Abstract: Reconstructing bomb trajectories resulting from Strombolian activity can provide insights into near-surface dynamics of the conduit system. Typically, the high number of bombs involved represents a challenge for both automatic and manual bomb identification and tracking methods. Here, we present a method for the automated recognition of hundreds of bombs (100 to 400 depending on the explosion observed) and for the reconstruction of their trajectories in time and 3D space by stereophotogrammetry. The data involve video collected at 30 Hz with two synchronized cameras (Basler 1300-30), separated by 11°, targeting explosions at Stromboli (Aeolian Islands, Italy) in September–October 2012. In total, six data sets were collected for emissions lasting less than 15 s. The 3D reconstructions provided more accurate velocity estimations (error < 10%) than 2D analyses (errors up to 90%–100% for bombs moving parallel to the line of sight of the camera). By coupling the measured trajectories with a numerical ballistic model, we show that the method can be used to estimate the directional distribution of bombs and their velocities at the vent (which in this case was 30–130 m s⁻¹), the wind velocity (~3.5 m s⁻¹ from the NW) and the drag coefficients (10^{-3.5}–10^{-0.5}) of the bombs. The 3D reconstructions also provide a quantification of the directions of explosions and show that explosions can be radial, oriented in a predominant direction of ejection or in several directions; these dispersion patterns can change during a few seconds in a single explosion. We relate the changing directions of ejections to rheological variations in the upper part of the magmatic system probably filled with a mixture of partially crystallized magma which can direct rising slugs along preferential paths.

3D space, stereophotogrammetry, Strombolian explosions, launch velocity, ballistic trajectory

43 **Introduction**

44 An in-depth understanding of volcanic activity requires a combination of modelling and field
45 observations. Models make it possible to determine natural properties that are not accessible for direct
46 measurement, and can be used to predict the future evolution of a natural system. To do this, field
47 observations are used in parallel with models, to ensure that the models correctly reproduce observable
48 parts of the natural phenomena, thus giving confidence that they can also be used for the unobservable
49 parts and for predictions (for modelling ballistic fields see, for example, Waythomas and Mastin, 2020).
50 For Strombolian and Vulcanian activity, bomb velocities and directions are essential parameters for
51 calculating the distance affected by bomb impacts (Mastin, 2001), and for the understanding of the
52 superficial activity of the magmatic system and the nature of the interactions between gas and conduit
53 magma to generate the ensuing explosion (Wilson et al., 1980; Mastin 1995).

54 Velocity estimations for volcanic bombs have been previously performed using image analysis
55 (e.g., Chouet et al. 1974, Formenti et al. 2003; Zanon et al. 2009; Vanderkluysen et al. 2012; Taddeucci
56 et al. 2015). Manual tracking methods, suitable for a limited number of bombs, have been recently
57 improved by automated tracking to capture a large number of bombs (Bombrun et al., 2014; Gaudin et
58 al., 2014). However, analyses have usually been 2D, meaning that the velocities can only be estimated
59 correctly if the bombs move solely in a plane, vertical or perpendicular to the line of sight of the camera.
60 Volcanic ejecta generally move in diverse directions and 2D approaches can thus induce error in the
61 estimation of bomb absolute velocities. Moreover, 2D methods cannot estimate the direction of motion
62 of the ejecta.

63 More recently, 3D calculations have been performed by focusing on selected bombs using
64 stereoscopic reconstructions derived from two synchronized cameras (Gaudin et al. 2016). The main
65 limitations of their method was that manual tracking of pyroclasts limited the number of bombs
66 analysed. As a further step, we present here a method for the automated recognition of hundreds of
67 bombs and for the reconstruction of their trajectories in time and space by stereophotogrammetry.

68 During the course of an eruption, many thousands of bombs can be ejected (Bombrun et al., 2014).
69 The more of these that can be tracked, the better the statistical analysis of the trajectory variations, and
70 the greater the insight into eruptive dynamics. Tracking and identifying the bombs manually is complex,
71 since they are launched at a range of times, angles and velocities so that at any one time thousands of
72 different trajectories will be active. This means so bombs will be ascending while other are descending
73 with intersecting paths, and frequently masking each other. Bombs are present over a large volume of
74 space rather than on a planar surface, making the identification of any given bomb within images
75 acquired from different camera positions even more difficult. To facilitate trajectory identification and
76 3D reconstruction, we have developed a new methodology using stereoscopic calculation based on the
77 automated recognition of bombs. Three-dimensions reconstruction of topography has made substantial
78 progress in recent years and has been used to follow the dynamics of natural phenomena such as glaciers,
79 landslides and lavas flows (e.g., Eiken and Sund 2012; James and Robson, 2014; James et al, 2014;
80 Eltner et al, 2017). Bundle adjustment (Granshaw, 1980) and recent developments that include structure-
81 from-motion (SfM) and multi-view stereo (MVS) algorithms has widened the use of the techniques and
82 facilitates automatic estimation of camera positions, orientations and lens characteristics. Difficulties
83 associated with reconstructing volcanic bomb trajectories come from (1) the bomb locations that cover
84 a large volume of space and are not restricted to a known surface, (2) the high bomb velocities that
85 require synchronised cameras and prevent the use of a single moving cameras and (3) the high number
86 of bombs with similar size, shape and luminosity making bomb recognition challenging in multiple

87 images. This explains why the bundle adjustment method has not been used for this study. Instead, we
88 here use a custom-built 3D tracking routine.

