25 **Abstract.** Inter-tropical regions are nowadays faced to major land-use changes in data-sparse context leading to
26 difficulties to assess hydrological signatures and their evolution. This work is part of the theme *Panta Rhei* of the
27 IAHS, and aims to develop a combined approach of data acquisition and a new semi-distributed model taking into
28 account land-use changes to reconstruct and predict annual runoff on an urban catchment. Applications were
29 conducted on the Mefou catchment at Nsimalen (421 km²; Yaoundé, Cameroon) under rapid increase in
30 urbanization since 1960. The data acquisition step combines an historical data processing and a short-term
31 spatially-dense dedicated instrumentation (2017-2018), leading to 12 donor catchments, 6 from historical studies
32 and 6 from the instrumentation presenting various topographic, soil and land-use characteristics. We developed an
33 annual rainfall-runoff model based on mathematical relationships similar to the SCS model. The model needs the
34 definition of a hydrological index *I* which is time variable and enables to take into account land-use changes and
35 non-stationary relationships between rainfall and runoff. The index *I* is an empirical indicator defined as a
36 combination of several components such as topography, soil, and land-use. The rules for the construction of *I* are
37 obtained from data analysis on donor catchments. Then, the model was calibrated on donor catchments. Finally,
38 two applications were conducted on eight target catchments composing the Mefou in order: i) to study the spatial
39 hydrological functioning and calculate the water balance during the short instrumentation period; ii) to reconstruct
40 the hydrograph at the Mefou and to simulate the impact of future scenarios of land-use and urbanization. Results
41 show that that the Mfoundi catchment, integrating the three more urbanized sub-catchments, contributes near to
42 40 % of the Mefou despite covering only 23 % of the basin. The most urbanized sub-catchments present annual
43 runoff coefficient about 0.86 against 0.24 for the most natural sub-catchments. The second result is the
44 reconstruction of historical annual runoff from 1930-2017 with $r^2 = 0.68$, $RMSE = 99$ mm and a mean absolute
45 normalized error $\bar{E} = 14.5$ % over the 29 observed years. The reconstruction of the annual runoff at Nsimalen
46 confirms the moderate impact of urbanization on annual runoff before 1980. However, a decrease of about 50 %
47 of the forest cover and an increase from 10 % to 35 % of the urban area between 1980 and 2017 are associated
48 with an increase of 53 % of annual runoff coefficient for the Mefou at Nsimalen (0.44 against 0.29). Application
49 for a fictive plausible scenario of urbanization in 2030 leads to an increase of more than 85 % of the annual runoff
50 in comparison of the values observed in 1980. The coupled experimental-modelling approach proposed herein
51 opens promising perspectives regarding the evaluation of the annual runoff in catchments under changes.

52

53

54 **1 Introduction**

55 The link between the hydrological cycle and human societies has been strong with changes and
56 intensification of these interactions over time (Koutsoyiannis, 2013; McMillan et al., 2016). In response to the
57 imperative to include human increasing impacts as integral to hydrological research, the International Association
58 of Hydrological Sciences (*IAHS*) launched the hydrological decade (2013-2022) with theme “*Panta Rhei: Change*
59 *in Hydrology and Society*”. Due to rapid and complex anthropic changes, the *IAHS* emphasize the necessity to
60 improve the capability of decision maker and water resources stakeholders to make predictions of hydrological
61 dynamics and support sustainable societal development in a changing environment (Montanari et al., 2013).
62 Quantifying and understanding past changes in hydrological processes are necessary to suggest reliable future
63 predictions of hydrological signatures. Reconstructing past data and predicting annual, monthly and daily
64 hydrographs in a changing environment, and especially on poorly gauged catchments with sparse data, remains a
65 challenge for hydrological science.

66 Long-term hydrological modelling requires integrating the impact of global changes in terms of climate,
67 land-use and infrastructures. Nowadays, urban areas represent only 2 % of the total surface of the Earth but
68 concentrate more than 50 % of world population, cities count close to four billions people, this figure was
69 multiplied by five since 1950 (Janicot et al., 2015). This huge urbanization rate combined with a demographic
70 explosion is especially significant in the inter-tropical regions where most of developing countries and numerous
71 in development megalopolis are located (UNDESA, 2017). For example, population in Africa is projected to reach
72 2.5 billion people by 2050 with about 55 % living in urban areas (Güneralp et al., 2017). Hence in this context,
73 the impact of land-use changes on runoff, especially in urban and peri-urban zones, seems to override rainfall
74 changes impacts.

75 Empirical, conceptual, probabilistic and physically-based models can be used to simulate the impact on
76 runoff of global changes. Conceptual models such as *HBV* (Bergström and Singh, 1995), *GRIA*, *GR2M* or *GR5J*
77 (Mouelhi, 2003; Mouelhi et al., 2006; Le Moine, 2008) or physically-based models as *MIKE-SHE*
78 (Abbott et al., 1986) were applied to assess global changes impacts on hydrology. On tropical climate, such models
79 were applied at the local scale (Giertz et al., 2006), the mesoscale (Beck et al., 2013; Wagner et al., 2013;
80 Yira et al., 2016) or large scale catchments (Genwei, 1999; Zhou et al., 2010) at daily, monthly or annual time
81 steps. All these models require accurate information about the basin physiographic characteristics, long series of
82 rainfall-runoff data, climate and land-use changes data; moreover an adequate calibration/validation strategy must
83 be undertaken in order to take into account the spatio-temporal evolution of some parameters. However, on basins
84 with sparse data at various time steps (e.g. only monthly rainfall available on a given period), and in the absence
85 of continuous long series rainfall-runoff data, simple modelling approaches must be adapted for reconstructing
86 annual runoff taking into account available sparse historical data and information on climate and land-use changes.
87 For that, empirical approaches in non-dimensional spaces were largely used since Turc (1954) and Budyko (1974)
88 which were largely applied, analysed and extended the last decade (Zhou et al., 2015; see a synthesis
89 in Moussa and Lhomme, 2016). Ponce and Shetty (1995) developed an original annual rainfall-runoff model based
90 on a formulation similar to the one developed in the Soil Conservation Service method (SCS, 1956;
91 Mishra and Singh, 2013), and Sivapalan et al. (2011) extended this approach to model different components of the
92 water cycle at the annual scale. However, all these models generally don't take into account changes in climate

93 and land-use. Hence, there is a need to develop simple parsimonious approaches modelling for annual runoff taking
94 into account non-stationarity due to land-use long term evolution, and adapted to basins with sparse data.

95 In most of developing countries, environmental monitoring as precipitation and streamflow are often limited.
96 This data-sparse condition results of a poor knowledge of basin climatology and hydrological signatures, such as
97 annual runoff. Even for areas faced with recurring high water management issues, most of national organizations
98 do not have resources to purchase and maintain the necessary instrumentation for field monitoring
99 (Hughes et al., 2015). The availability of continuous and long term data sets of runoff varies dramatically
100 throughout the world (Kundzewicz et al., 2007). Prediction in ungauged basins (*PUB*) approaches are tools to cope
101 with this data-sparse context (Blöschl, 2013) and are based on regionalization of hydrological characteristics by
102 spatial proximity or geomorphological similarities from donor to target catchments (Parajka et al., 2013; Salinas
103 et al., 2013). However, recently development of soft monitoring (Crabit et al., 2011) and crowdsourced hydrology
104 (Lowry and Fiennen, 2013; Le Coz et al., 2016; Mazzoleni et al., 2017) gave encouraging results. To cope with the
105 lack of long-term observation (rainfall-runoff) on catchment faced to land-use changes a solution is to set up a
106 dedicated short-term instrumentation on catchment faced to various land-use states associated with a best
107 valorisation of historical database. This methodology lets to observe hydrological processes of catchments
108 characterized by various states of land-use and under various climatic contexts.

109 The scope of this paper is to develop a combined approach of data acquisition and the development of a new
110 semi-distributed model taking into account land-use changes to reconstruct and predict annual runoff on a
111 catchment exposed to high urban increase. The data acquisition step implies (1) to deploy a complementary and
112 dedicated short-term and multi-scale space hydro-meteorological network, (2) to analyse the most recent global
113 land-use products with adapted time and space resolution and (3) to maximize the valorisation of historical studies
114 for the evaluation of catchment characteristics (land-use, topography, soils map) and some environment variables
115 (evaporation, precipitation, runoff). The model developed from the data acquisition is mainly based on land-use
116 changes impacts on annual runoff.

117 The Mefou catchment (421 km²) including the city of Yaoundé capital of Cameroon was used for applications
118 to reconstruct the annual runoff at the outlet for the period 1930-2017. A dedicated hydrological instrumentation
119 during the hydrological year 2017-2018 was conducted, and completes the review of historical studies over the
120 period 1960-2016.

121 First, we introduce the annual non-stationary rainfall-runoff model structure, hypotheses and general
122 calibration-validation procedure. The inputs of the model are the annual precipitation and an hydrologic index
123 taking into account topography, soil and land-use temporal evolution. Second, we describe the study area including
124 the review of historical hydro-meteorological data and a description of the dedicated short-terms instrumentation.
125 Third, we present a spatio-temporal analysis of precipitation. Fourth, we present the methodology to construct the
126 hydrological index from the analysis of hydrologic and physiographic data. Then, we present the model
127 parametrization, calibration and validation, and finally we show and discuss the application results of
128 reconstruction and prediction of historical annual runoff. The Appendix A gives the list of notations and
129 abbreviations. The Supplementary Material gives additional information on data sets.

130

131 **2 The annual rainfall-runoff model**132 **2.1 Model structure**

133 The model is based on mathematical relationship between precipitation P and runoff R similar that proposed
134 by Ponce and Shetty (1995) and Sivapalan et al. (2011) for applications at the annual scale on the basis of the SCS
135 equations (Mishra and Singh, 2003). P ranges between P_n and P_x which respectively correspond to the minimal
136 and the maximal precipitation values over a large historical period of the main study catchment. Applications were
137 conducted in tropical basins where R is not nil. Therefore, in order to simplify, we use a simple second order
138 polynomial relationship between R and P such as (Fig.1):

$$139 \quad R = AP^2 + BP, \quad (1)$$

140 and the annual runoff coefficient:

$$141 \quad \rho = R/P = AP + B, \quad (2)$$

142 where A and B are empirical parameters which can be linked to catchment properties (e.g. topography, soil, land-
143 use).

