1 **Abstract**

2 Calcium carbonate (CaCO_3) precipitation in tunnel drainage system poses serious problems to
3 railway tracks. In this study, the calcification phenomenon identified in Meyssiez tunnel was
4 analyzed through laboratory testing and site water monitoring. In particular, the surrounding soils
5 were investigated in the laboratory. Site water table was regularly monitored in the field and site
6 water was taken for laboratory analyses in terms of pH and electrical conductivity (EC). Examination
7 of the test results showed that the calcification phenomenon was mainly induced by the calcium
8 carbonate dissolution in the fine fractions ($d < 0.08\text{mm}$) of surrounding soils. Due to this dissolution,
9 the void ratio of fine fractions (e_f) and the hydraulic conductivity (k) of soils both increased.
10 Meanwhile, calcium carbonate dissolution increased the pH values and electrical conductivity (EC)
11 of groundwater. However, any recharge of water table by rainfalls decreased both pH and EC.
12 Further analysis showed that a calcium carbonate dissolution degree can be defined in terms of pH
13 and/or electrical conductivity (EC) values. The lower the pH values or the higher the EC, the higher
14 the calcium carbonate dissolution in surrounding soils.

15
16 **Key words:** tunnel drainage; calcium carbonate dissolution; fines fraction; pH values; electrical
17 conductivity

1 **1. Introduction**

2 Railway has been one of the most important transportation means over the world. In France, more
3 than 34000 km of rail lines have been constructed, including 6% of high-speed lines [1-2].
4 Nowadays, there are 1548 tunnels with a total length of 631 kilometers in the French railway
5 network [3]. However, most of these tunnels have been affected by the calcification phenomenon
6 [4-5]. This problem has been also involved in other countries, for instance, Switzerland [6], Austria
7 [7], Korea [8] and China [9]. The calcium carbonate (CaCO_3) precipitation can cause clogging of
8 tunnel drainage system, heavily increasing the cost of maintenance [2,7]. Therefore, better
9 understanding the calcification phenomenon in tunnel drainage system is of paramount importance in
10 railway maintenance.

11 Through investigations on some specific cases, Dietzel *et al.* (2008) [7] and Jung *et al.* (2013)
12 [8] reported that this calcification phenomenon was induced by the degradation of concrete lining
13 and shotcrete. Recently, Chen *et al.* (2019) [5] studied problematic tunnels with calcification in some
14 countries (including France, Austria, Korea and China) and proposed that this phenomenon is mainly
15 induced by the dissolution of calcium carbonate (CaCO_3) in the surrounding soils. Basically, when
16 rain water infiltrates into underground through the fissures of surrounding soils, the H^+ and HCO_3^- in
17 the water react with the calcium carbonate (CaCO_3) in the soils, leading to the generation of calcium
18 bicarbonate (Ca^{2+} and HCO_3^-) [2,5,7,10], as shown in equation (1). As a result, the pH value and the
19 electrical conductivity (EC) of groundwater increase. Meanwhile, progressive dissolution of calcium
20 carbonate creates additional fissures, increasing the void ratio (e) and hydraulic conductivity (k) of
21 surrounding soils.

1 Thereafter, the groundwater carrying Ca^{2+} and HCO_3^- flows through the soils, finally reaching
2 the drainage gutters through the drain holes. As the external environment (air pressure in the tunnel
3 and the temperature of drainage solutions) changes, reaction (1) would happen in the inversed
4 direction, from right to left, causing calcium carbonate precipitation in tunnel drainage gutters
5 [2,5,7].

6 It should be noted that the viewpoint of Chen *et al.* (2019) [5] was made based on a statistical
7 analysis and needed to be verified by test results on both soil and water. This paper reports a detailed
8 case study of Meyssiez Tunnel in France. After identification of the calcification in this tunnel, core
9 samples of the surrounding soils were taken from the site for laboratory characterization. Field water
10 table was also regularly monitored and site water was taken for laboratory analyses in terms of pH
11 and electrical conductivity. The test results allowed the calcium carbonate (CaCO_3) dissolution in the
12 surrounding soils to be identified as the main mechanism involved in the calcium carbonate
13 precipitation in the tunnel drainage system.