89 The target chosen for the study is Stromboli volcano (Aeolian Island, Italy) because of its
90 permanent activity characterised by discrete bursts every 5–20 mins (Chouet et al. 1974; Patrick et al.
91 2007), relatively easy access to the summit, and the complexity of the trajectory reconstruction related
92 to the high number of bombs. Moreover, despite the activity of Stromboli being widely studied (e.g.,
93 Ripepe et al. 2001, Ripepe et al. 2002; Rosi et al. 2006; Harris and Ripepe 2007; Pistolesi et al. 2011;
94 Gurioli et al. 2014), there remain open questions regarding conduit ascent dynamics and explosion
95 mechanisms. The most frequent activity consists of repeated explosive events related to slow magma
96 ascent in the upper conduit and/or ascent of bubbles in a low viscosity magma (Wilson et al., 1980).
97 Several models have been proposed based on experimental and geophysical data but a number important
98 characteristics remain poorly constrained, such as the conduit geometry, the depth at which the explosion
99 is triggered, and the origin of the different activity types observed at the vents (e.g., Chouet et al., 1997;
100 Chouet et al., 2008b; Harris et al. 2008; Gurioli et al. 2014; Gaudin et al. 2017). A multidisciplinary
101 field campaign took place during September and October 2012 to increase understanding of the normal
102 explosive activity at Stromboli, as well as to compare the results obtained using a large set of
103 observational techniques (Harris et al. 2013; Bombrun et al. 2015; Chevalier and Donnadieu 2015).
104 Among the spectrum of techniques used, a system of stereoscopic cameras forming the basis of the new
105 3D reconstruction methodology described in this article, was deployed to improve the identification of
106 ejecta trajectories in space and time.

107

108 **Methodology**

109 System characteristics

110 The system comprises two digital cameras recording greyscale images from visible wavelengths
111 (Basler 1300-30, lens Edmund Optics 8 mm F1.4). These acquire 1280- by 960-pixel images, 8 bytes
112 per pixel, at frame rates of up to 30 frames per second, so that data acquisition rates were around 37
113 Mb/s for each camera. They were connected by Ethernet to the same computer to ensure that the
114 acquisition time reference was identical for both cameras, an essential requirement for the spatial
115 reconstruction processing stage. The positions of the two cameras were located with centimetre-
116 accuracy using differential GPS. One camera was set to film the vent continuously and the images were
117 analysed in real time to detect eruption occurrence (using the software Genika Trigger by Airylab).
118 Recording was made at night to facilitate the bomb recognition: bombs appear as white on a black
119 background. When the eruption is detected, the observing camera triggered a recording of the images
120 from both cameras onto the computer over a period of 30 s. The triggering analysis is sufficiently fast
121 (<20 ms) that data can be acquired from the onset periods of eruptions without an image buffer. If bombs
122 continued to be detected, the acquisition was automatically extended by successive periods of 30 s.

123

124 The principles of a 3D reconstruction

125 The location of an object projection on the sensor array (i.e. the charge coupled device, CCD)
126 within a camera depends on the position of the object in space, the camera position, the camera
127 orientation and lens characteristics. To calculate the 3D-position of the object in real-space we thus
128 invert this imaging model. To do this, we first need to locate the object on two images taken at the same
129 time by the two cameras. Using a correction for the lens distortion and misalignment, we can then

130 calculate the undistorted position of each projection (p_1 and p_2 on Fig. 1). From the orientations of the
 131 cameras and their positions, we next calculate two lines (L_1 and L_2 on Fig. 1) that pass through each
 132 point and the optical centre of the lens (O_1 and O_2 on Fig. 1). The 3D-position of the object corresponds
 133 to the intersection of the two lines. Identifying the object on a sequence of images taken during an
 134 eruption allows a reconstruction of the trajectory to be made, i.e. in both 3D space and time.

135
 136 **Fig. 1** Principle of position calculation by stereophotogrammetry. The 3D position of an object is
 137 calculated by the intersection of the lines L_1 and L_2 which pass by the object projections p_1 and p_2 and
 138 the optical centres of the lenses

139
 140 **Stereo-system geometry**

141 At a given distance from the vent, the distance between the cameras (i.e. the baseline) is chosen
 142 based on a compromise between bomb identification, practical aspects, and precision of the 3D-
 143 reconstruction. The greater the baseline, the larger the angle camera 1 – bomb – camera 2 (angle θ on
 144 Fig. 1). If θ is very small, errors in camera orientation or subpixel uncertainty in the object detection can
 145 induce large errors in the calculation of the 3D-position. The system was installed around 430 m east of
 146 Stromboli's NE crater (Fig. 2) chosen for the study. In this configuration, with an angle θ of 2° , an error
 147 of 1 pixel induces an error in the bomb position of up to 6 m. The most accurate calculation would be
 148 obtained for $\theta = 90^\circ$ (an error of 1 pixel induces a 20 cm error in the bomb position). However, because
 149 an eruption can emit thousands of bombs per second, a strong difference in the view angles (i.e. large
 150 values of θ) gives very different images on the two cameras. This makes bombs impossible to recognise
 151 visually, and makes some steps of our bomb identification method more complex (e.g. the auto
 152 calibration of camera orientations – see next section - is simpler if supervised). Thus, the smaller the
 153 distance between the two cameras, the easier it is to match the bombs. Given the above considerations,
 154 we estimated the ideal angle θ of about 10° . For the observation distance of about 430 m and for
 155 installation convenience, we chose a distance of 81.6 m that corresponds to an angle between the
 156 positions of the cameras and of the crater of about 11° . The system is convergent (Fig. 1) and the angle
 157 between the optical axes of the cameras (i.e. their lines of sight) is 9° . In this configuration, an error of

158 1 pixel in the bomb location on the image induced an error of about 1 m in the East-West direction
 159 (called x in the following) and less than 30 cm in North-South (y -direction) and in elevation (z -direction).
 160 The error is higher in the East-West direction because of the positions and the orientations of the cameras
 161 (to the West).

162

163

164 **Fig. 2** Location of the NE crater, of the two cameras used for observation of ejecta trajectories and of
 165 the photograph of Fig. 10, Stromboli, Italy, 2012. Lidar-derived DEM courtesy of INGV-Pisa (Favalli et
 166 al., 2009)

167

168 Due to the distance chosen to observe the crater and the camera characteristics, each pixel in an
 169 individual image (also called the ground sample distance) corresponds to an area about 20 cm in width
 170 and height at the crater location. This, in principle, determines the minimum detectable bomb size but
 171 hot bombs much smaller than the pixel size could still illuminate the pixel and hence be detected at
 172 night.

