180°C exhibited the highest weight loss, even if this latter remained limited to only a few percent. The mass loss was found to start at 100°C. It was first assigned to the departure of water molecules based on MS analyses. Above 250°C and up to about 350°C, a sharp decrease of the weight loss was observed. It was associated to the elimination of residual carbon as a mixture of CO and CO₂. This range of temperature appeared to be lower than that reported by Martinez *et al.* when studying the thermal behavior of uranium(IV)-cerium(IV) hydrated oxides³⁹, which once

again argues for the rapid and efficient elimination of carbon species through a hydrothermal process. A continuous mass loss was then recorded up to 600°C and was assigned to the elimination of water molecules. Based on a total weight loss of about 4% and considering the contribution coming from carbon species, the hydration rate of the sample was then found to be close to 0.7 H₂O per mole of UO_{2+x}. This low value agreed well with the mechanism proposed for the formation of UO_{2+x}.nH₂O samples, i.e. hydrolysis of U(IV) as U(OH)₄ after hydrothermal conversion of U(C₂O₄)₂.nH₂O, followed by its rapid aging to form hydrated uranium oxide. Indeed, even if the evolution of uranium(IV) tetrahydroxide should yield UO₂.2H₂O, it is known to further partially dehydrate as the number of water molecules reported in the literature for such compounds is generally between 0 and 2¹³. This dehydration was even more pronounced at 200°C, and led to 0.4H₂O per formula unit.

For higher temperatures of hydrothermal treatment, a very low weight loss, that did not exceed 0.7%, was observed. As the carbon content was almost negligible in these conditions, the mass loss was mainly assigned to water molecule, leading to hydration ratio of about 0.1 H₂O per formula unit. Nevertheless, one must keep in mind that partial reduction of the samples could also occur when heating in highly pure argon atmosphere. In these conditions, the total reduction of UO_{2.12} into UO_{2.00} would also account for a weight loss of about 0.7%. As the dehydration of the oxide sample and its reduction probably process concomitantly, it was then difficult to accurately conclude on the hydration of the sample. Nevertheless, owing to the value determined, they can be considered as almost anhydrous.

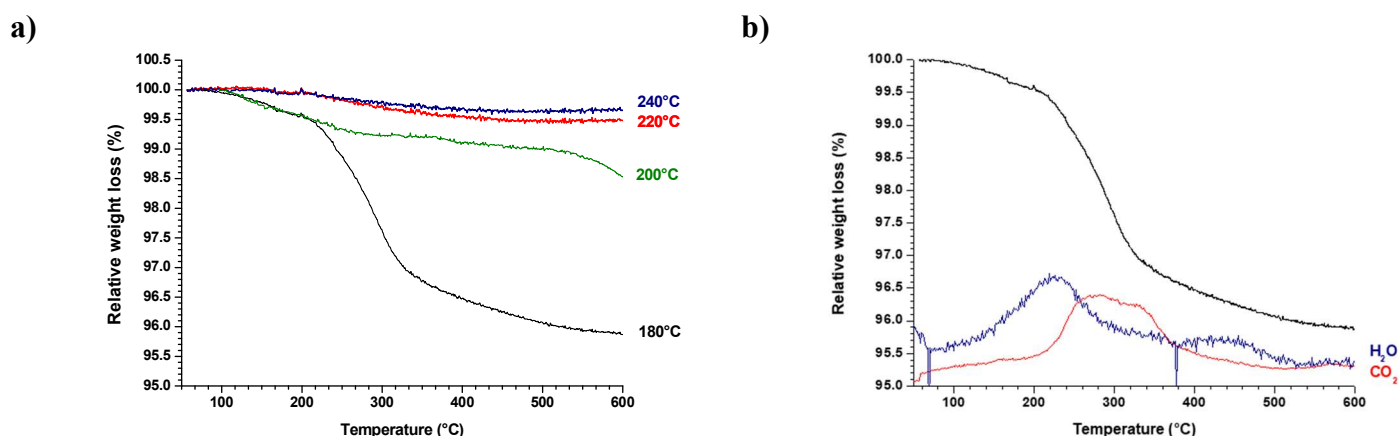

Figure 6. TG analyses of UO_{2+x}.nH₂O samples synthesized by hydrothermal conversion of U(C₂O₄)₂.nH₂O (pH < 1, t = 24h) at 180, 200, 220 and 240°C (a). Associated mass spectroscopy analyses of emitted gases (H₂O : m/z = 18; CO₂ : m/z = 44) for the sample prepared at 180°C (b).

