ABSTRACT

The relative biological effectiveness (RBE) in particle therapy is currently estimated using biophysical models. We compared experimental measurements to the α (LET) curves computed by the Local Effect Model (LEM I-IV), the Microdosimetric Kinetic Model (MKM) and the NanOx model for HSG, V79 and CHO-K1 cells in response to monoenergetic irradiations. Although the LEM IV and the MKM predictions accurately reproduced the trend observed in the data, NanOx yielded a better agreement than the other models for more irradiation configurations. Its χ^2 estimator was indeed the lowest for 3 over 7 considered cases.

1. INTRODUCTION

Due to its increased efficiency in inducing biological damage, particle therapy offers advantages over the standard radiotherapy modalities for the treatment of radioresistant, unresectable tumors close to organs at risk [1, 2]. Several experimental studies have shown evidence that the relative biological effectiveness (RBE) of ions with respect to photons depends on multiple parameters related to the incident beam, the irradiation conditions and the intrinsic properties of the biological system [2]. Therefore, to optimize the 3-dimensional distribution of the dose to be received by the patient during a session, the predictions of RBE are integrated into the treatment planning system (TPS). While the first approach used in clinics was based on RBE values derived empirically from the *in-vitro* response of a well-known tumor cell line to neutron beams [3], the progressive diffusion of active beam delivery favored the implementation of biophysical models in the TPS. This triggered the development and the improvement of many frameworks, the most acknowledged ones being the Local Effect Model (LEM) and the Microdosimetric Kinetic Model (MKM).

The LEM I [4, 5], II [6], III [7] ascribes the biological effectiveness of ions to the specific energy deposition pattern at “local” scale, which is estimated in terms of a radial dose ($D(r)$). Although enabling fast and efficient calculations, the use of the expected quantity $D(r)$ to describe processes occurring at the nanoscale leads to some incongruities; for example, the shoulder in cell survival curves results from an artifact due to the superimposition of the radial doses associated to several impacting ions [14]. The issue was solved in the LEM IV [8], a substantially different version of the local effect model in which the cell nucleus is divided into critical regions corresponding to DNA giant loops. In these domains the microscopic spatial distribution of DNA double strand breaks is computed on the basis of the radial dose.

The MKM [9] combines a microdosimetric description of the energy deposition (accounting for the statistical fluctuations) with a kinetic representation of the repair and injury processes. The probability of cell survival, however, is not computed considering an average process over the irradiation configurations, but simply in terms of a Poisson distribution of the mean number of lethal lesions. The distribution is corrected defining a geometry for the cell nucleus in order to avoid the overestimation of the ions efficacy in the tumor [10].

More recently, NanOx [11, 12, 13] was developed by the authors to address the challenge of implementing the stochasticity of the energy depositions at nanometric and microscopic scales when predicting radiation-induced effects. This is fulfilled in the modeling of the number of radiation impacts associated to a given dose, of the dose-deposition pattern along the track and of the inter-track processes. The cell inactivation is ascribed to two classes of biological events occurring at different spatial and temporal scales, in a manner similar to that proposed by Katz *et al.* [15]. Local lethal events are attributed to one track and are described in terms of nanodosimetry, while global events resulting from the contribution of several tracks are represented by the accumulation of oxidative stress and sublethal damages.

We decided to benchmark the predictions issued from these models against experimental data to verify if the implementation of a fully stochastic theory at nano and micro-scale had an impact on the precision of the predictions. In this paper we considered as biological endpoint the slope of cell survival curves since this is the one reported most extensively in the literature, both for measurements and theoretical calculations.

2. MATERIALS AND METHODS

2.1 Experimental data

Our study focused on the response of three cell lines to monoenergetic beams of several ion types (from hydrogen to neon) and energies (from 0.8 to 266 MeV/n). We chose normal lung fibroblast (V79) and ovary (CHO-K1) cells from a Chinese hamster due to the large amount of data available in the literature, and human tumor cells from salivary glands (HSG) since head and neck cancers match the therapeutic indications for particle therapy.