173 Lens distortions

174 In order to calculate bomb positions accurately, the image distortions induced by the camera lenses
 175 need to be corrected. The corrections are done with the Brown–Conrady equation (Brown, 1966):

$$\begin{cases} x_{cor} = x_n (1 + k_1 \times r + k_2 \times r^2 + k_3 \times r^4) + 2 \times q_1 \times x_n \times y_n + q_2 \times (r^2 + 2 \times x_n^2) \\ y_{cor} = y_n (1 + k_1 \times r + k_2 \times r^2 + k_3 \times r^4) + 2 \times q_2 \times x_n \times y_n + q_1 \times (r^2 + 2 \times y_n^2) \end{cases} \quad (1)$$

177 where x_{cor} and y_{cor} is the corrected position, x_n and y_n is the uncorrected normalized position calculated
 178 by $x_n = (x_p - x_c)/f$ and $y_n = (y_p - y_c)/f$. The variables x_p and y_p are the uncorrected image

179 position in pixels, f is the calibrated focal length (Fig. 1; Granshaw 2016), $r = \sqrt{x_n^2 + y_n^2}$ is the distance
 180 between the position to be corrected and the position (x_c, y_c) of the principal point (i.e. the intersection
 181 between the optical axis and the CCD, c_1 and c_2 , Fig. 1), and q_1, q_2, k_1, k_2, k_3 are the distortion correction
 182 parameters. Note that the principal point is not generally located at the geometric centre of the image
 183 due to lens distortion and lens misalignment. The distortion parameters, the position of the principal
 184 point and the calibrated focal length were calculated using adapted grids and protocols of the *Institut*
 185 *Pascal* based on the work of Lavest et al. (1999). The calibration was done in laboratory with a distance
 186 of the calibration target of 3 meters and the same focus as used in the field. Lens distortions caused
 187 differences of up to 30 pixels at the edges of the images between the corrected and uncorrected positions.
 188 The standard deviation of the correction has been calculated by comparing the parameters of Eq 1 to
 189 parameters obtained with other sets of images. It is of less than 0.3 pixel. The codes used for the
 190 reconstruction, including that for lens distortions, are available in Online Resource 1.

191 Orientation of the cameras

192 We used three angles to define our cameras (Granshaw 2016): φ is the pitch, i.e. the angle between
 193 the horizontal and the optical axis of the camera, where $\varphi > 0$ means that the camera is pointing upwards
 194 (Fig. 1). The angle κ defines the azimuth, i.e., the orientation of the optical axis in the horizontal plan,
 195 where $\kappa = 0$ means that the camera is oriented to the North, and $\kappa > 0$ is rotated to the east. The angle ω
 196 defines the roll, i.e. the rotation around the optical axis, with $\omega > 0$ for a counter-clockwise tilt of the
 197 camera.

198 If $\varphi = 0, \kappa = 0$ and $\omega = 0$, the orientation of the camera is defined by $X_{ini} = \begin{pmatrix} u_i \\ v_i \\ w_i \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix}$, which

199 conveys that the camera is horizontal and pointing northward, u_i and v_i defining respectively the
 200 orientation of the horizontal and the vertical for the images (CCD sensor is vertical if the camera is
 201 horizontal, Fig. 1) and w_i defining the orientation of the optical axis of the camera. The rotation matrices
 202 are:

$$203 \quad R_\varphi = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \varphi & -\sin \varphi \\ 0 & \sin \varphi & \cos \varphi \end{pmatrix}, R_\kappa = \begin{pmatrix} \cos \kappa & 0 & \sin \kappa \\ 0 & 1 & 0 \\ -\sin \kappa & 0 & \cos \kappa \end{pmatrix} \text{ and } R_\omega = \begin{pmatrix} \cos \omega & -\sin \omega & 0 \\ \sin \omega & \cos \omega & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (2)$$

204

205 Using these matrices and these references, the orientation of the camera can be calculated by:

$$206 \quad X = R_\omega \times R_\varphi \times R_\kappa \times X_{ini} \quad (3)$$

207 Calculating the camera orientation on an active volcano can be challenging. The common method
 208 consists of placing ground control points (GCP), with accurately measured positions, in the camera's
 209 field of view (Diefenbach et al, 2012). Using the images of the GCP, in combination with the lens
 210 characteristics, allows the camera orientations to be calculated. However, placing GCPs on active
 211 volcanoes is often impossible for security and accessibility reasons. To solve this problem, we used a
 212 two-step process, first calculating the approximate orientation of the camera using the surface of the sea

213 and the volcano topography, then improving the relative orientation of the cameras using the positions
214 of selected bombs on the images.

215 For the first step we used high-resolution topography (lidar topography, resolution 1 m, Favalli et
216 al. 2009) and calculated its projection on the CCD sensors as well as the projection of the sea surface.
217 The projection depends on the values of φ , κ and ω , and the angles were adjusted by fitting the
218 projections on the real images (the sea and the topography were visible on the first images taken after
219 sunset). For details, the readers may refer to Online Resource 1 and 2 for numerical codes and an
220 explanation of the methodology respectively. The angles φ and ω could be estimated using the sea
221 surface, which appeared clearly and sharply on images, and can be located with a precision of less than
222 2 pixels. Such a precision of the sea surface gives a precision better than 0.2° for φ and ω . The calculation
223 of κ was carried out using the digital topography (except for crater area which has evolved over time
224 due to volcanic activity). The precision is better than 1° . Such precision in the angles ($\varphi \pm 0.2^\circ$, $\omega \pm$
225 0.2° and $\kappa \pm 1^\circ$) induces uncertainties in the bomb locations of less than ± 10 m in y and z and about
226 100 m in x (i.e. East-West direction). In the second step, to improve the precision of the relative
227 orientations of the cameras and of the bomb locations, we manually matched 30 volcanic bombs which
228 could be recognized unambiguously in the two cameras. The image of each bomb projected on the first
229 camera must be located on the second camera along a line, called epipolar, which is defined by the
230 orientations and positions of the cameras (Fig. 1). It was then possible to find the best relative orientation
231 of the two cameras by using a least squares minimisation of the distances between all 30 bombs on the
232 second camera with their corresponding epipolar lines. The precision of the angles is better than 0.1° ,
233 the method mainly improving the precision of κ .