3.2. Effect of initial pH

In order to improve the uranium precipitation yield and to control the morphology of the final powder, a second study was dedicated to the effect of pH value in the starting mixtures. Based on our previous results, the hydrothermal treatment temperature was fixed to 250°C, which corresponded to the samples presenting the lowest O/U ratio as well as the lowest contents of residual carbon and water. The duration of the hydrothermal treatment remained unchanged (24 hours) while the pH of the initial reacting mixture was fixed to different values between 1 and 10. Monitoring the initial pH of the reacting media quickly led to the quantitative recovery of uranium. Indeed, PERALS analyses undertaken on the supernatants showed that the precipitation yield was close to 100% for $\text{pH} \geq 1$ (**Table 3**), even though Rai *et al.* reported the hydrolysis of U(IV) only for $\text{pH} > 2$ at room temperature ⁴⁰. This difference could be explained by the use of hydrothermal conditions, which can lead to the modification of equilibrium constants, and allowed the complete complexation of tetravalent uranium for a lower pH value.

Table 3. Uranium(IV) precipitation yield measured by PERALS analyses as a function of pH ($T = 250^\circ\text{C}$, $t = 24\text{h}$).

pH	$n(\text{U})_i$ (mol.)	$n(\text{U})_{\text{sol.}}$ (mol.)	Uranium(IV) precipitation yield (%)
<1	$4.79 \cdot 10^{-4}$	$(1.35 \pm 0.03) \times 10^{-4}$	71.7 ± 2.3
1	$4.78 \cdot 10^{-4}$	$(2.27 \pm 0.07) \times 10^{-6}$	99.5 ± 2.9
2	$4.79 \cdot 10^{-4}$	< L.D.	99.9 ± 0.2
4	$4.79 \cdot 10^{-4}$	< L.D.	99.9 ± 0.2
5	$4.78 \cdot 10^{-4}$	$(1.3 \pm 0.2) \times 10^{-7}$	$99.9 \pm 12.2^*$
6	$4.78 \cdot 10^{-4}$	$(6.9 \pm 0.6) \times 10^{-7}$	$99.9 \pm 9.0^*$
8	$4.78 \cdot 10^{-4}$	$(3.6 \pm 0.1) \times 10^{-7}$	99.9 ± 3.0
10	$4.79 \cdot 10^{-4}$	$(4.9 \pm 0.1) \times 10^{-6}$	99.0 ± 3.4

Limit of detection (L.D.) : 1.10^{-8} mol.

*Huge measurement uncertainty due to the very low activity measured in solution.

The samples prepared for $1 < \text{pH} < 10$ were characterized by PXRD (**Figure 7**). The powder previously obtained at 250°C without any control of the pH was also reported as a matter of comparison, and further labelled as “pH < 1”. Whatever the initial conditions tested

in terms of acidity, all the PXRD diagrams collected matched well with a single fluorite-type structure characteristic of UO_{2+x} oxides or of $\text{UO}_{2+x} / \text{U}_4\text{O}_9$ mixtures³⁵. Once again, no XRD lines splitting, that could sign the formation of U_3O_7 , was observed. Also, bringing the pH towards high values then did not lead to stabilize $\text{U}(\text{OH})_4$, which systematically aged to form uranium oxide. While previous authors only reported samples prepared close to neutral pH values¹⁸⁻²⁰, the hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ was then proved to be possible on a wide range of operating conditions.

Figure 7. Variation of the PXRD patterns recorded for $\text{UO}_{2+x} \cdot n\text{H}_2\text{O}$ samples prepared by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($T = 250^\circ\text{C}$, $t = 24$ h) as a function of the initial pH value. * : XRD lines associated to the sample holder.