14 **2. Calcium carbonate precipitation in Meyssiez tunnel**

15 Meyssiez tunnel is located near Meyssiez village, approximately 50 km south of Lyon, France. It was
16 constructed in the period from 1990 to 1993 in the sedimentary limestone area and has a total length
17 of 1878 m. The geology environment is shown in **Fig. 1**, indicating that the surrounding soils are
18 mainly Mill-stone, Mill-sand and Mill-sandstone. Note that these soils all have a high content of
19 limestone (up to 60%). The top layer involves a normal surface soil without limestone and its
20 thickness changes with the locations: 12.7 m at the hillcrest and 5 m at the southern hill toe. **Fig. 2**
21 shows the tunnel structure with concrete linings and shotcrete of 55 cm and 25 cm, respectively. Note
22 that in order to decrease the water pressure applied on the structure, a number of drainage holes and

1 two lateral gutters were set up.

2 Meyssez tunnel has been exploited for twenty-five years. Its drainage system has been seriously
3 affected by calcium carbonate precipitation [4-5], as shown in **Fig. 3**. Dietzel *et al.* (2008) [7] and
4 Jung *et al.* (2013) [8] concluded that this problem was induced by the degradation of shotcrete and
5 concrete lining. Indeed, Laver *et al.* (2013) [11] conducted a series of tests on shotcrete samples
6 extracted from London tunnel. Results revealed a greater permeability and an altered shotcrete
7 composition in the older shotcrete samples (1902-1926s). However, this was not the case for the new
8 shotcrete (1970s) [11]. Considering the construction date for Meyssez tunnel (1990s-1993s), it is
9 normal to ignore any degradation of the shotcrete of this tunnel. On the other side, the calcium
10 carbonate precipitation in Meyssez tunnel has been occurring since several years, without any
11 noticeable change of the concrete lining state (leaking and cracking) based on the field investigations
12 on this tunnel. Therefore, it can be concluded that the calcification phenomenon observed is not
13 closely related to the shotcrete and concrete lining in Meyssez tunnel. The responsible is most likely
14 the surrounding soils.

15 **3. Laboratory characterization of the surrounding soils and pore-water**

16 **3.1 Materials**

17 The natural soil core with dimensions of 10 cm in diameter and 20 m in height was taken at
18 01/08/2017 by drilling at a location 50 m far from the south exit of Meyssez tunnel. Thereafter, the
19 soil core was sealed in plastic tubes with ends closed to avoid water loss by evaporation. After
20 sampling, the borehole was kept as a piezometer for the monitoring of site water table and a source
21 for groundwater sampling. The field monitoring of water table was undertaken every two weeks from
22 31/08/2017 to 07/06/2018, together with the groundwater sampling after each monitoring. Note that

1 when it was possible, the rainwater was also collected for the purpose of comparison. For both
2 rainwater and groundwater, the pH and electrical conductivity (EC) were measured in the laboratory
3 following American standard [12-13].

4 The basic parameters of soils at different depths are shown in **Fig. 4**. The natural water content
5 (w_n) was determined by oven-drying. The liquid limit (LL) and plastic limit (PL) were measured
6 using Casagrande method and rolling method, respectively [14]. The specific gravity (G_s) was
7 determined following ASTM standard [15]. The sand content (w_s ; $d \geq 0.08$ mm) and the fine fractions
8 ($d < 0.08$ mm) were obtained by wet sieving [16]. The Calcium carbonate (CaCO_3) contents in
9 surrounding soils (w_{caT}) and that in the fine fractions (w_{caf}) were measured following AFNOR
10 standard [17].