234

235 Trajectory reconstruction for a single camera

236 For trajectory reconstruction, the first step was to identify the maximum number of bombs on all images
237 corresponding to a given eruption. To locate the maximum of bombs and minimize false detections, we
238 used the algorithm written by Crocker and Grier (Crocker et al. 1996), and Blair and Dufresne (see
239 Online Resource 1). It suppresses pixel noise and long-wavelength image variations to detect circular
240 objects and locate their centres from their luminosity. This was made easier when image acquisition was
241 carried out at night so that bombs appeared as bright pixels on a black background. More than 1000
242 bombs can be detected unambiguously on an image.

243 The second step was to follow all the identified bombs on the successive images of each camera.
244 We developed our own algorithm for counting and tracking the rise and fall of bombs because no
245 tracking algorithm available was found to be adapted to the complexity of bomb trajectories. The values
246 of the arbitrary parameters given here have been estimated by several tests, retaining the values that give
247 the greatest number of correct trajectories. Starting from each detected bomb in the first image of a given
248 camera, the algorithm first initialises the trajectory by detecting all bombs in the next image from the
249 same camera that are not 'too far' from its initial position. A distance of 100 pixels, that can detect all
250 bombs of velocities slower than 300 m s^{-1} , gives the best results for the explosions studied (see
251 detect_trajectories in Online Resource 1 for details). At this stage, hundreds of trajectories are possible
252 for a given bomb. Then, for each trajectory, the algorithm estimates the position of the bomb on the third
253 image by extrapolation of its position on the previous two images. It detects if a bomb with similar
254 brightness (i.e. the bomb luminosity must be greater than 20% of the luminosity of the bomb initially
255 detected) exists in the third image in the neighbourhood of the estimated position (5 pixels, i.e. ~ 1.5 m

256 between the estimated and the real positions). If no bomb exists, the trajectory is deleted. If a bomb is
257 detected, it extrapolates the position onto the fourth image and so on until the end of the sequence. Once
258 a trajectory has been identified by more than 10 consecutive positions, it is fixed and the algorithm will
259 ignore the absence of a bomb within a subsequent image to take into account the fact that bombs can be
260 hidden by others or by an ash cloud. At this stage, the algorithm has only detected the trajectories of the
261 bombs visible on the first image. To allow the detection of trajectories of bombs that were not present
262 or were hidden on the first image, the algorithm starts again from the second image, then from the third
263 and so on. Trajectories that have already been detected are not recorded again. An example of a trajectory
264 reconstruction is shown on figure 3 for more than 1600 unambiguous bomb trajectories. A movie of the
265 eruption with superimposed trajectories and the related code are provided in Online Resource 1 and 3.

266
267 **Fig. 3** Example of a trajectory reconstruction. More than 1600 bomb trajectories are identified
268 unambiguously. The coloured trajectories A and B are used as examples in the text. Eruption of 17:20
269 UT, on October 5, 2012, taken by camera 2 (location shown on Fig. 2). Axes are the image distance in
270 pixels

271
272 **Trajectory matching between the two cameras**
273 In order to calculate the real position of bomb trajectories in space, we need to match all the pairs
274 of trajectories that correspond to similar bombs. Some bombs are easy to identify due to their size,
275 brightness or position, but overall matching is very difficult (and often impossible to do manually).

276 The first step is to account for the short delay (<20 ms, i.e. 2 m for a bomb moving at 100 m s^{-1})
277 between image acquisition at the two cameras due to the second being triggered by the first. With the
278 cameras connected to the same computer, the delay value is known and can be used to interpolate the
279 trajectories of the second camera to estimate the bomb positions at the same time as the images of the
280 first camera.

281 The automated method we have developed for trajectories matching is illustrated by the animation
282 and a tutorial code in Online Resource 1 and 4. It first selects a bomb in the first image. Using its epipolar
283 line, it is then possible to estimate which of the bombs observed in the second image it may be. To allow
284 for errors in the camera orientations, in distortion corrections and in trajectory fluctuations, an
285 uncertainty of 5 pixels around the epipolar line is accepted for the bomb matching. Continuing this
286 process for all the images over the time sequence, we could identify the matching trajectory, i.e. the
287 trajectory of camera 2 whose bombs are always on the epipolar lines of the selected trajectory of camera
288 1. However, due to the high number of trajectories, this method can give non-unique solutions,
289 particularly for short trajectories close to the crater. We then filter the solution by calculating the 3D
290 shape of the trajectory in space (see next section). A match is rejected if the calculated trajectory does
291 not originate from the crater area and if the estimated value for gravity is outside an acceptable range.
292 A range of 8 m s^{-2} to 12 m s^{-2} is chosen so as not to eliminate trajectories that could have been influenced
293 by wind, blast explosion, collisions, etc. If several trajectories still match the chosen trajectory, we
294 discard them even though it might still have been possible to identify the most probable corresponding
295 trajectory by analysing errors in the epipolar calculation and the gravity value. We also discard
296 trajectories that are too short. As a conservative result, only 10% to 20% of the total trajectories is
297 retained in order to improve the chance to delete all the false matching trajectories. For example, at
298 17:20, about 1600 2D-trajectories have been reconstructed for each camera (Fig. 3) but only 230 have
299 been retained for 3D reconstruction and hundreds of correlations, being non unique with the accuracy
300 chosen, have been discarded.

301

302 3D reconstruction

303 The last step is based on classic 3D reconstruction. Using camera positions and orientations, lens
304 characteristics and the matching trajectories, it is possible to calculate the position of each bomb at each
305 time step following the principle of Fig. 1 (see also Gaudin et al. 2016). Using the recorded time of each
306 image, we reconstructed the 3D position – in time and space – of the bombs. Due to the uncertainties in
307 camera orientations and lens correction and in pixel locations, the lines L1 and L2 do not intersect in 3D
308 but their closest distance of approach is generally less than 50 cm. The accuracy of the bomb positions
309 is not easy to estimate because it is not possible to identify objects in the images whose positions have
310 been measured by independent methods. From a comparison of the trajectories of the bombs that roll
311 around the crater with the lidar topography, accuracy appears better than a few meters.