144 The first hypothesis is that the annual volume V_O at the outlet of the main catchment is the sum of the annual
145 volumes V_i on each sub-catchment T_i (Fig. 2b):

$$146 \quad V_O = \sum_{i=1}^n V_i, \quad (3)$$

147 where n is the number of sub-catchments and i is the index representing a sub-catchment noted T_i . We define the
148 annual runoff R_i on each sub-catchment T_i as:

$$149 \quad R_i = V_i/A_i, \quad (4)$$

150 where A_i is the area of T_i and A_O is the area of the whole catchment with:

$$151 \quad A_O = \sum_{i=1}^n A_i, \quad (5)$$

152 Consequently the annual runoff R_O of the whole catchment is defined as:

$$153 \quad R_O = V_O/A_O. \quad (6)$$

154 The second hypothesis presumes that the runoff coefficient $\rho = R/P$ and the annual runoff R are only
155 functions of P and an “hydrological index” noted I with $\rho = f(P, I)$ and $R = g(P, I)$ similar to the SCS approach
156 used in Ponce and Shetty (1995) and Sivapalan et al. (2011). As for the curve numbers CN in the Soil Conservation
157 Service method (Mishra and Singh, 2003), the index I characterizes topography, soil and land-use of the basin,
158 and enables to take into account land-use evolution through time: I is considered low for permeable soils and/or
159 low urbanization areas producing low runoff, and I is considered high for impermeable soils and/or high
160 urbanization areas producing high runoff. The index I is an empirical indicator and can be defined as a linear
161 combination of several components C_i . As for the CN method, in this study we choose the following three
162 components: topographic component (C_T) such as slope classes impacting runoff, and soil component (C_S) such
163 as permeability classes and land-use component (C_{LC}) such as urbanization classes.

$$164 \quad I = \sum_{i=1}^m \omega_i C_i, \quad (7)$$

165 where ω_i is the weight attributed to component i and m the number of components including in the hydrological
166 index. If m is equal to 1, the hydrological index I is based on only one component, for example the land-use
167 characteristics (C_{LC}) if this descriptor is considered as the main factor changing in time.

168 We note I_n and I_x respectively the lowest and the highest values of I over the catchment dataset used to
169 construct the model. Therefore, for a given rainfall P , R increases when I increases; for a given index I , R increases
170 when P increases.

171 For a given value of I the runoff coefficient ρ increases when the rainfall increases from P_n to P_x . Let $\rho_{n,I}$ and
172 $\rho_{x,I}$ be the corresponding values of ρ for P_n and P_x respectively. Let $\beta_1 = \rho_{x,I} - \rho_{n,I}$ as shown in Fig. 1a. For a given
173 value of P , the runoff coefficient ρ increases when I increases from I_n to I_x . Let $\rho_{n,P}$ and $\rho_{x,P}$ be the corresponding
174 values of ρ for I_n and I_x respectively. Let $\beta_2 = \rho_{x,P} - \rho_{n,P}$ as shown in Fig. 1a. As we have a linear relationship
175 between P and ρ (Fig. 1a), the value of β_2 is constant and similar for all values of P . In order to calculate β_2 , we
176 need data on different catchments and periods with the same value of P but with different values of I ranging
177 between I_n and I_x .

178 The annual runoff model proposed herein uses a simple relationship $R = f(P, I)$ as shown in Fig. 1b. The
179 domain of application of the model is for the precipitation $P \in [P_n, P_x]$ and the hydrological index $I \in [I_n, I_x]$. The
180 model needs as input the precipitation P which has to be calculated on each sub-catchment T_i (see an application
181 in Sect. 4). The model needs also the definition of the hydrological index I which is time variable and enables to
182 take into account land-use changes and non-stationary relationships between R and P . The definition of the rules
183 to construct the components C_i and the weights ω_i of I (Eq. 7) are obtained from data analysis on the study site as
184 shown later in Sect. 5.

185

186 2.2 Calibration, validation, reconstruction procedure

187 The annual rainfall-runoff model developed herein is calibrated using data from donor catchments (noted D)
188 historical information, and from the dedicated short-term instrumentation. Donors could be catchments or sub-
189 catchments inside or near to the main study catchment (Fig. 2a). Sets of annual precipitation P and annual runoff
190 R data are available for donors characterized by different geomorphologic and land-use states (e.g. topography,
191 soil, urbanization). Selecting distant past, recent past and present in P and R values from donors enable to cover a
192 large range of climate, land-use and geomorphological conditions in order to elaborate a reliable and robust model.
193 Donors are used to calibrate the model parameters then the calibrated model is applied on target catchments (noted
194 T , Fig. 2b) and let to evaluate runoff for the main catchment (Eq. 3 to 6). The model can be applied for several
195 periods (past, present and future) for different climate and land-use scenarios.

196 We consider the set of sparse annual rainfall-runoff data. The set is split into two datasets, the first one is
197 used for the calibration of the model parameters and the second one for the validation. The dataset used for the
198 calibration must include data from different ranges of precipitation $P_n < P < P_x$ and land-use characterized by the

199 hydrological index $I_n < I < I_x$. The *RMSE*, the r^2 , the normalised error (E) and the mean normalised absolute error
200 (\bar{E}) criteria functions are used to assess and compare simulation performance:

$$201 \quad RMSE = \sqrt{\frac{1}{n} \sum (\widehat{R}_{Oj} - R_{Oj})^2}, \quad (8)$$

$$202 \quad r^2 = \frac{[\sum (\widehat{R}_{Oj} - \overline{\widehat{R}_O})(R_{Oj} - \overline{R_O})]^2}{\sum (\widehat{R}_{Oj} - \overline{\widehat{R}_O})^2 \sum (R_{Oj} - \overline{R_O})^2}, \quad (9)$$

$$203 \quad E_j = \frac{\widehat{R}_{Oj} - R_{Oj}}{R_{Oj}}, \text{ and } E_{i,j} = \frac{\widehat{R}_{i,j} - R_{i,j}}{R_{i,j}}, \quad (10)$$

$$204 \quad \bar{E} = \frac{1}{n} \sum (|E_j|), \quad (11)$$

205 where \widehat{R}_{Oj} is the simulated annual runoff and R_{Oj} the observed annual runoff for the main study catchment; n the
206 number of the evaluated year and j the index corresponding to a given year. $\widehat{R}_{i,j}$ is the simulated annual runoff for
207 target i for the evaluated year j and $R_{i,j}$ the observed annual for target i for the evaluated year j . In order to evaluate
208 the robustness of the model, a sensitivity analysis is conducted on the impact of the number of donor catchments
209 used establishing the rules of the hydrologic index I . Finally, the performance of the developed model is compared
210 to a classical annual runoff model generally applied under stationary conditions (i.e. the *GRIA* model based on the
211 Turc (1954) equation; Mouelhi, 2003).

212

213

214 3 Study site

215 3.1 Oro-hydrography and climate

216 The Mefou River is a tributary of the Nyong. The Mefou catchment at Nsimalen (421 km²) includes the
217 capital city of Cameroon, Yaoundé (Fig. 3a). The upstream part of the basin (70 km²) is controlled by the Mopfou
218 dam built in 1969 planned to provide about one third of the drinking water to the Yaoundé urban area
219 (100,000 m³.day⁻¹).

220 The catchment is hilly (peaks at 1000 m a.s.l) with important wetland areas (around 700 m a.s.l) at the
221 downstream parts (Fig. 3a). The Mefou River is 35 km length from the Mopfou dam to Nsimalen. The main
222 tributaries of the Mefou is the Mfoundi which drains the most urbanized parts of the whole catchment (Fig. 3a).
223 The river channel slope ranges between 1 ‰ and 5 ‰ causing frequent floods in the lowlands. Canalization of the
224 upstream Mfoundi and its tributaries were undertaken since 2002 in order to reduce floods in the urbanized zone.
225 The landform of the South Cameroon Plateau corresponds to the dismantling of an old iron crust undergoing more
226 humid climatic conditions (Bilong et al., 1992; Beauvais, 1999; Bitom et al., 2004). This multi-convex landform
227 is composed of rather closely spaced hilly compartments, typically of few hundred metres in diameter, separated
228 by flat swampy valleys of variable stretch from 50 to 500 m width (Bitom et al., 2004). We used the slope index
229 S_f of Roche (Roche, 1963) to characterize the topography component of the hydrological index I for donor and
230 target catchments.

231 The climate is humid tropical with two dry and wet seasons (wet-and-dry equatorial savannah with dry winter
232 according to the Köppen-Geiger classification, Kottek et al., 2006). The mean annual precipitation P_m from Mvan

233 station (P_I) in Yaoundé on the period 1930-2015 is 1580 mm. We distinguish four seasons: long rainy season from
234 March to June, short dry season from July to August, short rainy season from September to November, and long
235 dry season from December to February. The hydrological year is defined from March to February. Ikounga (1978)
236 has estimated the potential evapotranspiration PET between 900 mm (Sunken Colorado pan) to 1200 mm
237 (Thornthwaite method). Supplementary Material (Sect. 2, Fig. S1) shows the mean monthly precipitation,
238 temperature and PET .

239

240 3.2 Soil and land-use

241 The regolith is developed on a granito-gneissic basement. Ferralsol (laterite) regolith is developed on the
242 hillslopes while in the swampy valleys, it is topped with bleached hydromorphic soils developed on colluvium and
243 river alluvium (Bachelier, 1959; Braun et al., 2005; Braun et al., 2012). In the region of Yaoundé,
244 Humbel and Pellier (1969) calculated a soil surface permeability between 20 and 70 $\text{cm}\cdot\text{h}^{-1}$ up the hill, and 200
245 $\text{cm}\cdot\text{h}^{-1}$ near the swampy valleys. These values of permeability are very high and limit the surface runoff, especially
246 in swampy valleys. The clay amount is generally higher at the top of the hills than at the bottom. In the field
247 experiment we conducted in 2017, we measured in the region of Yaoundé the soil surface permeability by a
248 simplified Beerkan method (Bagarello et al., 2014) and obtained values ranging between 2 and 125 $\text{cm}\cdot\text{h}^{-1}$ which
249 are comparable to the values given by Humbel and Pellier (1969). Humbel and Pellier (1969) also showed that for
250 both types of soil, the surface permeability decreases quickly with the depth until an impermeable layer facilitating
251 lateral flow. In this study we use the proportion of hydromorphic soil (HS) to characterize the soil component of
252 the hydrological index I for donor and target catchments (see Sect. 5.1).