The experimental α values were gathered from the database made available by the PIDE project [17]. Although for most of the measurements the error bars are not reported, the great data dispersion allows one to infer the important biological

102 variability and the effects of the use of different biological and irradiation protocols. In spite of this dispersion, however,
103 it is noticeable that α values rise for LET values up to 150-200 keV/ μ m (depending on the ion type), and drop for higher
104 LET values. The initial trend is associated to the action of swift ions, which scarcely ionize the traversed biological
105 tissues by depositing only small amounts of energy; progressively slower ions, on the contrary, produce a considerable
106 ionization density in the medium leading to the increase of the biological effectiveness. The decrease of the α curves is
107 due to the “overkill” effect, which may be explained in terms of two phenomena: firstly, for constant irradiation doses the
108 fluence of incident particles is inversely proportional to the LET, and secondly, the tracks of high LET ions are narrow;
109 the probability of hitting the cellular sensitive targets and inducing biological damages is, thus, fairly low.
110

111 2.2 Models predictions

112 The α values predicted by the LEM I, II, III, IV and the MKM for all the considered radiation types and cell lines were
113 extracted from [8, 16] and for each of these models, the calculations were reported only for the irradiation cases for
114 which published results could be found. The values of α predicted by NanOx, on the contrary, were computed by the
115 authors especially for this work. Precisely, theoretical cell survival curves were first calculated as explained in [11, 13],
116 and then a linear fit at low doses allowed extraction of the slope α .

117 As Table 1 shows, all the models were evaluated considering a unique set of parameters per cell line, *i.e.* avoiding tuning
118 and optimizations which would depend on the irradiation ion type. As explained in [8, 12, 16], the choice of the
119 parameters was made in order to optimize the conformity between the predicted α values and the experimental ones
120 available from the literature.
121

122 2.3 Benchmark estimator

123 In order to quantify the agreement between the predictions issued from each model and the data, we computed the χ^2 as:

$$124 \chi^2 = \frac{1}{M} \sum_{i=1}^M \left(\frac{\alpha_{exp}^i - \alpha_{pred}^i}{\alpha_{exp}^i} \right)^2 \quad (1)$$

125 In Eq. 2, M represents the total number of experimental points pertaining to the PIDE dataset [17] for a given cell line
126 and ion type, and α_{exp}^i (respectively α_{pred}^i) denotes the i^{th} experimental (resp. predicted) α value.
127

128 3. RESULTS

129 **Figure 1** shows the slope α as a function of LET for HSG, V79 and CHO-K1 cells in response to hydrogen, helium,
130 carbon, oxygen and neon ions. While the LEM I was inadequate to reproduce the experimental trend for almost all of the
131 considered cell lines and radiation types, some amelioration was visible for the LEM II and III, mostly in the high LET
132 range. An important disagreement between theoretical and observed α values, however, was apparent in the low LET
133 range: the curves predicted by the LEM II (except for CHO-K1 cells in response to carbon ions) and by the LEM III in
134 the case of irradiation by light ions, were overestimated, whilst the curves predicted by the LEM III for heavy ions
135 irradiation, on the contrary, were underestimated. On the other hand, the experimental increase of α for LET values up to
136 150-200 keV/ μ m and the subsequent decrease observed for higher LET were overall well reproduced by the MKM, the
137 LEM IV and the NanOx model. **Figure 2** and **Table 2** present the χ^2 estimator for each model, cell line and ion type. The
138 intercomparison highlighted that NanOx’s predictions were the most precise over the seven configurations, yielding the
139 minimum χ^2 in three cases: for HSG cells in response to He ions, for V79 cells in response to C ions and for CHO-K1
140 cells in response to C ions. Our model was followed by the LEM IV and the MKM, which achieved the smallest χ^2 in two
141 cases each.
142

143 DISCUSSION

144 The optimization of treatment plans in particle therapy strongly relies on the link between the energy deposition pattern
145 and the expected biological response. Since such a link is currently provided by the biophysical model specifically
146 implemented, it is of utmost importance to review and compare the main existing frameworks.
147

148 Recently, Stewart *et al.* [18] pointed out the differences among the LEM IV, the MKM and the Repair-Misrepair-
149 Fixation (RMF) model in the input parameters, the relevant biological targets and the computational strategies. The main
150 principles and the seemingly contradictory aspects of the models were discussed, but the article did not report an
151 extensive benchmark of the different predictions against radiobiological measurements. Stewart *et al.* concluded that
152 “future comparisons of model predictions with experimental data are needed to fully discriminate among competing
153 mechanisms and models of particles RBE”. We hence decided to test the accuracy of well-known cell survival models