312 The precision is estimated by selecting all the matching trajectories and by calculating 10000
313 variations of each trajectory by adding small random offsets to the image positions, the camera
314 orientations and distortion parameters of the lenses. The bomb images are circular and some pixels of
315 diameter for the largest and their centres are located quite accurately. Their offsets are assumed to follow
316 a normal distribution law with a standard deviation $\sigma = 1$ pixel in row and column. For the orientation
317 of the cameras, the three angles of each camera follow a standard deviation $\sigma = 0.1^\circ$. A standard
318 deviation of 0.3 pixel is used for the uncertainties related to the distortion parameters q_1, q_2, k_1, k_2, k_3
319 and in the calibrated focal length. The effect on the estimated positions of the bombs in space is $\sigma \sim 4.5$

320 m. The standard deviation is smaller than 2 m in y and z , and of 4 m in x (i.e. East-West direction) due
321 to the system geometry (Fig. 2). If the random offset is only applied to the image positions of the bomb
322 centre, the standard deviation on the bombs in space is less than 1 m. If the random offset is only applied
323 to the lens distortion parameters, the standard deviation on the bombs in space is less than 0.3 m. The
324 main uncertainty is caused by the camera orientations, due to the calibration method used and the
325 inaccessibility of the crater area that prevent the installation of ground control points.

326

327 **Results**

328

329 Estimation of bomb velocity using 2D and 3D trajectory reconstruction

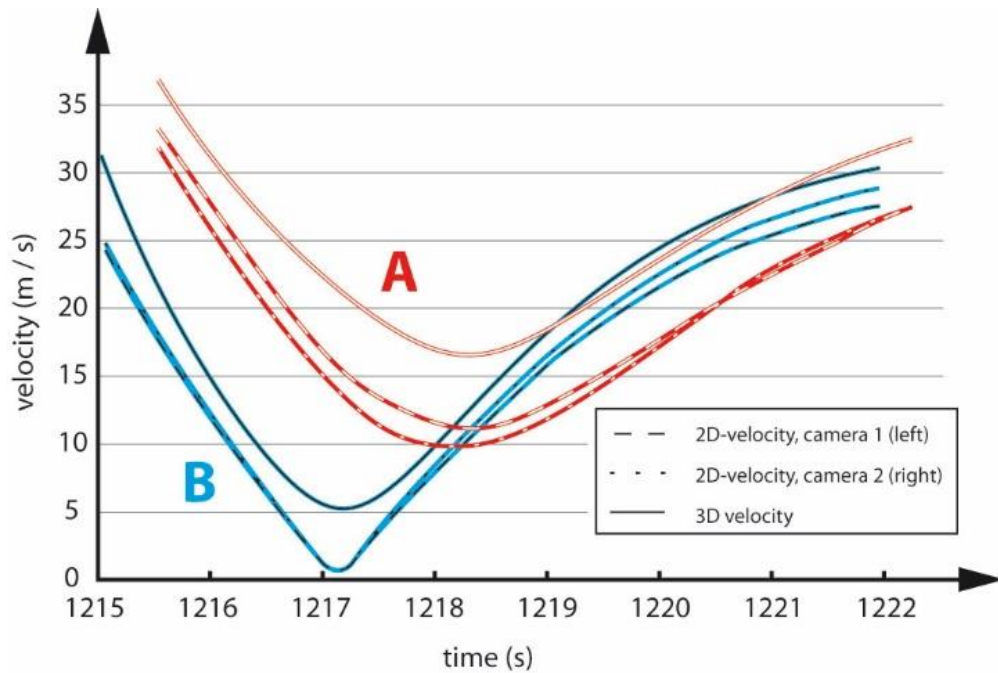

330 Fig. 4 compares velocities estimated by the 2D method (assuming that the bombs move in a vertical
331 plane passing through the crater) with those measured by our 3D reconstruction method. Two bombs
332 from the October 5 2012 17:20 UT eruption are used as examples (throughout the article, time is given
333 in Universal Time, UT, which corresponds to the local time minus 2 hours). One bomb moved
334 approximately perpendicular to the lines of sight of the cameras (bomb A, Fig. 3), the other moved
335 approximately parallel (bomb B, Fig. 3). Both methods show a deceleration of the bomb during the
336 rising phase followed by a downward acceleration that decreased towards a constant terminal velocity
337 when the air drag (related to the bomb velocity) equilibrates the bomb weight. On the curves shown, the
338 bombs impacted the ground before a constant fall velocity was reached. Fig. 4 shows that the curves are
339 not superimposed and that the error on bomb velocity incurred using the 2D assumption leads to
340 systematic underestimations of the true velocity between 20% and 95%, the maximum error being
341 associated with the trajectory high point. Bomb B, which moved parallel to the camera's line of sight,
342 had a very small horizontal component of displacement on the images. For example, where it reached
343 the highest elevation ($t = 1217.15$ s, Fig. 4) the 2D velocity was near to zero while the 3D analysis shows
344 that the bomb was actually moving away from the cameras with a horizontal velocity of 5 m s^{-1} .

345

346 Characteristics of the explosions using 3D-analysis

347 Fig. 5 shows a 3D-view of the bomb trajectories through time for six eruptions that occurred on
348 October 5, 2012. The trajectories reveal the highly asymmetric ejection of the largest pyroclasts as a
349 function of time, the strong variability of jet directivity and of the maximum bomb heights among
350 eruptions over a period of 2 hours. Fig. 6 is a plot of the maximum elevation reached by the bombs
351 according to the azimuthal direction of their ejection. It illustrates the differences in direction and
352 intensity between the recorded explosions. Maximal ejection heights above the vent (about 755 m a.s.l.)
353 vary between 105 m (860 m in elevation) for the weakest eruption (i.e. 17:47) to 165 m (920 m in
354 elevation) for the strongest (i.e. 17:20). Maximum heights tend to be reached in the predominant ejection
355 direction (Fig. 6a, 6c) but exceptions occur (Fig. 6b).