11 **Fig. 4** shows that the values of natural water content (w_n), liquid limit (LL), plastic limit (PL),
12 natural density (ρ_n), specific gravity of soils (G_{sT}), specific gravity of fine fraction (G_{sf}) and sand
13 content (w_s), equal to 7.8% to 24.6%, 34.9% to 72.8%, 16.9% to 28.8%, 1.55 Mg/m³ to 2.09 Mg/m³,
14 2.71 to 2.79, 2.73 to 2.80 and 8.16% to 75.6%, respectively. **Fig. 4** also reveals that in the soils at
15 depths of 6.0 m, 7.3 m, 12.7 m and 15.4 m, the sand contents (w_s) exceed 60%, categorizing these
16 soils into sandy soils. Therefore, their liquid limit (LL) and plastic limit (PL) could not be
17 determined.

18 In addition, **Fig. 4** shows that w_{caT} and w_{caf} are equal to zero when the depth is less than 5 m,
19 indicating that calcium carbonate does not exist in this zone. However, calcium carbonate is widely
20 distributed beyond 5 m depth, in agreement with the geology environment shown in **Fig. 1**. **Fig. 4**
21 also presents the change of R_{caT} and R_{caf} with the depth. The definitions of R_{caT} and R_{caf} are shown
22 below:

$$R_{caT} = \frac{m_{caT}}{m_{sT}} * 100\% \quad (2)$$

$$R_{caf} = \frac{m_{caf}}{m_{sT}} * 100\% \quad (3)$$

where m_{caT} and m_{caf} refer to the mass of calcium carbonate (CaCO_3) in the total soils and fine fractions, respectively; m_{sT} is the total soil mass. It can be observed from **Fig. 4** that R_{caT} is close to R_{caf} , suggesting that the calcium carbonate is mostly distributed in the fine fractions of surrounding soils.

According to *LL* and *PI*, the classification of soils is obtained and shown in **Fig. 5**. Meanwhile, through the visual observation of soil color, the soil layer distribution at this site (from 0-20 m) was determined and is shown in **Fig. 4**. It reveals that the normal surface soils (0-5 m) are mainly gravel, high-plasticity clay (M-CH) and low-plasticity clay (M-CL). For the soil layers below 5 m, they mainly consisted of Millsand, Millclays.

3.2 Void ratio and hydraulic conductivity

To measure the void ratio (e) and hydraulic conductivity (k) of natural soils at different depths, a steel sampler with dimensions of 18 mm in height and 70 mm in diameter was used for the preparation of specimens. Thereafter, these soil specimens in the steel sampler were carefully introduced into an oedometer cell. Note that the inner wall of the cell was lubricated in advance with grease to avoid water infiltration between soil samples and the cell. Prior to hydraulic conductivity measurement, the in-situ effective stress σ_v' calculated by equation (4) was applied on the soil specimens with recording of the vertical displacement, as shown in **Fig. 6**.

$$\sigma_v' = \sum_{i=1}^n \gamma_i' h_i \quad (4)$$

In equation (4), σ_v' is the effective in-situ stress, (kPa); n stands for the number of soil layers; h

1 refers to the depth of soil (m). When h is less than 7.50 m (corresponding to the groundwater level at
 2 sampling time of 01/08/2017), the γ_i' was taken equal to the bulk unit weight γ_i (kN/m³). If h exceeds
 3 7.50 m, the γ_i' is the buoyant unit weight (kN/m³).

4 Note that in the loading process, the equilibrium state was regarded as reached when the vertical
 5 displacement rate was lower than 0.01 mm every 8 h [18-20]. After loading, a constant water
 6 pressure of 20 kPa was applied from the lower base of cell for the sample saturation. The vertical
 7 displacement was monitored in this process (shown in **Fig. 6**). When the deformation stabilized, the
 8 hydraulic conductivity (k) was measured using the constant water head method [21]. Based on the
 9 experimental data, the final void ratio (e) and hydraulic conductivity (k) were calculated by:

$$10 \quad e_0 = \frac{G_{sT}(1+w_n)\rho_w}{\rho_n} - 1 \quad (5)$$

$$11 \quad e = e_0 - \frac{\Delta h}{H_0}(1+e_0) \quad (6)$$

$$12 \quad k = \frac{QH_f}{AH_w t} \quad (7)$$

13 where e_0 and e refer to the initial and final void ratios of soil specimens; G_{sT} is the specific gravity of
 14 soils; w_n stands for natural water content, (%); ρ_w and ρ_n are the unit masses of water and natural soil,
 15 respectively, (Mg/m³). Δh is the total displacement of samples in the loading and saturation process,
 16 (m); H_0 and H_f are the initial and final heights of samples respectively, (m). Q is water volume
 17 injected, (m³); A refers to the of samples' section, (m²); H_w stands for the water head applied, (m); t is
 18 the elapsed time, (s).