Although the characteristic XRD lines of the fluorite-type structure were systematically obtained, Rietveld refinements of the PXRD patterns (**Figure 8**) once again revealed that pH variation impacted both the unit cell parameters and the average crystallite size. Conversely to what was observed when studying the effect of hydrothermal treatment temperature, the lattice volume mostly remained in the classical range of variation for UO_{2+x} . For the lowest pH values investigated (*i.e.* up to $\text{pH} = 1$), it was found near the reference value reported for $\text{UO}_{2.00}$ ($V = 163.781 \text{ \AA}^3$)⁴⁶, therefore indicating that the O/U ratio probably remained close to 2 in such

operating conditions. Increasing the pH in the initial reacting media led to favor the uranium oxidization, which was illustrated by the decrease of the unit cell volume. This latter first remained constant around 161.3 \AA^3 for $2 \leq \text{pH} \leq 6$, which typically corresponded to $\text{UO}_{2+x} / \text{U}_4\text{O}_9$ mixtures with a global O/U ratio in the 2.20 - 2.25 range based on the data reported in the literature⁵¹. In basic media (i.e. for $\text{pH} = 10$), the lattice volume was finally found to be below 161 \AA^3 , which might indicate an increase of O/U towards higher values, and the presence of U(VI) in the system, as it was observed when studying the effect of the hydrothermal treatment temperature.

In the same time, a strong decrease of the average crystallites size was noted when raising the pH of the reacting media. Indeed, samples prepared around $\text{pH} = 1$ led to crystallite size between 80 and 110 nm while this value drastically dropped down to 20-30 nm for $2 \leq \text{pH} \leq 5$. Such trend could be easily explained by the more rapid uranium(IV) hydrolysis then $\text{U}(\text{OH})_4$ precipitation in basic media, which led the crystallites nucleation step to be favored over the growth processes.

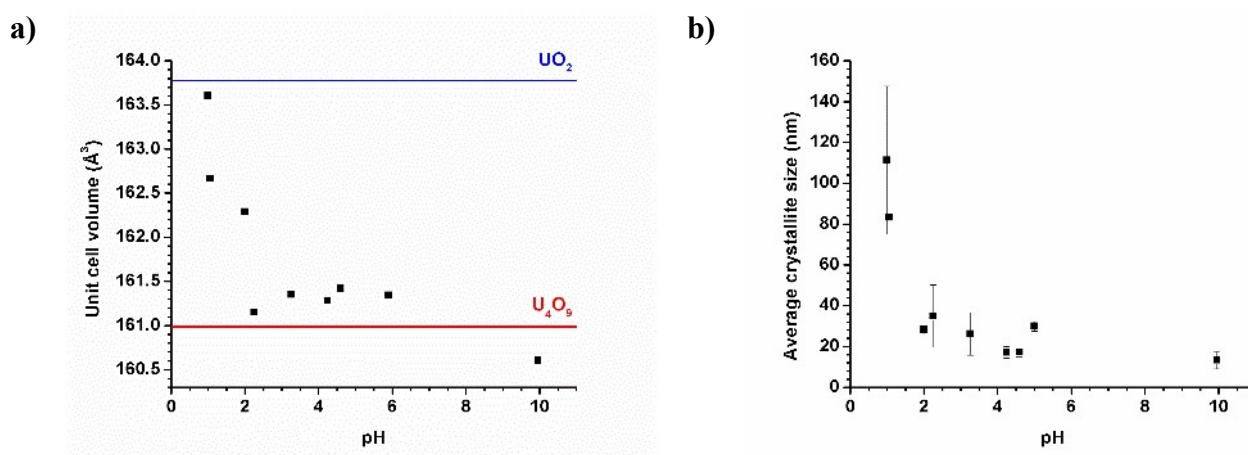

Figure 8. Variation of the unit cell volume (a) and average crystallites size (b) of uranium oxide samples as a function of initial pH ($T = 250^\circ\text{C}$, $t = 24\text{h}$). Reference values for UO_2 and U_4O_9 are taken from references⁴⁶ and⁴⁵, respectively.