356

357

358 **Fig. 4** Comparison of the bomb velocities estimated using the 2D method (vertical plan passing by the
 359 crater) and those calculated with the 3D reconstruction (eruption of 17:20, October 5, 2012). A and B
 360 (and their respective colours) correspond to the bombs of Fig. 3

361

362 Fig. 7 links the azimuth of the ejection, the ejection time, the initial velocity (calculated in a further
 363 section) and the trajectory duration. In Fig. 5d and 7d, it can be seen that during the small eruption at
 364 19:00, bombs were ejected for a period of 2 s with no preferential azimuth. For the more energetic
 365 eruption at 17:47 (Fig. 7c), the bombs were ejected over a wide azimuth range from south-east to north-
 366 west, although with an overall predominant direction towards the south-west (azimuth, N200). This
 367 predominant direction of ejection was also visible during other high energy explosions (17:04, 17:20,
 368 19:12 and 19:22). For example, bombs were ejected continuously for a period of 8 s at 17:04 and again
 369 at 17:20 (Fig. 7a and 7b). These two eruptions were also characterized by an initial ejection of bombs
 370 with no preferential azimuth for about 1 s, before becoming predominantly oriented to the south-west.
 371 The eruption at 19:22 (Fig. 7f) began with an emission predominantly oriented towards the south-west
 372 for the first 7s. Two seconds after the beginning of the eruption, a number of bombs were ejected in all
 373 directions. When the bomb trajectories exhibit a high directivity, the highest bomb velocities tend to be
 374 recorded in the predominant ejection direction. The eruption of 19:12 had two predominant directions
 375 of ejection (Fig. 5e, 6c and 7e). The eruption began with an ejection of bombs in the same direction
 376 (SW) as the other eruptions for 5 s. However, two seconds after the beginning of the eruption, another
 377 preferential direction of ejection joined the first, in which bombs were ejected towards the north-west
 378 for 2 s. This direction of emission was detected too for other eruptions but is less clear. It can be seen at
 379 17:04 on Fig. 5a, with the two short pulses recorded at 17:47 on Fig. 7c (at $t = 2841$ s and $t = 2843$ s)
 380 and with few bombs ejected at 17:20 (Fig. 5b and 7b).

 385 time in seconds from the onset of the explosion. Black lines are parabolic fits of the trajectories

386

387 Discussion

388

389 Bomb modelling

390 To illustrate the potential of our 3D-reconstruction method, this section gives an example of the
 391 parameters that can be deduced by comparing a simple ballistic model with our 3D-trajectories
 392 reconstruction. Details of the model are presented in Online Resource 2. The model is simple and more

393 complex models have been developed (Taddeucci et al., 2017 and references therein). It is presented
 394 here only to illustrate the possibilities given by the 3D-reconstruction of trajectories. Our model
 395 calculates the bomb velocity from the Newton's First Law and the drag force exerted by the atmosphere
 396 on a bomb:

$$397 \quad \frac{d\mathbf{v}}{dt} = \mathbf{g} - c \times (\mathbf{v} - \mathbf{w}) \times u \quad (4)$$

398 where t is time, $\mathbf{v} = (v_x, v_y, v_z)$ is the bomb velocity, $\mathbf{w} = (w_x, w_y, w_z)$, the wind velocity, $u = \|\mathbf{v} - \mathbf{w}\|$
 399 the relative velocity between the bomb and the air and $\mathbf{g} = (0, 0, -9.81)$ is gravity in m s^{-2} . For a
 400 spherical bomb, the parameter c is defined by:

$$401 \quad c = \frac{3}{8 \times r} \frac{\rho_a}{\rho} \times C_d \quad (5)$$

402 with ρ_a the atmosphere density, ρ the bomb density, r its radius and C_d the drag coefficient (Alatorre-
 403 Ibarguengoitia et al. 2012; Konstantinou, 2015).

404 By fitting the model to our 3D trajectories, we can estimate the three components of the bomb
 405 velocity (v_x, v_y, v_z) at the first detection (black dot in Fig. 8), the horizontal wind velocity (w_x and w_y)
 406 and its orientation (β_w , azimuthal origin), and the coefficient c related to the atmospheric drag on the
 407 bomb. Best fit estimations of these parameters were obtained by systematically varying the six
 408 parameters and minimizing the standard deviation between the model and the observed trajectories in
 409 both space and time. Fig. 8 shows a simulation of bomb B (see Fig. 3). For this bomb, the set of
 410 parameters that reproduces the observed data (gray line, Fig. 8) are: $v_x = -7 \text{ m s}^{-1}$, $v_y = -1.5 \text{ m s}^{-1}$, $v_z = 25.5$
 411 m s^{-1} , $c = 0.0055 \text{ m}^{-1}$, $w = 3.5 \text{ m s}^{-1}$, $\beta_w = -55^\circ$ (wind from NW). The effects of misestimating the projection
 412 positions of the bombs and the camera orientations are dominantly accommodated by translations of the
 413 trajectories. This is why, even in the worst cases, the errors are low for the above values. They are
 414 estimated to be less than 10% for velocities and the drag coefficient, by varying the bomb positions, the
 415 camera angles and the lens distortion parameters with the normal laws of the 3D reconstruction section.

416 By using the values obtained for the parameters v_x, v_y, v_z, c, w and β_w , and inverting the time, we
 417 can determine the initial velocity and the initial direction of each bomb at the vent. The fitting between
 418 the measured trajectories and the model can be done automatically for all bombs detected during an
 419 eruptive phase. Fig. 9a is a histogram of the initial bomb velocities of the 17:20 eruption. The majority
 420 of the bombs were ejected at a velocity of 50 m s^{-1} , with the velocities ranging from 30 to 130 m s^{-1} . At
 421 the crater where the bombs are ejected nearly vertically, the 3D characterisation improves only the
 422 velocity estimation of less than 10% compared to 2D methods. The 3D method is, however, a powerful
 423 tool for the estimation of ejection velocities if the bomb cannot be observed directly at the vent.