19 **3.3 Void ratio**

20 Normally, with the calcium carbonate dissolution, the total void ratio e of soils increases. To
 21 investigate this point, the relationship between total void ratio (e) and calcium carbonate content

(w_{caT}) in total soils is established and shown in **Fig. 7 (a)**. As the soils located above 5 m do not contain any calcium carbonate (shown in **Fig. 4**), the data of these soils is excluded in further analysis.

Fig. 7 (a) reveals that the total void ratio e increases gradually with the decrease of w_{caT} due to the calcium carbonate dissolution. It is worth noting that due to the data scatter the fitting line shown in **Fig. 7 (a)** has a low regression coefficient R^2 (equal to 0.35). Considering that the calcium carbonate mostly exist in the fine fractions ($d < 0.08\text{mm}$; shown in **Fig. 4**), the calcium carbonate dissolution must mainly affect the change of void ratio of fine fractions (e_f). To determine e_f , a four-phase model [22-28] shown in **Fig. 8** is adopted, where the void ratio of fine fractions (e_f) is defined as the ratio of void volume (V_v) to the fine fraction volume (V_f), calculated by the following equations:

$$\rho_{df} = \frac{(w_f / 100) \rho G_{ss} \rho_w}{G_{ss} \rho_w (1 + w / 100) - \rho (1 - w_f / 100)} \quad (8)$$

$$e_f = \frac{G_{sf} \rho_w}{\rho_{df}} - 1 \quad (9)$$

where ρ_{df} is the dry unit mass of fine fractions, (Mg/m^3); w_f stands for the fine fraction (in dry mass, %); ρ is the unit mass of soil samples after saturation, (Mg/m^3); ρ_w denotes the unit mass of water, (Mg/m^3); w is the water content of samples after saturation, (%); G_{sf} is the specific gravity of fine fractions; G_{ss} refers to the specific gravity of sand, which is calculated by the weighted average method. Note that in case of pure fine soils, the fine fraction (w_f) is equal to 100; the ρ_{df} and e_f shown in Eq. (1) and Eq. (2) become total dry density ρ_d and total void ratio e of pure fine soils, respectively. If the fine fraction (w_f) is equal to 0, the soil is pure sand and the ρ_{df} and e_f are equal to 0.

Fig. 7 (b) shows the change of e_f with the calcium carbonate content in the fine fraction w_{caf} . It is observed that there is a satisfactory correlation between e_f and w_{caf} , and the regression coefficient (R^2) is as high as 0.81. **Fig. 7 (b)** also reveals that e_f increases progressively with the decrease of w_{caf} ,

1 indicating the effect of calcium carbonate dissolution in the fine fractions.

2 **3.4 Hydraulic conductivity**

3 **Fig. 9 (a)** shows the change of hydraulic conductivity k with calcium carbonate content w_{caT} in the
4 semi-logarithm plane. It is observed that the hydraulic conductivity k increases with the decrease of
5 w_{caT} . This is consistent with the increase of total void ratio e by the calcium carbonate dissolution. It
6 is worth noting that due to the data scatter the regression coefficient R^2 of fitting line is as low as
7 0.54.

8 Indeed, the calcium carbonate (CaCO_3) mostly exists in the fine fractions of surrounding soils,
9 and the calcium carbonate dissolution mainly increases the void ratio of fine fractions (e_f) (shown in
10 **Fig. 7 b**), which finally leads to the increase of hydraulic conductivity k . This can be obviously
11 proven from **Fig. 9 (b)**. Note that the fitting line shown in **Fig. 9 (b)** has a regression coefficient R^2 as
12 high as 0.88, suggesting that calcium carbonate dissolution mainly occurred in the fine fractions.