154 considering a common biological endpoint, the α (LET) curves of HSG, V79 and CHO-K1 cells in response to
155 monoenergetic irradiations, and as well as to examine the predictive power of NanOx. In order to quantify the agreement
156 of the predictions with the experimental measurements found in the literature, a χ^2 calculation was performed for each
157 cell line and irradiation type: NanOx yielded the lowest χ^2 for more configurations than the other models. This result
158 should be considered in light of two facts: first, in some cases the difference in the χ^2 was small; and second, according to
159 the published references several calculations were missing for the seven irradiation configurations that we considered. In
160 particular, since the LEM IV predictions were available for only 3 cases, this model achieved the highest percentage of
161 lowest χ^2 values. More generally, our study highlighted that the predictions issued by the LEM IV, the MKM and the
162 NanOx model were appropriate considering the important dispersion of the experimental data, while the LEM I, II and III
163 did not satisfactorily reproduce the observed biological effect of ions.

164 Even though the irradiation of *in-vitro* cells considered in our study are by far not representative of particle therapy
165 treatments, a question may arise on the relevance of the current implementation of biophysical models in the clinical
166 TPS.

167 The LEM I represents the standard in the European particle therapy facilities since it minimizes the risk of overestimating
168 the doses prescribed to patients, and complies with the need of radiotherapists to rely on stable protocols. However, its
169 description of the radiobiological response of V79, CHO-K1 and HSG cells was the least accurate among the models
170 considered in our study. A modified version of the MKM (mMKM [21, 22, 23]) developed by Kase *et al.* is instead
171 integrated in the Japanese clinical TPS. It predicts the decrease of RBE caused by the overkill effect owing to a revised
172 saturation correction, and is based on amorphous track structure models (i.e. on the controversial radial dose), allowing
173 fast calculations. We believe that in the context of clinical research it would be relevant to evaluate the predictive
174 qualities of other biophysical models and of the several modified and improved versions of the existing frameworks. This
175 could be achieved, for example, by performing calculations with each model in clinical conditions and trying to correlate
176 them to clinical data; it would be fruitful to bridge over the advances in research and the clinical routine of particle
177 therapy.

178 In conclusion, we showed in this paper that NanOx predictions for three cell lines irradiated by monoenergetic ions were
179 more often more accurate than the ones issued from 5 other biophysical models; however, in some cases the difference
180 with respect to the LEM IV and the MKM was small, and some theoretical calculations were missing. More reliable
181 conclusions may be derived if an experimental dataset characterized by lower biological variability was available, and if
182 all the biophysical models were tested more systematically for a wide range of irradiation configurations.

183

184 **ACKNOWLEDGMENTS**

185 This work was supported by ITMO Cancer (Project Nos. PC201312 and PC201606) and was performed in the
186 framework of the LABEX PRIMES (ANR-11-LABX-0063) within the program “Investissements d’Avenir” (ANR-11-
187 IDEX-0007) operated by the French National Research Agency. We thank Jayde Livingstone for her careful reading.