424 Modelling of the 3D-trajectories is also a powerful tool for estimating the drag of the bomb through
 425 the air. To illustrate the sensitivity of the model to the parameter c , two other curves are added to the
 426 initial curve ($c = 0.0055 \text{ m}^{-1}$) on Fig. 8 with values of $c = 0.01 \text{ m}^{-1}$ and $c = 0.0025 \text{ m}^{-1}$. Fig. 9b is a
 427 histogram of the coefficient c calculated for all the bombs of the 17:20 eruption. The coefficient ranges
 428 between 5×10^{-4} ($10^{-3.25}$) and 0.25 m^{-1} ($10^{-0.6}$). To first order, the histogram can be used to estimate the
 429 size distribution of the bombs from Equation 5. If, for example, we assume a value of $C_d = 0.7$, which

430 has been estimated for natural bombs (Alatorre-Ibargüengoitia and Delgado-Granados 2006;
 431 de'Michieli Vitturi et al. 2010) and a bomb density of 1800 kg m^{-3} (e.g., Gurioli et al. 2013; Bombrun
 432 et al 2015; Lautze and Houghton 2007; Harris et al. 2013), a value of $c = 10^{-3} \text{ m}^{-1}$ corresponds to a radius
 433 of 14.6 cm. The bomb radii corresponding to $C_d = 0.7$ and $\rho = 1800 \text{ kg m}^{-3}$ are plotted on Fig. 9b. They
 434 range between $<1 \text{ mm}$ and $>30 \text{ cm}$. Note that, below 64 mm down to 2 mm, the term lapilli must be
 435 used instead of bomb, and ash below 2 mm. It should also be pointed out that it seems unlikely for the
 436 smallest size particles of the histogram (in particular ash $< 1 \text{ mm}$) to be sufficiently radiative to be
 437 detectable with a pixel size (i.e., a ground sample distance) of 20 cm. The sizes given are dependent on
 438 the assumptions about the bomb/lapilli density and the drag coefficient. A particle with a low density,
 439 and a complex shape and roughness might show the same coefficient c as a smaller particle with the
 440 density chosen and the spherical shape used for the example. A strong deceleration, comparable to that
 441 of a small particle, can also be observed for a larger particle leaving a gas jet above the crater. Our
 442 method of 3D-reconstruction can be used with more complete numerical models that would take into
 443 account these parameters.

444 (a) 17:20 UT (b) 17:47 UT (c) 19:12 UT

445 **Fig. 6:** Maximal elevation reached by the bombs and azimuthal direction of ejections. The elevation of
 446 the NE crater in October 2012 was about 755 m a.s.l. The graphics show that the bombs were essentially
 447 ejected in a SW direction. The eruption at 19:12 was characterized by a significant amount of ejecta to
 448 the NW, a direction that is rare or absent from the other eruptions

449

450 Limitations and improvements for the method

451 In the future, the number of trajectories detected by our methodology can be improved by
 452 improving the camera resolution and frame rates. For example, more than 3000 trajectories were
 453 detected for each camera, but fewer than 300 bombs were identified unambiguously. The use of higher
 454 resolution cameras would improve the precision of the bomb locations, would give more precise
 455 estimation of the bomb size and would reduce bomb identification uncertainties. Higher frame rates,
 456 using high speed cameras, would also reduce uncertainties of bomb recognition and facilitate trajectory
 457 reconstruction for each camera because bomb positions would be very close on successive images. With
 458 more confidence in the recognition, selection criteria that reject some trajectories could be lowered. This
 459 would allow complex trajectories, such as those induced by bomb collisions, to be detected
 460 unambiguously (Vanderkluyesen et al. 2012). Another parameter that could be improved is the dynamics
 461 of the sensor. The challenge is to be able to see the bombs in the first phase of the eruption, when the
 462 number of hot bombs is high and tends to saturate the sensor. However, if the sensitivity is too low, the

463 bombs that cool rapidly are not detectable. With the cameras used, it was possible to acquire images
 464 with a higher dynamic range, for example 12 or 16 bytes. However, this would have produced a very
 465 high flux of data to be transmitted and recorded (55 to 73 Mb/s), which exceeded the capability of the
 466 laptop used during fieldwork. Finally, the system could be improved by using more than two
 467 synchronized cameras around the area under observation. This would combine the advantages of easier
 468 recognition of similar bombs with the accuracy related to a wider angle of view and would highly
 469 improve bomb recognition.

470 time (in seconds) time (in seconds)

471 **Fig. 7** Azimuth of the bomb ejection against time for the six eruptions studied on Oct. 5 2012. The
 472 horizontal axis is the time in seconds (a-c from 17:00 UT, and d-f from 19:00 UT). The black dots
 473 indicate the ejection time of each bomb and their size indicates the initial ejection velocity (see inset in
 474 7a). The grey lines represent the time-period of the reconstructed trajectories (up to the point the bombs
 475 reach the ground, are masked by the topography or are too cooled to be detected)

476

477 **Fig. 8** Measurement of the 3D trajectory of bomb B (in grey; cf. Fig. 3) and simulations (in black) for 3
 478 values of c (see Equation 8). The data are fitted in space (a, d) and time (b, c). The dashed line
 479 corresponds to the extrapolation of the bomb trajectory from its first detected position back to the vent
 480 using the best-fit values

481

482

483 **Fig. 9** (a) Histogram of calculated initial ejection velocities at the vent for the 230 bombs trajectories
 484 reconstructed during the 17:20 eruption using the model and its extrapolation. (b) Apparent drag
 485 coefficient c calculated using the model. The vertical lines indicate the radii corresponding to the values
 486 of c for $Cd=0.7$ and a bomb density of 1800 kg m^{-3}

487

488 Contribution of 3D reconstruction for conduit processes

489 The computed trajectories for six eruptions show a preferential direction of ejection to the south-
490 west. It could be argued that such a direction, away from the camera, could be an artefact. Bombs ejected
491 parallel to the line between the vent and the cameras could be more difficult to identify because of their
492 location in the brightest area above the vent, potentially causing larger errors on their trajectories. To
493 check if the calculated direction is correct, we have also taken photos of the same vent from the summit
494 of Stromboli (Fig. 2). From this view angle perpendicular to the view angles of the cameras, the direction
495 of ejection calculated, towards the south-west, is clearly confirmed (Fig. 10).