13 **3.5 Water pH value**

14 **Fig. 10** shows the changes of pH values ($\text{pH}=-\log\text{H}^+$) and water level with the sampling date. It is
15 observed that the measured pH values of groundwater range from 6.6 to 7.6, which is higher than
16 that of rainwater (5.6), suggesting that calcium carbonate dissolution occurred in soil pore water,
17 because in this process the H^+ in water is consumed and the pH value increases accordingly (see Eq.
18 1). This is confirmed by the comparison between the change of pH and the change of water table
19 (**Fig. 10**). Indeed, in general the pH values of groundwater decrease over the sampling time, but this
20 change is not totally compatible with the change of groundwater level: with rainfalls that recharge
21 the groundwater, the concentration of H^+ in the groundwater increases because of the higher H^+
22 concentration ($1 \times 10^{-5.6}$) and lower pH value (5.6) of the rainwater, leading to the decrease of pH

1 values. However, punctually, increase of pH occurred with the increase of groundwater level. This
2 suggests that the pH values are not only affected by the increase of H^+ concentration through the
3 recharge of groundwater, but also by the calcium carbonate dissolution.

4 To further investigate the change of pH values, a characteristic pH values (pH_c) is defined that
5 excludes the calcium carbonate dissolution, using the model shown in **Fig. 11**. It is worth noting that
6 in the calculation process, the H^+ concentration ($pH=-\log H^+$) and water volume
7 ($V_w = \pi \times r^2 \times (20 - 7.53)$) at point A (shown in **Fig. 10**) are considered. When the groundwater level
8 increases from D to E, the added H^+ and rainwater volume can be determined, and then the
9 characteristic pH value (pH_c) at point B can be calculated by superposition. When the groundwater
10 level decreases from E to F or remains unchanged, the pH_c values at point C is kept the same as that
11 at point B, although the water volume at the borehole decreases. Adopting the above method, the pH_c
12 values were calculated for the whole monitoring period. Note that the calcium carbonate content in
13 the soils located above 5m is zero (**Fig. 4**). Meanwhile, the hydraulic conductivity of soils between 5
14 m to 7.2 m (the average groundwater level) is as high as 10^{-3} m/s (**Fig. 9**). Therefore, the calcium
15 carbonate dissolution between rainwater and surrounding soils in the water infiltration process is
16 neglected.

17 **Fig. 10** shows the comparison between the measured and the characteristic pH values. It is
18 observed that the pH_c values are lower than the measured ones (pH_m), suggesting that a higher H^+
19 concentration is obtained by excluding the calcium carbonate dissolution process, indirectly
20 confirming the occurring of calcium carbonate dissolution. **Fig. 10** also reveals that the difference
21 between these two values is quite small at high pH values (corresponding to high pH_c value/low H^+
22 concentration) and quite large at low pH values (corresponding to low pH_c value/high H^+

1 concentration). This difference corresponds to the degree of calcium carbonate dissolution, defined
2 as follows:

$$3 \quad D_{Dp} = \frac{pH_m - pH_c}{pH_c} \quad (10)$$

4 **Fig. 12** shows the change of calcium carbonate dissolution degree (D_{Dp}) with pH values. It is
5 observed that the dissolution degree D_{Dp} is strongly correlated to pH. The higher the pH in
6 groundwater, the lower the D_{Dp} in surrounding soils.

7 **3.6 Water electrical conductivity**

8 **Fig. 13** shows the change of electrical conductivity (EC) and groundwater level over the sampling
9 time. It is observed that the EC of groundwater ranges from 4.6 us/m to 6.6 us/m, higher than that of
10 rainwater (0.45 us/m). This difference is also caused by the calcium carbonate dissolutions. Due to
11 this reaction, the calcium bicarbonate (Ca^{2+} and HCO_3^-) are generated and entered in groundwater,
12 resulting in the increase of EC. **Fig. 13** also reveals that the EC of groundwater has an increase trend
13 over the sampling time. But the change pattern of EC is different from that of groundwater level,
14 suggesting that EC was affected by both the change of groundwater level and the calcium carbonate
15 dissolution. With rainfalls, groundwater was recharged; the concentrations of Ca^{2+} and HCO_3^- were
16 expected to decrease by dilution, leading to a decrease of EC. On the other hand, through the calcium
17 carbonate dissolution process, the concentrations of Ca^{2+} and HCO_3^- in water were expected to
18 increase, leading to the increase of EC. The general increase observed from **Fig. 13** shows that in the
19 monitoring period, the dissolution process prevailed over the dilution process.