253 The administrative urban area of Urban Community of Yaoundé (CUY) covers nowadays about 297 km^2 . As
254 most part of the Nyong basin (Olivry, 1979), the Mefou catchment was originally mainly covered by humid tropical
255 forest. The study area is faced to major land-use changes due to human activities mainly urbanization and
256 agriculture (see more details in Supplementary Material, Sect. 3). Population in Yaoundé has increased from
257 90,000 in 1960 (Franqueville, 1968) to 3.65 million in 2017 (UNDESA, 2017) with an annual growth rate of 5.7 %
258 per year between 1987 and 2005 according to the Central Office of Cameroonian Population Study and Census.
259 This huge demographic change is characterized by an important expansion of the urban area Fig. 3b and the
260 increase of population density (Bopda, 2003). In the opposite, forest and wetlands areas decreased, and were
261 generally replaced by agricultural and urban areas as shown in Fig. 3c with the land-use classification over the
262 Mefou catchment from the land cover product of the European Space Agency available for Africa ($ESA-CCI LC$)
263 for the year 2016. Moffo (2017) analysed a set of aerial photography in 1956 and estimated that the impervious
264 areas covered 3.5 km^2 , less than 1 % of the Mefou catchment area. We used $ESA-CCI LC$ and OpenStreetMap®
265 2015 layers to calculate impervious areas of around 64 km^2 (15 %) in 2016. Ebodé (2017) used Landsat images to
266 study the evolution of land-use from 1978 to 2015. He noticed at the Mefou catchment until the Nyong confluence
267 (basin area of 802 km^2 , approximately two times the Mefou basin area at Nsimalen) a decrease of 160 km^2 of the
268 total forest cover, with specifically a decrease of 60 % of the primary forest area from 235 km^2 in 1978 to 94 km^2
269 in 2015, a decrease of 73 % for swampy forest from 206 km^2 to 57 km^2 , and an increase of 60 % in degraded and
270 secondary forest from 223 km^2 to 353 km^2 . For the Mefou at Nsimalen, Ebodé (2017) estimated that the agricultural

271 area increased from 10 km² (3.5 % of the catchment area) in 1978 to 28 km² (10 %) in 2015, and that the urban
272 area (integrating impervious surfaces) increased from 45 km² (11 %) in 1978 to 151 km² (36 %) in 2015. We used
273 the proportion of urban area U over donor and target catchments to characterize the land-use component of the
274 hydrological index.

275 The impact of these land-use changes on hydrological processes is not yet quantified on the Mefou
276 catchment. The urbanization of the Mefou catchment also impacts both groundwater and river water quality due
277 to domestic and industrial untreated wastewater from urban areas but also contamination by peri-urban agriculture.
278 For example, Branchet et al. (2018) recently shows high Diuron® concentration on surface water that frequently
279 exceeded the European water quality guideline. These growing issues of water management drive the removal of
280 wetlands in lowlands impacting their ecosystem services as the natural purification of water (Daily, 1997; Russo,
281 2013).

282

283 3.3 Historical sparse data

284 Precipitation measurements are available at a monthly time step at two historical raingauges (Fig. 3a): P_1
285 from 1930 to 2017, and P_2 from 1955 to 1978. The correlation coefficient for the common period between both
286 stations at the annual time step is 0.74. A long-term reference precipitation dataset was calculated using the mean
287 of P_1 and P_2 when data from both stations are available, and from P_1 for the remaining periods.

288 Daily runoff measurements at the Mefou catchment outlet at Nsimalen started in 1963 but with long periods
289 of gaps. Annual runoff is available for only 29 years (1964-1977, 1979, 1982-1986, 2005-2011 and 2017), and
290 ranges between 250 mm and 850 mm. Annual runoff coefficient ranges between 0.21 and 0.48.

291 Few studies are available on the hydrology of Yaoundé, and most of them date before the 80th. They
292 particularly focused on water balance at monthly and annual scales: on the Mefou river (Lefèvre, 1966; SNEC,
293 1969; Olivry, 1979), on the Mfoundi (Srang, 1972; Nguemou, 2008), and on sites downstream Nsimalen
294 (Ikounga, 1978). From these studies, we retain six historical donors (noted D_H ; Fig. 4a), and Table 1 presents their
295 characteristics: area between 24 and 235 km², period of observation, annual precipitation P between 1640 and
296 1930 mm, annual runoff R between 392 and 1340 mm, and annual runoff coefficient ρ between 0.22 and 0.77.
297 Under the hypothesis that the storage annual variation is nil, we estimate an annual evapotranspiration $AET = P - R$
298 which ranges between 400 and 1400 mm. Information relative to precipitation measurements are well documented
299 in the historical studies previously cited. Note that the donor D_{H6} is located out of the Mefou catchment but quite
300 close from Yaoundé area (40 km) and presents a similar topography, soil and land-use conditions of the Mefou
301 catchment (Ikounga, 1978). These donors cover different land-use states: e.g. forestry natural cover for D_{H4} and
302 D_{H6} ($U < 1\%$) and highly urbanized cover for D_{H3} ($U > 75\%$).

303 Other historical studies of smaller ($< 10\text{km}^2$) and larger ($> 5000\text{km}^2$) catchments in Nyong basins in natural
304 land-use context give P between 1420 and 1730 mm, R between 392 and 530 mm, ρ between 0.18 and 0.30 and
305 AET between 1070 and 1470 mm. The urbanized catchment Odza (6 km²), located in Yaoundé (Mfoundi

306 catchment), was monitored in 2011-2012 by Ngoumdoun (2013) who calculated $P = 1840$ mm, $R = 1640$ mm,
307 $\rho = 0.88$ and $AET = 220$ mm (see Supplementary Material, Sect. 4).

308

309 **3.4 Dedicated short-term multi-scale instrumentation (03/2017-02/2018)**

310 In order to complete historical data, we undertook dense spatial rainfall-runoff instrumentation during one
311 hydrological year (03/2017-02/2018). Eleven daily time step raingauges were installed in order to study the spatial
312 variability of precipitation (Fig. 4a). The choice of limnimetric stations location was determined by the position of
313 the main confluences, by the position of historical limnimetric stations, and the need to measure runoff from basins
314 with different degrees of urbanization (Fig. 4a). This instrumentation provides six additional experimental donors
315 (noted D_I) with different ranges of heterogeneities in terms of area, land-use, topography and soil (Table 1). The
316 limnimetric station D_{I1} is located downstream the dam and enables to measure the outflow from the reservoir at
317 100 ± 25 mm.yr⁻¹. The lack of measurements of the outflow value until 2017-2018 makes this results the first
318 assessment of the dam impact on Mefou water budget. The donor D_{I4} corresponds to the intermediate basin between
319 D_{I3} and D_{I2} . Table 1 presents their characteristics: area between 21 and 120 km², P between 1620 and 1715 mm, R
320 between 712 and 1250 mm, ρ between 0.40 and 0.76 and AET between 405 and 908 mm. Annual precipitation on
321 these donors D_I are of the same order as for historical donors D_H while runoff and runoff coefficients are generally
322 higher for catchments with higher urbanization rate.

323

324 **3.5 Main characteristics of the donor catchments**

325 The Mefou catchment originally covers by dense tropical forest includes the most part of the city of Yaoundé.
326 The urban area started growing since 1960 (1 % of the total basin area) to currently reach about 30-35 % of the
327 basin area with an impervious area estimated to 15 %. The forest cover has vanished of more than 50 % since 1980
328 with a huge conversion of the primary forest into secondary and degraded forests. Nowadays, the forests cover
329 about 40 % of the Mefou at Nsimalen. The various sources cited in Sect. 3.2 showed a growth of agricultural areas
330 around the urban area of Yaoundé, with cropland and grassland covers around 30 % of the catchment area in 2015.
331 The catchment can be considered as peri-urban due to the noticeable urbanization and the development of
332 agricultural activities observed in lowlands and outskirts. However, the south-west part and the area drained by
333 the Mopfou dam in upstream remain slightly affected by urbanization.

334 Combining historical studies and dedicated short-term instrumentation 2017-2018, we have 12 donor
335 catchments, 6 from historical studies (D_H) and 6 from the instrumentation (D_I) presenting various topographic, soil
336 and land-use characteristics; the area ranges between 21 and 235 km², P ranges between 1620 to 1930 mm, R
337 between 390 and 1340 mm, ρ between 0.22 and 0.77 and AET between 400 mm to 1400 mm. S_I varies from 6.7 %
338 to 13.5 %, HS varies from 0 to 44 % and U varies from 0 to 83 % over donor catchments of the study area. We
339 observe that ρ can vary widely for the same catchment function of the land-use: e.g. from 0.33-0.4 for D_{H1} ($U =$
340 5 %) and D_{H2} to 0.77 for D_{H3} ($U > 75$ %). All the observed data on the study site are analysed to understand

341 hydrological processes of the catchments faced to land-use changes in order to identify rules defining the
342 hydrological index I on donors and apply it on targets for the period 1930-2017.

343

344

345 **4 Precipitation**

346 The model needs as input the precipitation P which has to be calculated on both donor and target catchments
347 (Fig. 4). For donors, precipitation information are well documented in corresponding studies or issue of dedicated
348 short-term instrumentation (Table 1). For targets, we used the long-term historical raingauges and the spatially
349 short-term information (1968-1969 from SNEC (1969), and 2017-2018 from the short-term instrumentation) to
350 construct historical precipitation database for each target.

351

352 **4.1 Temporal variability of precipitation**

353 First, we study long-term precipitation trends (1930-2015) over the Mefou catchment from historical
354 raingauges P_1 and P_2 . The average precipitation is 1580 mm (P_m) and the minimal and maximal annual
355 precipitation are respectively $P_n = 1050$ mm and $P_x = 2200$ mm. Values of P_n and P_x set the limit of availability of
356 the developed model for the study catchment. Fig. 5a shows no significant trends of annual precipitation over the
357 period, but we observe a succession of humid (1960-1970, 1980-1990, and 2006-2013) and dry (1935-1950, 1970-
358 1980, and 1990-2000) periods. At the seasonal scale we observe some changes in amount of precipitation: i) no
359 change during the first wet season (March to June) (Fig. 5b); ii) during the first dry season (July and August),
360 increase of the mean precipitation from 100 to 220 mm (+120 %) on the period 1930 to 2015 (Fig. 5c); iii) during
361 the second wet season (September to November) slight increase from 700 to 760 mm (+9 % ; Fig. 5d); iv) during
362 the second dry season (December to February) decrease from 110 to 80 mm (-28 % ; Fig. 5e). This historical
363 precipitation database is used to construct the database precipitation for target catchments. Results shows also that
364 there is no a clear changes on annual precipitation between 1930 and 2015, and consequently the trend of annual
365 runoff coefficient increase can be related mainly to catchment change and particularly to the increase of urbanized
366 areas.