SEM observations were further undertaken and revealed important modifications of the morphology as a function of the starting pH value (**Figure 9**). At $\text{pH} = 1$, the powders exhibited the morphology already described when working in uncontrolled acidic media, made of submicrometric aggregates of elementary crystallites, even if they appeared to be more faceted. For $\text{pH} \geq 2$, the samples appeared to be systematically composed of microspheres exhibiting heterogeneous size distribution. Such a morphology was already reported for similar pH values

after the hydrothermal conversion of uranium(IV) aspartate ¹⁴. This clearly underlined the crucial role played by the pH in the design of morphology-controlled uranium oxides prepared through wet chemistry methods in hydrothermal conditions. The spherical morphology of the powders was further maintained up to pH = 5, although isolated crystallites became more and more visible. Finally, for the higher pH values (typically between 6 and 10), the powders were found to be mostly composed of elementary nanoscale crystallites. This observation clearly confirms the rapid hydrolysis of uranium (IV) in basic media, which prevented further growth of the particles and hindered aggregation phenomena. Consequently, the powder was found to exhibit a morphology close to that already described by Martinez *et al.* for uranium dioxide samples prepared through direct hydroxide precipitation ³⁹.

Figure 9. SEM images recorded for samples prepared by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($T = 250^\circ\text{C}$, $t = 24\text{h}$) at various pH.

Finally, the carbon content and hydration rate of the samples were followed by TGA and carbon analyzer. Whatever the conditions considered, the powders only contained limited amounts of impurities (**Table 4**), although it was found to increase with pH. Indeed, whereas very acidic conditions (*i.e.* for $\text{pH} \leq 1$) led to carbon amounts close to 100 ppm, it was found to be one order of magnitude higher between $\text{pH} = 2$ and 10. On this basis, it is probable that the increase of the precipitation kinetics with the pH favored the carbon trapping within the structure, and/or between the crystallites forming the aggregates. Another explanation could be

linked to the presence of carbonate ions in solution following the degradation of oxalate entities. Indeed, regarding to their speciation between pH = 3 and pH = 6, HCO_3^- groups could partially substitute OH^- ions during the precipitation process. Nevertheless, it is important to mention that the carbon amounts measured remained once again close to that obtained after heat treatment of oxalates ⁹, and far lower than those measured in UO_2 microspheres prepared through wet chemistry processes, which can reach up to 3 wt.% ^{14, 15}. On the other hand, the water content remained almost constant up to pH = 6 and reached about 0.1-0.2 H_2O per formula unit. Keeping in mind that the associated weight loss could be also linked with a partial reduction of uranium, the samples can then be considered as nearly anhydrous. Nevertheless, a strong increase was noted for pH ≥ 8 , where the hydration rate progressively rose up to one mole of H_2O per mole of uranium. Although this value was still in good agreement with a precipitation mechanism based on the hydrolysis of U(IV), it showed that basic conditions led to slow down the dehydration of the final compound. Also, owing to the high value suspected for the O/U ratio in this pH range, one cannot exclude the formation of amorphous uranium(VI) oxo-hydroxides such as schoepite⁵⁹ in our system, even if they were not evidenced though XRD.

Table 4. Carbon and water contents determined in the samples prepared by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($T = 250^\circ\text{C}$, $t = 24\text{h}$) for various starting pH values.

pH	Total weight loss at 1000°C (%)	C (wt.%)	H_2O (wt.%)	H_2O (mol. per unit formula)
< 1	0.80 ± 0.05	< 0.01	0.80 ± 0.05	0.12 ± 0.01
1	< 0.10	< 0.01	< 0.01	< 0.01
2	1.20 ± 0.05	0.09 ± 0.02	1.11 ± 0.05	0.17 ± 0.01
5	1.60 ± 0.05	0.10 ± 0.02	1.50 ± 0.05	0.23 ± 0.01
6	1.55 ± 0.05	0.32 ± 0.02	1.23 ± 0.05	0.19 ± 0.01
8	2.51 ± 0.05	0.07 ± 0.02	2.44 ± 0.05	0.38 ± 0.01
10	5.90 ± 0.05	0.08 ± 0.02	5.82 ± 0.05	0.93 ± 0.01

3.3. Effect of hydrothermal treatment duration

Finally, the last set of experiments was dedicated to the impact of kinetics on the physico-chemical properties of the uranium oxide samples resulting from hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$. With this objective, the heat treatment was maintained at 250°C while an initial pH value of 5 was chosen in order to guarantee the quantitative precipitation of

uranium. Such conditions were also found to yield hyper-stoichiometric oxide samples (typically with $2.20 \leq \text{O/U} \leq 2.25$) containing measurable amounts of carbon and water. In order to monitor the evolution of impurities contents as well as the O/U ratio, the hydrothermal conversion process was achieved with durations varying from 1 to 48 h.