20 Adopting the similar model shown in **Fig. 11**, the characteristic electrical conductivity (EC_c) can
21 be also calculated that excludes the calcium carbonate dissolution. The results are shown in **Fig. 13**.
22 It is observed that most of the EC_c values are lower than the measured ones (EC_m), except some

1 points in the beginning of the monitoring period, probably due to the hydrogeological environment.
2 This confirms that calcium carbonate dissolution was the prevailing mechanism over the monitoring
3 period. In general, the difference between the calculated and the measured EC is larger at higher EC
4 values (corresponding to lower EC_c /more rainfall/high H^+ concentration). This difference can be also
5 defined as the dissolution degree of calcium carbonate (D_{DE}), as follows:

$$D_{DE} = \frac{EC_m - EC_c}{EC_c} \quad (11)$$

7 **Fig. 14** shows the change of calcium carbonate dissolution degree (D_{DE}) with the electrical
8 conductivity (EC). A general increase trend of D_{DE} with the increase of EC can be observed. **Fig. 15**
9 shows the comparison between D_{Dp} and D_{DE} . Interestingly, a very close relationship is observed
10 between the two parameters, suggesting that both EC and pH can be used as indicator of the calcium
11 carbonate dissolution occurred in surrounding soils/pore water.

12 **4. Conclusions**

13 A case study of Meysiez Tunnel was conducted. After identification of the calcium carbonate
14 precipitation in this tunnel, surrounding soil samples were taken from the site for laboratory
15 characterization. The groundwater table was also monitored in the field and both pore-water and rain
16 water were taken for laboratory analyses in terms of pH and electrical conductivity. Results obtained
17 allow the following conclusions to be drawn.

18 (1) The calcium carbonate precipitation in tunnel drainage system was mainly induced by the
19 dissolution of calcium carbonate in the fine fractions ($d < 0.08$ mm) of surrounding soils. Due to this
20 dissolution, both the void ratio of fine fractions (e_f) and the hydraulic conductivity (k) of soils
21 increased.

22 (2) Calcium carbonate dissolution increased the pH values of groundwater. However, any

1 recharge of water table decreased pH values through increasing the H^+ concentration in water. A
2 model was proposed for calculating the characteristic pH value (pH_c), excluding the effect of calcium
3 carbonate dissolution. Results show a significant difference between the measured and characteristic
4 pH values, indirectly confirming the occurring of calcium carbonate dissolution. A calcium carbonate
5 dissolution degree was defined, showing that the higher the pH value (corresponding to a high pH_c
6 value/low H^+ concentration), the lower the calcium carbonate dissolution in the surrounding soils.

7 (3) Calcium carbonate dissolution increases the electrical conductivity (EC) of groundwater.
8 However, the recharge of groundwater table decreases EC through the dilution of ions in water. It is
9 found that the difference between measured EC value and the characteristic one (EC_c) determined
10 using a proposed model is significant, suggesting the occurring of calcium carbonate dissolution. The
11 calcium carbonate dissolution degree defined based on the measured and calculated EC values
12 showed that the higher the EC value (corresponding to a lower EC_c /more rainfall/high H^+
13 concentration), the higher the calcium carbonate dissolution in the soils. Interestingly, this calcium
14 carbonate dissolution degree is found to be well correlated with the one defined with pH values,
15 indicating that both EC and pH can be used as indicator of the calcium carbonate dissolution
16 occurred in surrounding soils/pore water.

17 Note that the calcium carbonate dissolution degree is an important index in practice because it
18 can be used to approximately estimate the dissolution amount every year. Subsequently, the amount
19 of $CaCO_3$ precipitated in the tunnel gutters can be estimated.