367

368 **4.2 Spatial variability of precipitation**

369 Second, we study the spatial distribution of annual precipitation over the Mefou catchment.

370 Figures 6a and 6b show the mean annual precipitation for respectively the hydrologic years 1968-1969
371 (SNEC, 1969) and 2017-2018 (dedicated short-term instrumentation), the only historical years with available
372 dense spatially measured precipitation.

373 For 1968-1969, P varies over the Mefou catchment between 1400 mm to 2000 mm with an average of 1780
374 mm. For 2017-2018, P varies between 1400 and 2100 mm with an average of 1640 mm. The hydrological year

375 2017-2018 seems quite representative of an average year in terms of annual precipitation ($P_m = 1580$ mm). The
376 annual precipitation observed at P_i is about 1730 mm for the same period with a difference of +6 % with average
377 precipitation P . The rain-gauge P_i seems quite representative of the average value for the Mefou catchment.

378 On both Figs. 6a and 6b, we observe that the highest annual precipitation values are located in the north-west
379 part of the basin, corresponding to the zone with highest elevations. The east and south parts, corresponding to the
380 flattest and lowest elevation parts of the basin are characterized by lower P .

381 Due to the lack of spatial information for the historical period, a precipitation weight w_{Ti} is assigned to a
382 target catchment T_i such as:

$$383 \quad P_{Ti} = w_{Ti} \cdot P, \quad (12)$$

384 where P is the mean annual precipitation on the Mefou catchment from the historical database and P_{Ti} the mean
385 annual precipitation on T_i . The term $w_{Ti} = P_{Ti}/P$ can be both calculated using historical data (Figs. 6a and 6c) and
386 the instrumentation 2017-2018 (Figs. 6b and 6d). For both cases, we obtain comparable and retain $w_{T1} = w_{T3} = w_{T5}$
387 $= w_{T6} = w_{T7} = 1$ for respectively T_1, T_3, T_4, T_5, T_6 and T_7 ; $w_{T2} = 1.05$ for T_2 is slightly high due to the high values
388 of P ; $w_{T4} = w_{T8} = 0.95$ for T_4 and T_8 .

389

390 4.3 Relationship between annual runoff coefficient and precipitation

391 Third we study the relationship between the annual runoff coefficient ρ and P for three stations in nearly-
392 steady land-use states (Fig. 7): the Mefou at Nsimalen on the period 1964-1984 with a low impact of land-use
393 evolution in comparison to the period 1984-2015, the Mefou at Etoa natural forested basin on the period 1967-
394 1983, and the semi-urbanized Mfoundi on the period 1969-1971. Both the Mefou at Etoa and Mfoundi are sub-
395 catchments of the Mefou at Nsimalen. For the Mefou at Nsimalen, we adjusted a linear relationship between
396 ρ and P ; ρ increases from $\rho_{n,P} = 0.2$ corresponding to $P_n = 1050$ mm to $\rho_{x,P} = 0.35$ corresponding to $P_x = 200$ mm;
397 this gives $\beta_I = \rho_{x,P} - \rho_{n,P} = 0.15$. For the Mefou at Etoa, $\rho = 0.15$ for $P = 1330$ mm and $\rho = 0.30$ for $P = 2200$ mm;
398 both values of ρ for the Mefou at Etoa are inferior than those observed on the Mefou at Nsimalen for similar values
399 of precipitation, showing the impact of land-use with low annual runoff coefficient on natural basins. For the
400 Mfoundi, $\rho = 0.33$ for $P = 1640$ mm and $\rho = 0.40$ for $P = 1930$ mm; both values of ρ for the Mfoundi are superior
401 than those observed on the Mefou at Nsimalen for similar values of precipitation, showing the impact of land-use
402 with high annual runoff coefficient on semi-urbanized basins. In summary, we obtain approximately similar values
403 of $\beta_I = 0.15$ on the Mefou at Nsimalen (1964-1984), but also on the natural Etoa catchment (1967-1983) and on
404 the in-urbanization Mfoundi upstream catchment (1969-1970). These three catchments have three different values
405 of the hydrological index I , but with I considered constant on the presented periods.

406

407

408 **5 The hydrological index I**

409 This section analyses the hydrological and physiographic data in order to define the rules for constructing
410 the hydrological index I calculated as a linear combination of three components:

$$411 I = \omega_T C_T + \omega_S C_S + \omega_{LC} C_{LC}, \quad (13)$$

412 where C_T is the topography component, C_S the soil component, C_{LC} the land-use component, ω_T the weight of C_T ,
413 ω_S the weight of C_S , and ω_{LC} the weight of C_{LC} .

414

415 **5.1 The components C_T , C_S and C_{LC}**

416 Heterogeneities of topography, soil condition and land-use variability in space and time observed on the study
417 area (Sect. 3) lead us to propose classification rules to highlight the main features of catchments and to define the
418 three components C_T , C_S , and C_{LC} of the hydrological index I using cartographical data. All three components
419 range between 0 and 1; when any of the terms (C_T , C_S and C_{LC}) increase, ρ increases. The topography (C_T) and soil
420 condition (C_S) are considered stable over the time contrary to land-use (C_{LC}) faced to major changes.

421 For topography C_T , the slope index S_I of Roche (Roche, 1963) is calculated for donors (Table 1) and targets
422 from SRTM (2014). We define: $C_T = 0$ for $S_I < 7\%$; $C_T = 0.5$ for $7\% \leq S_I \leq 12\%$; $C_T = 1$ for $S_I > 12\%$.

423 For soil condition C_S , the lack of accurate soil maps over the catchment constrains us to define indirectly soil
424 condition heterogeneities over the catchment. Historical studies of soil characteristics (Bachelier, 1959;
425 Pellier, 1969; Humbel and Pellier, 1969) are used to define soil classes depending on the altitude and the slope
426 derived from the SRTM 2014. For that, we calculate the area of lowlands (altitude < 730 m) with low slopes
427 ($< 7\%$) corresponding to hydromorphic yellow soil characterized by lower rate in clay and higher surface
428 permeability. The proportion of hydromorphic soil (HS) on each catchment is used to estimate the classes of C_S
429 (see for donors Table 1, and for targets: $C_S = 0$ for $HS > 15\%$; $C_S = 0.5$ for $2\% \leq HS \leq 15\%$; $C_S = 1$ for $HS < 2\%$).

430 For land-use component C_{LC} , historical references and global products (summarized in Table 2) are used to
431 characterize land-use of donors and the evolution of target land-use over past-period with available data (1930,
432 1950, 1980, 2000, and 2017) and future scenario (2030). In order to integrate the main land-use signature, we
433 define six classes for C_{LC} according to urban area proportion of (U ; see for donors Table 1, and for targets the
434 Supplementary Material, Table S3): $C_{LC} = 0$ for $U < 1\%$; $C_{LC} = 0.2$ for $1 < U < 5\%$; $C_{LC} = 0.4$ for $5 < U < 20\%$;
435 $C_{LC} = 0.6$ for $20 < U < 50\%$; $C_{LC} = 0.8$ for $50 < U < 70\%$; $C_{LC} = 1$ for $U > 70\%$. Different trends of land-use
436 changes are observed for the 8 target sub-catchments (Fig. 8). From 1930 to 1950, the whole main catchment is
437 considered to be mostly cover by originally forest ($C_{LC} = 0$ for all the targets). Development of urbanization
438 impacted first the Mfoundi sub-catchments from 1960 to 1980 (T_5 , T_6 and T_7) especially T_5 . Nowadays, these sub-
439 catchments reach a maximum of urbanization for T_5 and T_6 ($C_{LC} = 1$). T_2 and T_8 faced to major changes since 1980
440 with intensification since 2000. Nowadays, the urbanization process do not get the entire area of these catchments.
441 The urbanization continue and will be amplified in these surrounding areas due to the lack of space in the most
442 urbanized part of Yaoundé (T_5 , T_6 and T_7). T_1 , T_3 and T_4 are the last sub-catchments impacted by urbanization; a
443 high proportion of these catchments have forest or wetland covers. We propose a fictive but plausible scenario of
444 land-use for 2030, regarding to the current expansion of the urban area and the perspective of future population

445 estimation for Yaoundé (from 3.6 million in 2017 to 6.7 million in 2035; UNDESA, 2017). We suppose a high
446 development of urbanization for T_2 and T_8 (C_{LC} from 0.6 in 2017 to 0.8 in 2030) and in a lesser extent a development
447 of urbanization over the south part of the basin (T_4 with C_{LC} from 0 in 2017 to 0.4 in 2030). Values of C_T , C_S and
448 C_{LC} are presented for donors in Table 3 and for targets in Table 4.

449

450 5.2 Relationship between annual runoff ρ and C_T , C_S and C_{LC} for donors

451 D_{H4} , D_{H5} and D_{H6} correspond to forested areas ($C_{LC} = 0$) whereas D_{I5} and D_{H3} have high rates of urbanization
452 ($C_{LC} = 1$, Table 3). For these basins, precipitation presents a low range of variation between 1645 and 1810 mm.
453 D_{H4} , D_{H5} and D_{H6} present low values of annual runoff coefficient with ρ varying from 0.22 to 0.25. D_{I5} and D_{H3}
454 present very high values of runoff with $\rho = 0.76$ and 0.77. For catchments with intermediate levels of urbanization
455 (D_{I2} , D_{I3} , D_{I4} , D_{I6} , D_{H1} , D_{H2}), runoff ranges between those observed in the two previous cases with ρ ranging
456 between 0.33 and 0.54.