For all the conditions tested, the obtained powders were found to be crystalline and exhibited XRD lines compatible with the formation of UO_{2+x} oxides or of UO_{2+x} / U_4O_9 mixtures (**Figure 10**). Also, no additional signal, such as that of residual $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ was observed, which evidenced its full and rapid conversion in such operating conditions. This agreed well with the data published by Crossey³⁸. Indeed, assuming that the activation energy reported in this study ($E_A = 207 \text{ kJ.mol}^{-1}$) remained constant up to 250°C , one can determine the kinetic constant associated to the oxalate decomposition, supposed to be a first-order reaction. Such calculations yield a reaction half-time of about 1.5 minutes at $\text{pH} = 5$. On this basis, the decomposition was considered to be complete after 10 periods, i.e. 15 minutes, which corresponds to the conversion of 99.9% of the reactants. In good agreement with these calculations, the uranium precipitation yield was found to be almost complete after one hour of hydrothermal treatment (**Table 5**).

Figure 10. Evolution of the PXRD patterns obtained for samples prepared by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($T = 250^\circ\text{C}$, $\text{pH} = 5$).

Table 5. Uranium(IV) precipitation yield measured by PERALS analyses as a function of the heat duration ($T = 250^{\circ}\text{C}$, $\text{pH} = 5$).

Time (hours)	$n(\text{U})_i$ (mol.)	$n(\text{U})_{\text{sol.}}$ (mol.)	Uranium(IV) precipitation yield (%)
1	4.79×10^{-4}	$(1.20 \pm 0.01) \times 10^{-5}$	97.5 ± 0.4
5	4.78×10^{-4}	$(2.20 \pm 0.06) \times 10^{-7}$	99.9 ± 2.9
15	4.78×10^{-4}	$(4.7 \pm 0.2) \times 10^{-7}$	99.9 ± 3.9
24	4.79×10^{-4}	$(1.3 \pm 0.2) \times 10^{-7}$	99.9 ± 12.1

Even though the quantitative precipitation of uranium was reached very rapidly, Rietveld refinements of the PXRD patterns (**Figure 11**) revealed that 5 hours of heat treatment were required to reach a plateau in terms of lattice parameters and average crystallite size. Indeed, after only one hour of heat treatment, the unit cell volume was found to 160.8 \AA^3 , which accounted for a strongly oxidized system regarding to UO_2 . For longer hydrothermal treatment durations, the unit cell volume then increased to reach a constant value of about 162.0 \AA^3 , which fitted well with the usual range of variation of $\text{UO}_{2+x} / \text{U}_4\text{O}_9$ lattice parameters.

A similar evolution was observed for the crystallite size. It was found that the powders precipitated after only 1 hour of hydrothermal treatment were composed by small crystallites of less than 10 nm, which was only 2 to 3 times higher than that reported by Martinez *et al.* for uranium oxides prepared by direct precipitation of uranium hydroxide at room temperature. Rather than oxalate decomposition, the aging and growth of $\text{U}(\text{OH})_4$ nuclei then could be considered as the main limitation to the preparation of well-crystallized $\text{UO}_{2+x} \cdot n\text{H}_2\text{O}$ powders on such a short time. Conversely, the samples prepared after 5 to 48 hours of heating treatment presented larger crystallite size (i.e. up to 30-40 nm).

Figure 11. Evolution of the unit cell volume (a) and average crystallites size (b) of $\text{UO}_{2+x} \cdot n\text{H}_2\text{O}$ samples during the hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ ($T = 250^\circ\text{C}$, $\text{pH} = 5$). Reference values for UO_2 and U_4O_9 are taken from references ⁴⁶ and ⁴⁵, respectively.