496

497

498 **Fig. 10** Photograph of the eruption at 12:56 UT (Oct. 5, 2012); taken from the south-east (Pizzo) showing
499 that the ejection is oriented to the SW (location of the photo on Fig. 2)

500

501 Our method might also be a useful tool for understanding conduit processes. It shows that, during
502 the period studied, the direction of bomb ejection was either uni-directional or multi-directional and that
503 it varied over time during an eruption and among eruptions within timescales of tens of minutes. For the
504 eruptions at 17:04 and 17:20, the first bombs were ejected with relatively slow velocities ($50 - 100 \text{ m s}^{-1}$)
505 and in all directions (Fig. 7 a,b). The emissions then evolved to higher velocities with a predominant
506 direction of ejection (N200). This is compatible with a slug of gas that reached the surface (James et al.,
507 2004; Leduc et al., 2015). The explosions initially occurred close to the surface and they ejected bombs
508 radially. Afterwards, the successive explosions might have become progressively deeper, and more

509 influenced by the orientation of the magma conduit, which seems to have been oriented N200 with a dip
510 of about 75° (95% of the trajectories lie between 60° and 85°) during our field campaign. These values
511 are compatible with the inclinations obtained from the locations of VLP seismic events (Chouet et al.,
512 2008a) even if the comparison is limited by the strong morphological changes that have affected the
513 crater area within 15 years separating our field campaigns. The smallest eruptions at 17:47 and 19:00
514 correspond to superficial explosions, compatible with the radial directions of the bombs. However, it
515 appears that even during small and superficial eruptions the gas pressure can be high, based on the high
516 velocities recorded at 19:00.

517 The eruption at 19:12 provides a more complete view of the superficial geometry. It began by two
518 directions of ejection followed by a radial emission. The two directions of ejection, recorded to a lesser
519 extent at 17:04 (Fig. 5a), can hardly be explained by a simple conduit geometry. The explanation could
520 be that the directions of the explosions are controlled by the rheology of the superficial magma and its
521 spatial distribution. The upper part of the conduit may be clogged by pyroclasts (Capponi et al., 2016)
522 and is probably filled with a mixture of vesicular and denser, partially crystallized and degassed magma
523 (e.g. Lautze and Houghton 2007; Burton et al. 2007; Bai et al. 2011; Gurioli et al. 2014). The latter can
524 form static zones representing more difficult pathways, so that the preferential path of the rising slugs
525 would be around the edges of the degassed magma zones. An upper conduit that broadened towards the
526 surface, the top of which is partially obstructed by lava clots recycled from previous explosions in
527 variable amount and conditions, might explain how explosions could occur simultaneously in many
528 different orientations (Fig. 11). Perturbations of the static magma, rising of other slugs, or variations in
529 the slug properties (viscosity, gas content) downwards could explain how a radial explosion occurred 3
530 s after the beginning of the directed explosions.

531

532 **Conclusion**

533 We have developed a system of synchronised cameras for the automated reconstruction of hundreds of
534 volcanic bomb trajectories in 3D in space plus time. The synchronization, done by connecting the
535 cameras to the same computer, is essential for the study of high velocity phenomena. The reconstructed
536 trajectories, coupled with a ballistic model, allows deduction of bomb particle sizes (given shape and
537 density assumption) from their drag coefficients and to calculate their initial velocities at the vents as
538 well as their directions of ejection. Alternatively, if particle size is known, the drag coefficient can be
539 used to solve for shape and/or density. The trajectories reveal the time and space variations in velocities
540 and directions within single explosive events as well as between successive explosions. Their
541 interpretation is compatible with preferential paths of slugs, which can become focused at the edges of
542 the upper part of the conduit probably due to formation of a central viscous cap. Our method thus
543 represents a tool allowing insights into superficial magmatic conditions and their relation with particle
544 dynamics. It also provides calibration data for future techniques developed for emission dynamics
545 characterisation, such as the Doppler radar method (Gouhier and Donnadieu, 2008).

546

547

548 **Fig. 11** A possible scheme of the upper conduit of Stromboli compatible with the bomb trajectories
 549 observed. Radial ejections (red) can be explained by explosions near the surface. With time, the slug
 550 bursts at increasing depth, focusing the directions of ejections. The various directions observed may
 551 indicate heterogeneities in the magma rheology that can form more than a single path for the slugs

552

553 **Acknowledgements**

554 The multidisciplinary mission was funded by the Laboratory of Excellence ClerVolc (contribution
 555 number 393), the *Chaire d'Excellence de la region Auvergne* and the *Observatoire de Physique du*
 556 *Globe de Clermont-Ferrand*. The development of the stereoscopic system was funded by the

698

699 **Online Resource**

700 Numerical codes (ESM-1), movies (ESM-3 and ESM-4), explanations (ESM-2) and images sequences
701 of camera 1 and 2 can be downloaded from the OPGC (*Observatoire de Physique du Globe de Clermont-*
702 *Ferrand*) website: <http://opgc.fr/SO/televolc/stereovolc/data/Stromboli/Codes&data.html>

703

704 **ESM-1:** simplified versions of the codes used and sample images to explain the method (2 Mo).
705 The codes are written in Matlab and compatible with the free software Octave. Images sequences needed
706 by the codes must be download here (80 Mo):
707 <http://opgc.fr/SO/televolc/stereovolc/data/Stromboli/Codes&data.html>

708 **ESM-2:** list and description of the codes of ESM-1 and details of the numerical model.

709 **ESM-3:** movie of the bomb tracking used for the trajectories reconstruction of figure 3. Eruption
710 of 17:20 UT, on October 5, 2012, taken by camera 2 (location shown on figure 2).

711 **ESM-4:** animated images of the method of matching trajectories. The code used,
712 `Seeks_matching_trajectory_from_epipolar.m`, is given in Online Resource 1.

713

714