457 Analysis of ρ for donors D_{I2} and D_{I6} presenting the same value of C_{LC} (0.6) but extreme values of C_T and C_S
458 (D_{I2} is located in the hilly part of the Mefou catchment whereas D_{I6} present high portion of lowlands) enables to
459 quantify the impact of C_S and C_T on ρ . For the period September-December, D_{I6} presents runoff coefficient of 0.40
460 which is significantly lower than the value of 0.53 observed for D_{I2} on the same period. Differences observed are
461 quite clear in term of runoff with for D_{I4} runoff value up to 160 mm in October against 95 mm for D_{I6} (see
462 Supplementary Material, Sect. 5).

463 These results show the significant impact of land-use conditions on runoff, but topography and soil condition
464 could explain complex hydrological responses. Consequently when calculating the index I , we will give a higher
465 weight to the component C_{LC} in comparison to C_T and C_S .

466

467 5.3 The weights ω_r , ω_S and ω_{LC}

468 From data analysis (Sect. 5.2), we showed that the impact of land-use change on runoff is higher than the
469 impact of soil and topography. Consequently, we affect higher weight for ω_{LC} , with $\omega_{LC} > \omega_r$ and $\omega_{LC} > \omega_S$.
470 Figure 9 shows an example of the relationship between annual runoff of donors ρ and hydrological index for
471 donors I for $\omega_{LC} = 7/9$, $\omega_r = 1/9$ and $\omega_S = 1/9$. We observe a simple linear empirical relationship to estimate ρ_D :

$$472 \rho_D = aI + b \quad (14)$$

473 with $r^2 = 0.96$. We conduct a sensitivity analysis of the regression on the adjusted parameters a and b for four sets
474 of parameters ω_{LC} , ω_r and ω_S : i) $\omega_r = 1/5$, $\omega_S = 1/5$ and $\omega_{LC} = 3/5$; ii) $\omega_r = 1/7$, $\omega_S = 1/7$ and $\omega_{LC} = 5/7$; iii), $\omega_r =$
475 $1/9$, $\omega_S = 1/9$ and $\omega_{LC} = 7/9$; iv) $\omega_r = 1/12$, $\omega_S = 1/12$, $\omega_{LC} = 10/12$. We obtain very good correlation coefficient of
476 the four linear regressions ranging between 0.83 (case i) and 0.98 (case iv). The parameter a ranges between 0.66
477 and 0.83, and the parameter b between 0.10 and 0.19 (note that for $I = 0$ we have $\rho = b$). For $I = 1$, we have $\rho = a$

478 + b which varies between 0.80 and 0.84. Around a mean value of $I = 0.5$, all four configurations give $\rho = 0.51$ (See
 479 Supplementary Material, Sect.6).

480 For the configurations ii, iii and iv, we have $r^2 = 0.96 \pm 0.02$. In the following, we retain the intermediate
 481 set $\omega_r = 1/9$, $\omega_s = 1/9$ and $\omega_{LC} = 7/9$ (corresponding regression presented in Fig.9). Table 3 presents the values of
 482 I for donors and Fig. 10 gives the temporal evolution of I from 1930 until now for targets. Note that in 2017, the
 483 values of I are particularly high for the target catchments T_3 , T_6 and T_7 on the Mfoundi basin due to high
 484 urbanization. In contrast, some target catchments such as T_1 and T_4 are or not impacted nowadays by urbanization
 485 and presents very low values of I . Finally, the target catchments T_2 , T_3 , and T_8 are currently faced to the most
 486 important land-use change and have intermediate values of I .

487

488 5.4 Introducing I in the model structure

489 In the following, we choose a simple linear relationship between I and ρ (Eq. 14; Fig. 9) which leads that the
 490 value of β_I is constant and similar for all values of I .

491 We observe that the impact of land-use change (represented by I) on annual runoff (β_2) is higher than the
 492 impact of precipitation change (β_1), with $\beta_1 = 0.15$ (Fig. 7), $\beta_2 = 0.60$ (Fig. 9) and $\beta_1 \ll \beta_2$. We consider a
 493 reference precipitation $P_R = \frac{P_x + P_n}{2}$, and let ρ_D be the runoff coefficient calculated by the linear regression adjusted
 494 from donors under precipitation near of P_R (1625 mm). Then ρ is calculated as the sum of ρ_D and a factor G taking
 495 into account the impact of precipitation:

$$496 \rho = \rho_D + G, \quad (15)$$

497 with

$$498 G = \frac{\beta_1}{(P_x - P_n)} \left[P - \frac{P_x + P_n}{2} \right]. \quad (16)$$

499 For a given value of I (Fig. 9): for $P = P_n$, we have $G = -\beta_1/2$ and consequently $\rho = \rho_D - \frac{\beta_1}{2} = \rho_{n,P}$; for
 500 $P = P_x$, we have $G = \beta_1/2$ and consequently $\rho = \rho_D + \frac{\beta_1}{2} = \rho_{x,P}$.

501 Introducing Eq. (14) and (16) into Eq. (15), we obtain very simple second order polynomial relationship
 502 between R and P (Eq. 17 similar to Eq. 1) and a linear relationship between ρ and P (Eq. 18 similar to Eq. 2), and

$$503 R = AP^2 + BP, \quad (17)$$

$$504 \rho = AP + B, \quad (18)$$

$$505 \text{ with } A = \frac{\beta_1}{P_x - P_n} \quad \text{and} \quad B = aI + b - \frac{\beta_1(P_x + P_n)}{2(P_x - P_n)}. \quad (19)$$

506 In summary, the model needs the precipitation P as input and the three parameters a , b and β_I characterizing
 507 the relationship between ρ and I . These three parameters can be calibrated using data from donor catchments.

508 6 Applications

509 The model presented in Sect. 2 is function of precipitation P and the hydrological index I . Precipitation was
510 calculated on the target sub-catchments using historical precipitation dataset and the relationships established in
511 Sect. 4. The hydrological index I is defined in Sect. 5 and presented in Fig. 10 for target catchments for the period
512 1930 - 2030.

513 First a sensitivity analysis was conducted and the calibrated parameters a , b of the model are discussed (Sect.
514 6.1). Then two applications were conducted on the Mefou at Nsimalen subdivided into eight target sub-catchments
515 (Fig. 4.b) in order:

- 516 - to study the spatial hydrological functioning of the basin on eight target sub-catchments and calculate the
517 water balance during the short instrumentation period 2017-2018 (Sect. 6.2).
- 518 - to reconstruct the hydrograph at the Mefou at Nsimalen and on the eight sub-catchments for the historical
519 period 1930-2017 and to simulate the impact of future scenarios of land use and urbanization (Sect. 6.3).

520

521 6.1 Sensitivity analysis, calibration, validation and model comparison

522 Applications were conducted on the period 1930-2017, using precipitation data on P_1 and P_2 , to reconstruct
523 annual runoff for all eight target sub-catchments and the whole Mefou catchment at Nsimalen. Predictions for the
524 impact assessment of future land-use scenario on annual runoff were then also made. In the application, we
525 distinguish two cases, before and after the dam construction (1970). Before 1970, the catchment T_i (controlled
526 area of the dam location) is considered as other catchments (R depends of I and P). After 1970, the simulated R of
527 T_i corresponds to the proportion of precipitation discharged measured during the short-term instrumented period
528 ($\rho = 0.05$ to 0.15 ; see Table 1 for D_{II} and Sect. 3.4).

529 From data analysis in Sect. 4.3 (Fig. 7), we retain $\beta_i = 0.15$. We run a sensitivity analysis on the remaining
530 two parameters a and b (adjusted from the regression $\rho_D = aI + b$ with I calculated using Eq.13 with $\omega_r = 1/9$ and
531 $\omega_s = 1/9$, $\omega_{LC} = 7/9$) for different sets of donor catchments. We run the model for $n = 6, 8, 9$ and 10 donors (see
532 Table 1 and Sect. 3.3 and 3.4). In each run, we select randomly 30 sets of n donors, and in order to have a wide
533 range of variation of I , we add a constrain that for at least one point we have $I < 0.3$ and for at least one point we
534 have $I > 0.7$. The model output is given by Eq. 1 to 6 at the Mefou at Nsimalen, and the model is evaluated using
535 the three criteria $RMSE$ (Eq. 8) and r^2 (Eq. 9) and \bar{E} (Eq. 11) for the 29 observed years (see Sect. 3.3). For $n = 6,$
536 $8, 9$ or the 10 donors, we observe a low impact of the number of donors on the calibrated parameters (a and b) and
537 the three performance criteria with $a = 0.68 \pm 0.02$, $b = 0.12 \pm 0.01$, $RMSE = 101 \pm 1$ mm, $r^2 = 0.66$, and
538 $\bar{E} = 15\%$ (see Supplementary Material, Sect. 6). The low variability of the average of parameters a and b from
539 $n = 8$ lead us to select 8 donors by keeping the last two donors for validation.

540 In order to get a model adapted to various states of urbanization, the calibration and validation dataset at the
541 Mefou catchment scale should include periods of low and high urbanization rate. Observed annual runoff at the
542 Mefou at Nsimalen are used in alternate years for calibration (15 years) and validation (14 years). From the
543 sensitivity analysis, we calibrate a and b , choosing the set of 8 from 10 donors giving the lowest values of $RMSE$

544 on the 15 years calibrated period. We use the 9 donors D_{H2} , D_{H3} , D_{H4} , D_{H6} , D_{I2} , D_{I3} , D_{I4} , D_{I5} and D_{I6} . We obtain
545 $a = 0.74$; $b = 0.12$ with performance criteria $RMSE = 70$ mm, $r^2 = 0.79$ and $\bar{E} = 11$ %. Figure 9 presents the linear
546 regression for the calibrated parameters and Fig. 11 shows the abacus $\rho = g(P, I)$ for these parameters. In the
547 abacus, we plotted the donor catchments by specifying the corresponding estimation of I in parenthesis to compare
548 with the model. We also plotted the points of Etoa for the period 1967-1983 characterized by a stationarity value
549 of I (0.11) but with a wide range of P (1320 to 2150 mm).

550 The validation is made at two levels. First, the two remaining donor catchments D_{H3} and D_{I2} are used to
551 validate; we obtain $E_{D_{H3}} = +8$ % (+105 mm) and $E_{D_{I2}} = +12$ % (+110 mm). Second, at the Mefou at Nsimalen for
552 the remaining 14 years; we obtain $RMSE = 123$ mm, $r^2 = 0.60$, and $\bar{E} = 18$ %.