The accurate stoichiometry of the samples prepared after 1 and 5 hours of hydrothermal conversion ($T = 250^\circ\text{C}$, $\text{pH} = 5$) was then further checked through HERFD-XANES (**Figure 12**). The two samples investigated presented very different spectra. Indeed, after 1 hour of conversion, 4 peaks were clearly visible on the spectrum at 3725.5, 3726.9, 3728.8 and 3732.4 eV. They attested the presence of both U(IV), U(V) and U(VI) in the sample, including uranyl groups. As the coexistence of all these uranium species is not possible in a single phase, the formation of a polyphase sample can be suggested. Conversely, only 2 main contributions were recorded for the sample prepared after 5 hours of heating, meaning that the U(VI) amount drastically decreased in the system, which was then mainly composed of U(IV) and U(V).

In order to go further, the O/U ratio in each sample was quantified through a linear combination fitting coupled to the normalization of the uranium amount inside the references used (i.e. UO_2 , U_4O_9 , U_3O_8 and $\text{UO}_2(\text{NO}_3)_2 \cdot n\text{H}_2\text{O}$). The results presented in **Table 6** confirmed that the sample prepared after only 1 hour of heat treatment was strongly oxidized with $\text{O/U} = 2.65 \pm 0.14$ corresponding to an average uranium oxidation state equal to $+5.3$. As already suggested, this sample then probably corresponds to a mixture composed by a crystalline $\text{UO}_{2+x}/\text{U}_4\text{O}_9$ phase (evidenced by XRD) and an amorphous U(VI)-residue. The O/U ratio was further found to decrease after 5 hours of hydrothermal conversion down to 2.45 ± 0.06 ($\text{U}^{+4.9}$). One can note that these values remained significantly higher than that determined for heat treatment of 24 hours in more acidic conditions ($\text{pH} < 1$: $\text{O/U} = 2.13 \pm 0.04$).

These results suggested that the hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ could proceed in two distinct steps. The first one would correspond to the oxidative decomposition/dissolution of the oxalate initially precipitated when mixing oxalic acid and U(IV) hydrochloric solution. The oxide formation could then be achieved through the progressive reduction of uranium in hydrothermal conditions, thanks to the organic moieties generated in solution by the decomposition of oxalates. Indeed, such mechanism was reported for long in geologic media, where uranyl ions were precipitated as UO_2 in late diagenetic conditions ($T = 100\text{-}200^\circ\text{C}$) by interacting with simple organic matter^{60, 61}. Such a dissolution/precipitation process would explain both the initial formation of a mixture composed by a crystalline U(IV)/U(V) phase and a U(VI) amorphous residue, then the progressive reduction of the oxide sample with time, but also the drastic modification of the samples morphology compared to the starting square platelets.

Figure 12. Normalized HERFD-XANES spectra of reference samples and of oxide samples obtained after hydrothermal treatment of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ at 250°C and $\text{pH} = 5$ for various durations.

Table 6. Uranium oxidation state distribution obtained from the linear combination fitting of HERFD-XANES spectra.

Holding time (h)	U(IV) (%)	U(V) (%)	U(VI) (%)	O/U ratio	Average U oxidation state
1	14.9 ± 0.3	39.6 ± 1.6	45.5 ± 3.1	2.65 ± 0.14	5.3
5	26.5 ± 0.3	57.8 ± 1.6	15.7 ± 0.6	2.45 ± 0.06	4.9

The peculiar behavior of the sample prepared after only 1 hour of hydrothermal treatment was also confirmed during the determination of carbon and water contents (**Table 7**). Indeed, the residual carbon amount was found to be close to 10 000 ppm, which was by far the highest value measured during this study. Nevertheless, it dropped down to 500-1000 ppm when extending the hydrothermal treatment to 5 - 48 hours. The organic species coming from the initial decomposition of oxalate groups, which played an important role in uranium reduction, were then probably trapped during the formation of the first oxide nuclei, then were quickly and efficiently eliminated throughout the hydrothermal treatment. Simultaneously, the water content also decreased, going from about 0.7 H₂O per formula unit after 1 hour to 0.1 - 0.2 after 5 to 48 hours. Along with the carbon elimination, the crystallization of uranium oxide was then also accompanied by the partial dehydration of the samples.

Table 7. Carbon and water contents determined in the samples prepared by hydrothermal conversion of U(C₂O₄)₂.nH₂O (T = 250°C, pH = 5) for various holding times.