553 The semi-distributed model results were also compared to the stationary lumped annual runoff model *GRIA*
554 (Mouelhi, 2003) using the same calibration and validation procedure. *GRIA* is used to compare with a stationary
555 approach of the catchment characteristics. Results are shown on Fig. 12 with performance for *GRIA* significantly
556 lower with $RMSE = 126$ mm, $r^2 = 0.43$ and $\bar{E} = 19$ % for calibration and $RMSE = 128$ mm, $r^2 = 0.42$ and $\bar{E} = 22$ %
557 for validation over the both same periods at Mefou catchment scale. As the *GRIA* was calibrated using alternate
558 years on the whole period, we observe that *GRIA* slightly overestimate the runoff for the period 1963-1980 (with
559 low impact of urbanization), and underestimates runoff for the period 2011-2017 (with high impacts of
560 urbanization)

561

562 6.2 Annual water balance on the instrumented period 2017-2018

563 The rainfall-runoff data from the short-term instrumentation 2017-2018 enables to measure the contribution
564 of the catchments T_1 , T_2 , T_3 and T_6 of the Mefou catchment at Nsimalen. However, the target sub-catchments T_4 ,
565 T_5 , T_7 and T_8 were not gauged. Table 5 gives the values of P , R , AET , ρ and the contribution of each sub-catchment
566 K_i , corresponding to runoff volume of sub-catchment V_i divided by the volume at Nsimalen V_O (with $K_i = V_i / V_O$).
567 P ranges between 1580 and 1715 mm, R between 100 and 1325 mm, AET between 320 and 1260 mm, ρ between
568 0.21 and 0.76 and K between 2.5 to 18.5 %. We can classify the eight target catchments into four categories
569 according to land-use: i) controlled by the dam, T_1 ; ii) urbanized T_5 , T_6 and T_7 ; iii) peri-urban T_2 , T_3 and T_8 ; iv)
570 natural basins T_4 .

571 The first category concerns the sub-catchment T_1 controlled by the dam. The annual discharge R_1 measured
572 at the outlet of the dam is 100 mm +/-25 mm, corresponding to a contribution $K_1 = 2.5$ % on the total volume at
573 Nsimalen.

574 The second category corresponds to sub-catchments firstly faced to urbanization during the study period. We
575 have respectively $R_5 = 1230$ +/- 125 mm, $R_6 = 1130$ +/-125 mm and $R_7 = 1030$ +/- 200 mm. The contribution of
576 T_5 , T_6 and T_7 on the total volume at Nsimalen are respectively $K_5 = 18.0$ %, $K_6 = 10.0$ % and $K_7 = 11.0$ %. These
577 three catchments are characterized of by very low AET between 390 and 620 mm and very high ρ between 0.62
578 and 0.76.

579 The third category corresponds to peri-urban catchments. Runoff on T_2 (corresponding to D_{12}) is
580 characterized by $R_2 = 915 \pm 90$ mm (compared to 1030 mm simulated), $\rho_2 = 0.53$, $AET_2 = 800$ mm, and
581 corresponds to 15 % of V_0 . T_8 , presenting an intermediate land-use characteristics with low slope in the
582 downstream part, has $R_8 = 730 \pm 150$ mm, $\rho_8 = 0.46$, $AET_8 = 850$ mm, and $K_8 = 16$ %. The main differences
583 between T_2 and T_8 are the topography and the soil characteristics: T_2 is located in the upstream part of the Mefou
584 catchment and presents hilly landscape with steep slopes; T_8 is located in the east side presenting lowland with
585 important wetland area and overflow during wet seasons. These differences explain the lower values of R for T_8
586 in comparison with T_2 . These results are comforted by observed runoff coefficient for the second wet season in
587 2017: T_2 have an observed runoff coefficient of 0.53 compared to 0.40 for T_8 despite a similar urbanization rate
588 (40 % for T_8 and 46 % for T_2). In the same category, T_3 (D_{14}) presenting a most natural land-use (10 % of urbanized
589 area) than T_2 and T_8 , is characterized by $R_3 = 715 \pm 75$ mm (compared to 700 mm simulated), $\rho_3 = 0.43$,
590 $AET_3 = 905$ mm, and $K_3 = 18.5$ %.

591 For the fourth category, T_4 is not impacted by urbanization ($U < 1\%$). T_4 is located downstream with low
592 slope, with soil condition and topography favouring overflow, infiltration and evaporation. T_4 presents the lowest
593 $R_4 = 370 \pm 50$ mm, $\rho_4 = 0.24$, $AET_4 = 1290$ mm, and $K_4 = 9$ %.

594 For the Mefou at Nsimalen, we obtain by aggregation of the eight sub-catchments: $R_0 = 660 \pm 65$ mm
595 (compared to 645 mm measured at the outlet), $\rho_0 = 0.41$ and $AET_0 = 990$ mm. These values are very near from
596 observed data with annual runoff measured of 645 mm.

597 These results on the eight target sub-catchments are compared to other studies in the Nyong basin (see
598 Supplementary Material, Sect. 4) on natural basins (Maréchal et al., 2011; Olivry, 1979; Lefèvre, 1966) and on
599 one urbanized basin of the Nyong basin. These studies led to comparable results of ρ with $\rho = 0.24 \pm 0.06$ on
600 natural basins, and $\rho = 0.88$ on the urbanized of Odza (Ngoumdoum, 2013) on Nyong basin.

601

602 6.3 Reconstruction of historical runoff and prediction for scenarios of land-use

603 The past-period 1930-2017 simulated for targets and at Nsimalen are presented in Fig. 12. The grey envelope
604 curve represents the estimation of runoff uncertainties due to annual precipitation (± 10 %) and hydrological
605 index (± 15 %). Except for T_4 (downstream part of Mefou catchment) and T_7 (area controlled by the dam), all the
606 target sub-catchments present an increasing trend of runoff in earlier or later date. In a context of no annual
607 precipitation trends over the period 1930-2017, the urbanization development and forestry retreat for six of the
608 eight targets result in clear increasing of R . We notice that the impact on runoff is until now lesser for T_3 and T_8 .
609 In order to quantify impacts of land-use changes, we calculated mean values \bar{P} , \bar{R} and $\bar{\rho}$, 5th percentile Q_5 and
610 95th percentile Q_{95} for one past period (1950-1980) and one recent period (1987-2017) (see Table 6). The mean
611 precipitation over the first period is about 75 mm higher (+ 5%) than for the second period with a similar standard
612 deviation (200 mm). Excluding T_7 , controlled by the dam, we obtained on the period 1950-1980 \bar{R} between 315
613 and 764 mm, $\bar{\rho}$ between 0.20 and 0.47, Q_5 between 200 and 503 mm and Q_{95} between 502 and 1108 mm. On the

614 period 1987-2017, \bar{R} varies between 297 and 1104 mm, $\bar{\rho}$ between 0.19 to 0.70, Q_5 between 150 and 690 mm and
615 Q_{95} between 508 and 1627 mm.

616 For the second category (T_5 , T_6 , T_7), an increasing trend of R is observed very early among the whole period
617 for T_5 and T_6 which are nowadays the most urbanized target of the Mefou catchment following by T_7 . Between the
618 two periods (1950-1980) and (1987-2017), \bar{R} increases from 45 % for T_5 to 79 % for T_6 , $\bar{\rho}$ increases between 50 %
619 for T_5 to 85 % for T_6 . Q_5 increases of 37 % for T_5 to 74 % for T_7 and Q_{95} increases of 47 % for T_5 to 82 % for T_6 .

620 For the third category (T_2 , T_3 , and T_8), classified as peri-urban catchments, sub-catchments are characterized
621 by an increasing R more delayed compared to catchments of the first category. Current changes are deeply
622 modifying these catchments for the last decade and the urbanization processes will be certainly higher than on
623 other sub-catchments in the near-future due to the current extension of the urban area. Between the two periods, \bar{R}
624 increases of 25 % for T_3 to 62 % for T_8 . Q_5 increases of 30 % for T_2 and T_8 but decreases from of 26 % for T_3
625 whereas the Q_{95} increases for the three catchments, from 48 % for T_3 to 69 % for T_8 . Land-use changes were
626 significant only since 2000 for T_3 , and impact on R is moderate compared to the two other catchments.

627 For the fourth category (T_4), T_4 was not impacted by urbanisation, $\bar{\rho}$ is unchanged (0.20) and differences of
628 \bar{R} are only driven by \bar{P} difference of -5% (from 1625 mm to 1550 mm) and impact mainly low flows (-26 % for
629 Q_5). No major changes were observed in this area until nowadays, but in development projects and urban area
630 extension will certainly impact T_4 in near-future.

631 At the Mefou scale and for the same two periods, we observe an increase of \bar{R} of 27% (from 409 to 518 mm),
632 an increase of $\bar{\rho}$ of 31 % (from 0.25 to 0.33), an increase of Q_{95} of 29% (from 650 to 840 mm) and nearly no
633 changes for Q_5 (from 280 mm to 273 mm). The impact of land-use changes is clear on annual runoff but driest
634 years are much less impacted than wettest years.

635 In order to quantify only the impact of land-use changes on annual runoff, we applied a constant precipitation
636 of 1580 mm (mean precipitation over the period) for the period 1930-2017 (Fig. 13). Until 1980, the impact of
637 land-use changes seems quite limited, with an increase of 110 mm of R (+ 30%). However, between 1980 and
638 2017, the increase of R and ρ under the same precipitation condition seems quite relevant with an increase of 53%
639 (from 455 to 700 mm and from 0.29 to 0.44). These hydrological changes are associated with a huge increasing of
640 urban areas from 38 km² over the whole catchment to 130 km² over the same period.

641 Finally, the model was applied to simulate the impact of scenarios of land-use changes corresponding to
642 predictions of I for 2030 (Fig. 10). Results show for $P = 1580$ mm, $R = 840 \pm 150$ mm, $\rho = 0.53 \pm 0.06$ (Fig. 13).
643 We observe an increase of R and ρ of 85 % (from 455 to 840 mm and from 0.29 to 0.53) between 1980 and 2030.
644 Even if this scenario is fictive, it is quite reliable due to the dynamic of land-use changes observed these few
645 decades and knowing the most recent projection of population of Yaoundé.

646 In tropical context, few studies evaluated the impact of land-use conversion from natural to urbanized area.
647 Most of the studies quantified the impact of conversion from forest or shrub cover into cropland
648 (Gessess et al., 2015; Yira et al., 2016) or forest regeneration (Beck et al., 2013).

649 More studies of annual runoff urbanization impacts have been lead in temperate or Mediterranean climate
650 (see Supplementary Material, Sect. 7), Braud et al. (2013) observed a significate increases of quick-flow and
651 decrease of inter-flow and base-flow in urbanization context on the Yzeron catchment (150 km²). Through
652 modelling, Beighley et al. (2003) estimated for Atascadera Creek ($P = 610$ mm) an increase of R of more than
653 80 mm (+115 %) for 8 % to 38 % of urban area and an increases of R of 150 mm (+215 %) from 8 % to 52 % of
654 urban area.

655

656

657 7 Conclusion

658 Urbanization impacts drastically the water cycle, and this phenomenon will intensify in the future for most
659 tropical regions due to huge population growth and rural exodus. These impacts are complex and not yet quantified
660 especially in tropical area presenting sparse hydrological data. This work is part of the theme *Panta Rhei* of the
661 *IAHS*, and aims to study the impact of land-use change, especially due to urbanization, on annual runoff on the
662 tropical mesoscale catchment of the Mefou, Yaoundé, Cameroon.

663 The methodology combines the processing of historical sparse hydrological data and a dedicated short-term
664 instrumentation (2017-2018) in order to get heterogeneous set of catchments in terms of land-use. Data analysis
665 shows that there is no significant trend on annual precipitation for the last 90 years. However, the analysis of
666 historical precipitation/runoff data on different catchments with different land-uses show an increase of the annual
667 runoff coefficient due to urbanization from 22 % on natural basins to 77 % on urbanized basins.

668 A simple semi-distributed annual runoff model was developed taking into account non-stationarity due to
669 land-use changes. The model is based on a similar approach as proposed by Ponce and Shetty (1995) and uses a
670 hydrological index I characterizing soil, topography and land-use. From data analysis on donor catchments,
671 empirical rules were established to calculate I , and the model parameters. The model can be represented by simple
672 abacus giving relationships between the annual precipitation P , the annual runoff R and the hydrological index I .
673 The non-stationarity of the model is characterized by the hydrological index I which is time variable depending
674 on land-use evolution.

675 Applications were first done on target sub-catchments of the Mefou basin in order to calculate the annual
676 water balance for catchments with different land-uses. Results show that that the Mfoundi catchment, integrating
677 the three more urbanized sub-catchments, contributes near to 40 % of the Mefou catchment at Nsimalen despite
678 covering only 23 % of the basin. On the opposite, the natural sub-catchment T_4 , not yet impacted by urbanization,
679 contributes to only 9 % but covers 18 % of the Mefou catchment. The second result is the reconstruction of
680 historical annual runoff from 1930-2017 for the Mefou catchment at Nsimalen with satisfying performance in a
681 poorly-gauged context ($RMSE = 99$ mm; $r^2 = 0.68$; $\bar{E} = 14.5$ %) compared to the commonly used stationary annual
682 model (GR1A). The mean values of P , R , ρ , Q_5 and Q_{95} over the two periods of 30 years before and during the
683 urbanized processes show changes at both the sub-catchment scale and the whole Mefou scale: for a decrease of
684 about 50 % of the forest area and an increase from 8 % to 35 % of the urban area between 1980 and nowadays, we
685 observe an increase of 53 % of R (and ρ) for the Mefou catchment at Nsimalen. The Future scenario of land-use

686 proposed leads to an increase of R and ρ of 85 % between 1980 and 2030. The observed and simulated values for
687 heterogeneous land-use characteristics are in line with other studies which observed an increasing of annual runoff
688 for catchment faced to urbanization (Braud et al., 2013; White and Greer, 2006; Barron et al., 2003).

689 The coupled experimental-modelling approach proposed herein opens promising perspectives regarding the
690 evaluation of annual runoff in catchments under changes. Nowadays, development of low cost monitoring sensors
691 and crowdsourced sciences open opportunities to get more easily data to calibrate and validate models. In changing
692 context, the development of coupled non-stationary modelling and dedicated instrumentation can be useful to
693 improve the capability of stakeholders to make predictions of the hydrological dynamics of tropical peri-urban
694 catchments.

761 **Figure 7.** Relationship between the annual runoff coefficient ρ and the annual precipitation P on three stations
762 (Nsimalen, Mfoundi and Etoa; see the location on Fig. 3.a) for periods before 1985 with low impact of
763 urbanization.

764

765
 766
 767
 768

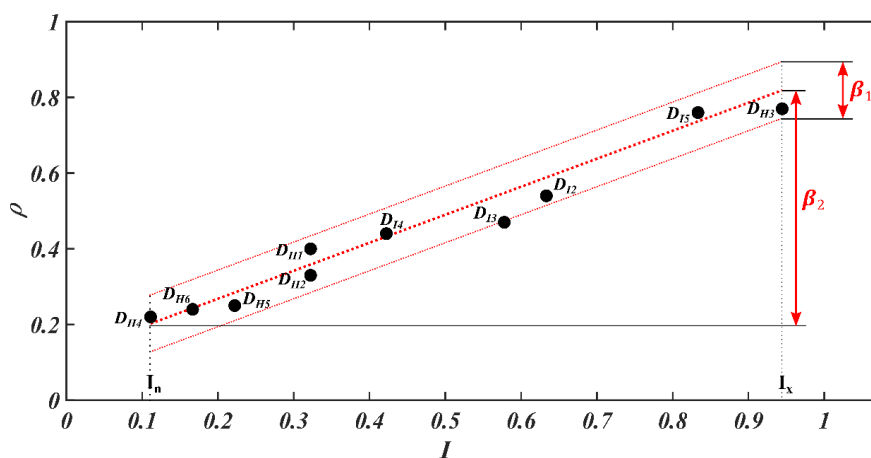

769

770 **Figure 8.** Evolution of the component C_{LC} (see Section 5.1) of the hydrological index I over the target catchments
 771 for 1930, 1950, 1980, 2000, 2017 and scenario for 2030 (see references of land-use sources in Table 2).

772

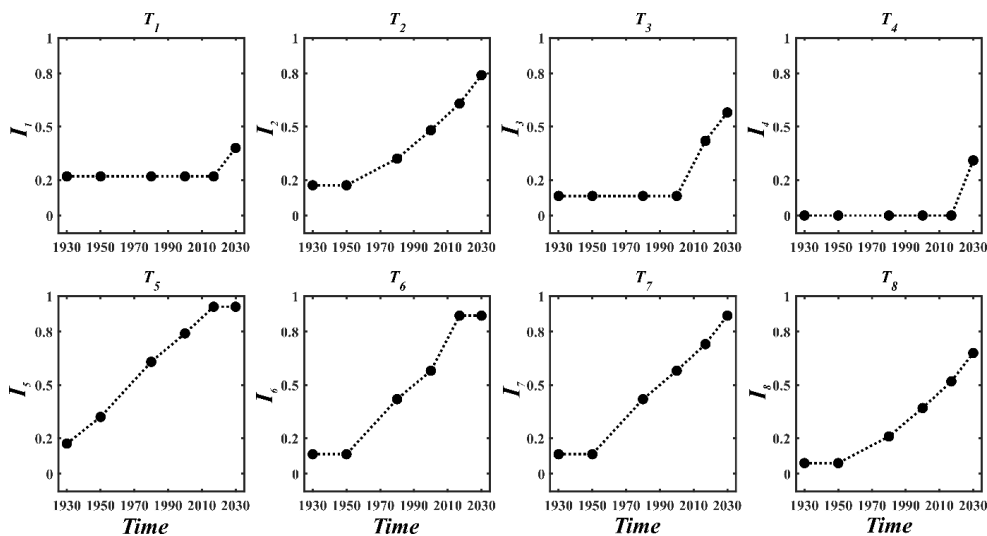

773

774

775 **Figure 9.** Linear relationship between the hydrological index I and the annual runoff coefficient ρ based on donor
 776 catchments (Table 1). The term β_1 represents the variation of ρ for a given value of I and for a large range of
 777 precipitation P with $P_n < P < P_x$. The term β_2 represents the variation of ρ for a given value of P and for a large
 778 range of I with $I_n < I < I_x$.

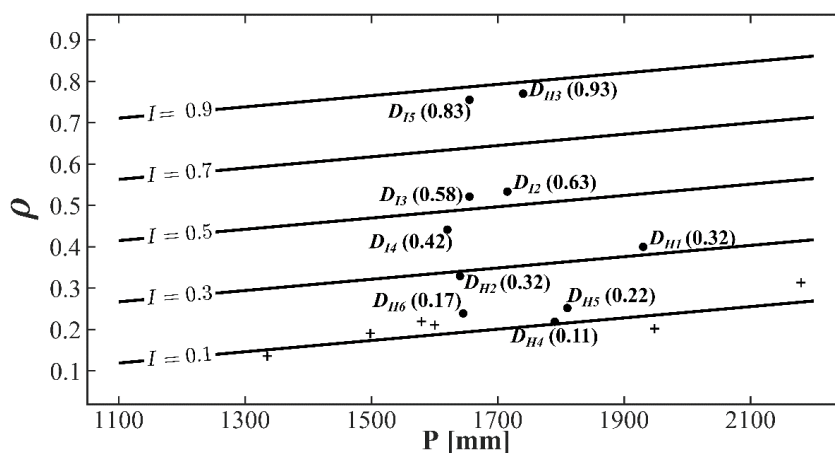

779

780
781

782 **Figure 10.** Evolution of the hydrological index I over time for target catchments for the period 1930 - 2030. The
783 points correspond to the dates where references of land-use sources are available (Table 2 and Fig. 8).