Holding time (hours)	Total weight loss at 1000°C (%)	C (wt.%)	H ₂ O (wt.%)	H ₂ O (mol. per unit formula)
1	5.00 ± 0.05	0.91 ± 0.01	4.09 ± 0.05	0.65 ± 0.01
5	1.40 ± 0.05	0.07 ± 0.02	1.33 ± 0.05	0.20 ± 0.01
15	1.00 ± 0.05	0.05 ± 0.02	0.95 ± 0.05	0.14 ± 0.01

48	1.00 ± 0.05	0.10 ± 0.02	0.90 ± 0.05	0.14 ± 0.01

4. Conclusion

Mixtures of uranium oxides, with a typical O/U ratio ranging from 2.12 to 2.65, were obtained by hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ in various operating conditions. In very acidic media (i.e. for $\text{pH} \leq 1$), the lowest temperatures explored (typically from 180 to 200°C) led to O/U ratio of 2.38 ± 0.10 while the XRD pattern did not present any characteristic reflections of U_3O_7 or U_3O_8 . A similar diffraction diagram, typical for UO_{2+x} or $\text{UO}_{2+x}/\text{U}_4\text{O}_9$ mixtures was further obtained for samples prepared between 220 and 250°C, while O/U was lowered to 2.13 ± 0.04 . The use of hydrothermal conditions, combined with the nanocrystalline nature of the powders then allowed to stabilize mixtures of cubic uranium oxide phases, which cannot be uniquely distinguished from XRD alone, while XANES results indicated an important U(V) contribution in some powders. In parallel, increasing the temperature of the hydrothermal treatment efficiently improved the elimination of residual carbon species. Typical amounts of about 100-200 ppm were measured in the samples, which was of the same order of magnitude than the values usually observed when performing thermal conversion of An(IV) oxalates in air. Additionally, high temperature of hydrothermal treatment was also found to yield almost anhydrous samples.

Hydrothermal conversion of $\text{U}(\text{C}_2\text{O}_4)_2 \cdot n\text{H}_2\text{O}$ also led to the drastic modification of the powders morphology. With this aim, pH monitoring could be used to shift from bipyramidal aggregates (up to $\text{pH} = 1$), microspheres ($2 \leq \text{pH} \leq 5$) and finally to nanometric powders ($\text{pH} > 5$). However, the increase of the kinetics of U^{4+} hydrolysis with the pH value led to enhance the amount of carbon trapped in the samples, even if this latter remained of the same order of magnitude than that reported for uranium(IV) oxalate heated under reducing atmosphere.

Finally, kinetics of the hydrothermal conversion suggested a two-step mechanism for the transformation of uranium(IV) oxalate into oxide. Indeed, if the complete decomposition of the initial oxalate was achieved in only few hours, the O/U ratio in the samples appeared to be strongly impacted by the duration of the hydrothermal treatment. After 1 hour, it suggested the existence of a U(VI)-bearing secondary phase, such as amorphous UO_3 , aside the crystalline $\text{UO}_{2+x}/\text{U}_4\text{O}_9$ mixture, which further tended to reduce to UO_{2+x} . The hydrothermal conversion is then likely to be composed of an oxidative dissolution of the initial precursor, followed by the *in situ* reduction of U(V) and/or U(VI) in solution thanks to organic species and the final hydrolysis process leading to the oxide sample.

By these means, hydrothermal conversion appeared as an easy and efficient way to yield highly pure uranium oxide samples in solution. The absence of impurities as well as the

possibility to monitor the samples morphology also paves the way to the direct sintering of the powders prepared. Avoiding the thermal conversion of oxalate will then give the opportunity to set up dustless processes that will lead from ions in solution to sintered pellets in a limited number of steps.

Acknowledgements

Authors are grateful to J. Lautru for his help during SEM observations. They would also like to thank the Materials Federative Project included in the NEEDS program (Nucléaire, Energie, Environnement, Déchets, Société) of CNRS for its continuous financial support. This study received funding from the GENIORS project (H2020 Euratom Research and Innovation Programme under grant agreement n°755171). We are also grateful to SOLEIL synchrotron for providing beamtime.