784
785

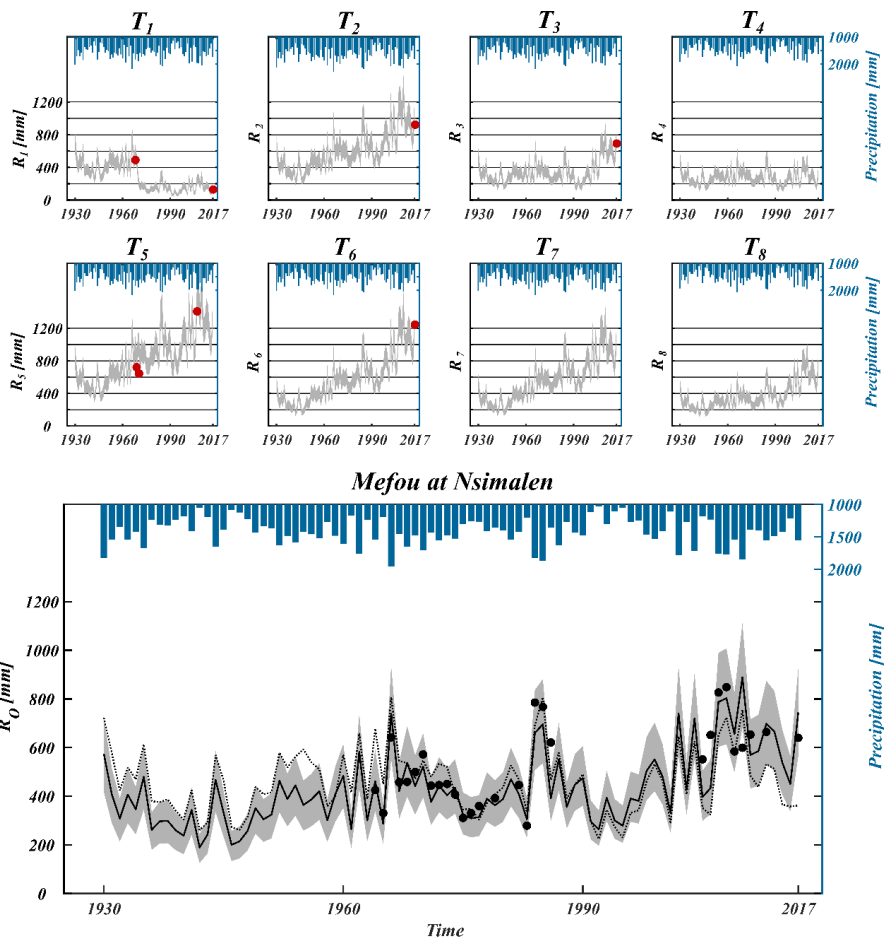

786

787 **Figure 11.** Abacus obtained from the model calibrated parameters for the relationship between annual runoff
 788 coefficient ρ and the annual precipitation P for different values of the hydrological index I . Each point corresponds
 789 to donor catchment; the value of the calculated hydrological index I (Table 3) is indicated into brackets. Crosses
 790 (+) correspond to available information at Etoa station between 1967 and 1983 for an unchanged hydrological
 791 index I estimated to 0.11.

792

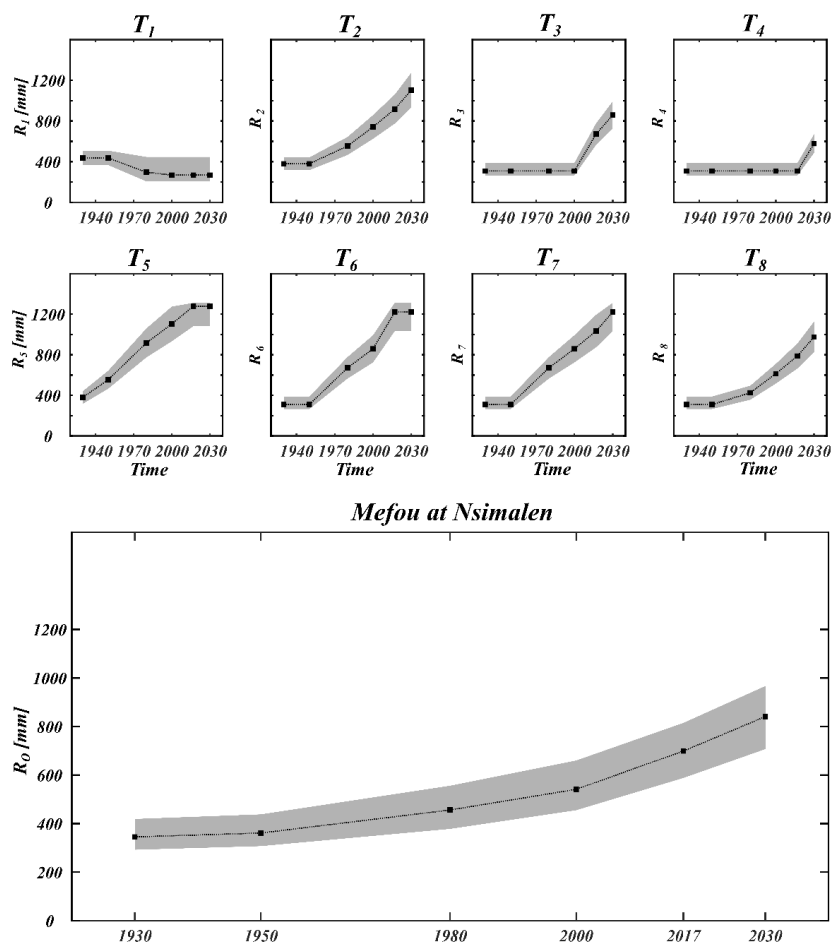

793

794

795 **Figure 12.** Annual runoff simulated on the 8 target catchments (T_1 to T_8) and on the Mefou catchment at Nsimalen
 796 for the period 1930-2017 (dark line with grey uncertainty range due to precipitation $\pm 10\%$ and hydrological
 797 index $I \pm 15\%$ estimation). The black points indicate the observed values on Nsimalen. The simulation with
 798 *GRIA* is presented with a dashed line.

799

800

801 **Figure 13.** Simulated annual runoff for the target catchments (T_1 to T_8) and on the Mefou catchment at Nsimalen
 802 for a reference precipitation $P_R = (P_n + P_s) / 2$ over the period 1930 – 2030 (dark line with grey uncertainty range
 803 due to the hydrological index $I \pm 15\%$ estimation).

804

806 **Table 1.** Characteristics of the donor catchments: name, reference, hydrometric station name, area, period of observation, annual precipitation P , annual runoff R , annual
 807 evapotranspiration $AET = P - R$, annual runoff coefficient ρ , the slope index S_i , the proportion of hydromorphic soil HS , and the proportion of urban areas U .

828 **Appendix A**

829

830 **List of Notations**

831	A	:	Parameter of the equation: $\rho = AP + B$ [-]
832	A_i	:	Area of target sub-catchment i [L ²]
833	A_o	:	Area of the whole catchment [L ²]
834	a	:	Parameter of the model in $\rho_D = aI + b$ [-]
835	AET	:	Annual evapotranspiration [L]
836	B	:	Parameter of the equation: $\rho = AP + B$ [-]
837	b	:	Second parameter of the model in $\rho_D = aI + b$ [-]
838	C_i	:	Component i of the hydrological index [-]
839	C_{LC}	:	Land-use component of the hydrological index I [-]
840	C_S	:	Soil component of the hydrological index I [-]
841	C_T	:	Topographic component of the hydrological index I [-]
842	CN	:	Curve Number in SCS method
843	D	:	Donor catchments [-]
844	D_{Hi}	:	Donor catchment i from dedicated short-term instrumentation [-]
845	D_{Hi}	:	Donor catchment i from historical database [-]
846	E	:	Normalized Error (Eq. 10) [-]
847	\bar{E}	:	Mean Absolute Normalized Error (Eq. 11) [-]
848	G	:	Term defined in Eq 16 [-]
849	HS	:	Proportion of hydromorphic soil [-]
850	I	:	Hydrological index [-]
851	I_n	:	Maximum value of I [-]
852	I_x	:	Minimum value of I [-]
853	K_i	:	Contribution of sub-catchment i to the whole catchment ($K_i = V_i / V_o$) [-]

854	P	:	Annual precipitation [L]
855	P_m	:	Mean annual precipitation over the historical database [L]
856	P_n	:	Minimal annual precipitation over the historical database [L]
857	P_R	:	Reference annual precipitation corresponding to $P_R = \frac{P_x + P_n}{2}$ [L]
858	P_{Ti}	:	Annual precipitation of target catchment i (Eq. 12) [L]
859	P_x	:	Maximal annual precipitation over the historical database [L]
860	\bar{P}	:	Mean annual precipitation for a period of 30 years (1950-1980 and 1987-2017)
861	P_1	:	Annual precipitation at historical raingauge P_1 [L]
862	P_2	:	Annual precipitation at historical raingauge P_2 [L]
863	PET	:	Potential evapotranspiration [L]
864	Q_5	:	Annual runoff corresponding to the 5 th -percentile over a period of 30 years [L]
865	Q_{95}	:	Annual runoff corresponding to the 95 th -percentile over a period of 30 years [L]
866	R	:	Annual Runoff [L]
867	R_i	:	Annual Runoff of target sub-catchment i [L]
868	R_O	:	Annual Runoff of the whole catchment [L]
869	\bar{R}	:	Mean annual simulated runoff for a period of 30 years (1950-1980 and 1987-2017)
870	r^2	:	Coefficient of determination (Eq. 9)
871	$RMSE$:	Roots Mean Square Error [L]
872	S_i	:	Slope index [%]
873	T_i	:	Target sub-catchment i [-]
874	U	:	Proportion of urbanized area [%]
875	V_i	:	Annual volume at sub-catchment i [L ³]
876	V_O	:	Annual volume at the whole catchment [L ³]
877			
878	β_1	:	Parameter of the model ($\beta_1 = \rho_{x,I} - \rho_{n,I}$) [-]
879	β_2	:	Constant characteristic ($\beta_2 = \rho_{x,P} - \rho_{n,P}$)
880	ρ	:	Annual runoff coefficient [-]

881	$\bar{\rho}$:	Mean simulated annual runoff coefficient for a period of 30 years (1950-1980 and
882			1987-2017) [-]
883	ρ_D	:	Simulated annual runoff coefficient from donors regression: $\rho_D = aI + b$ [-]
884	$\rho_{n,I}$:	ρ for P_n and I [-]
885	$\rho_{n,P}$:	ρ for I_n and P [-]
886	$\rho_{x,I}$:	ρ for P_x and I [-]
887	$\rho_{x,P}$:	ρ for I_x and P [-]
888	ω_i	:	Weight attributed to the component i of the hydrological index in Eq. 7 [-]
889	ω_{LC}	:	Weight attributed to the land-use component of the hydrological index [-]
890	ω_S	:	Weight attributed to the soil component of the hydrological index [-]
891	ω_T	:	Weight attributed to the topographic component of the hydrological index [-]