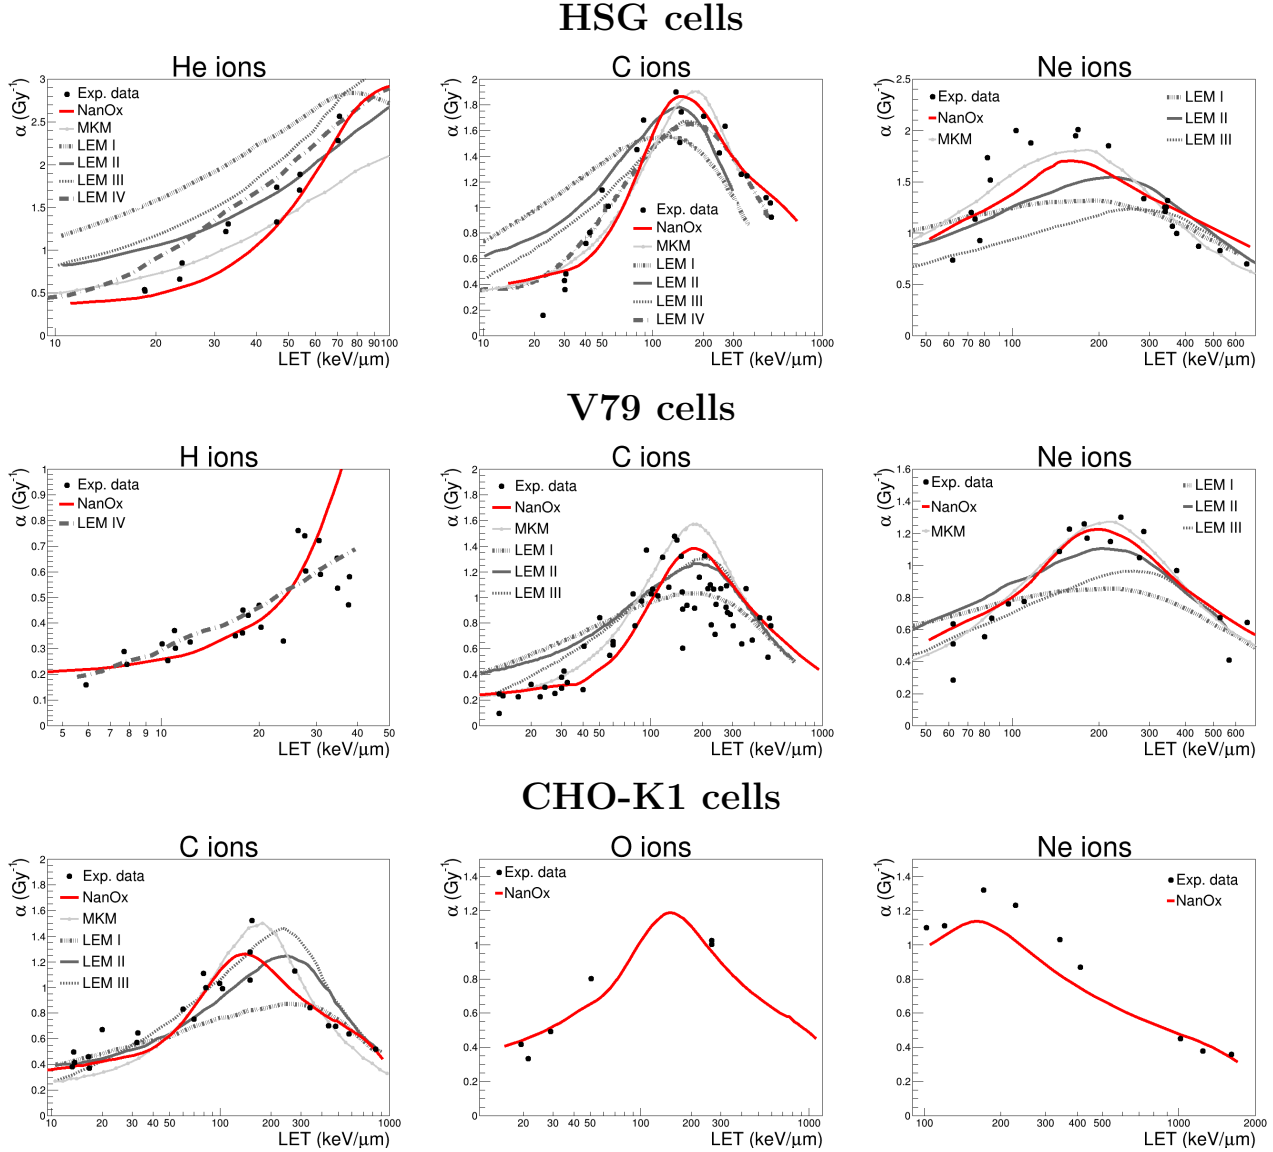

Figure 1: Evolution of the slope α with LET for HSG, V79 and CHO-K1 cells irradiated by hydrogen, helium, carbon, oxygen and neon ions. The experimental values gathered from the PIDE database [17] are compared with the predictions provided by the four versions of the LEM (when available), the MKM and NanOx. The data relative to the LEM and the MKM are extracted from [8, 16]. All the models are evaluated considering a single set of parameters for each cell line, which have been chosen as they optimize the agreement with the experimental points.

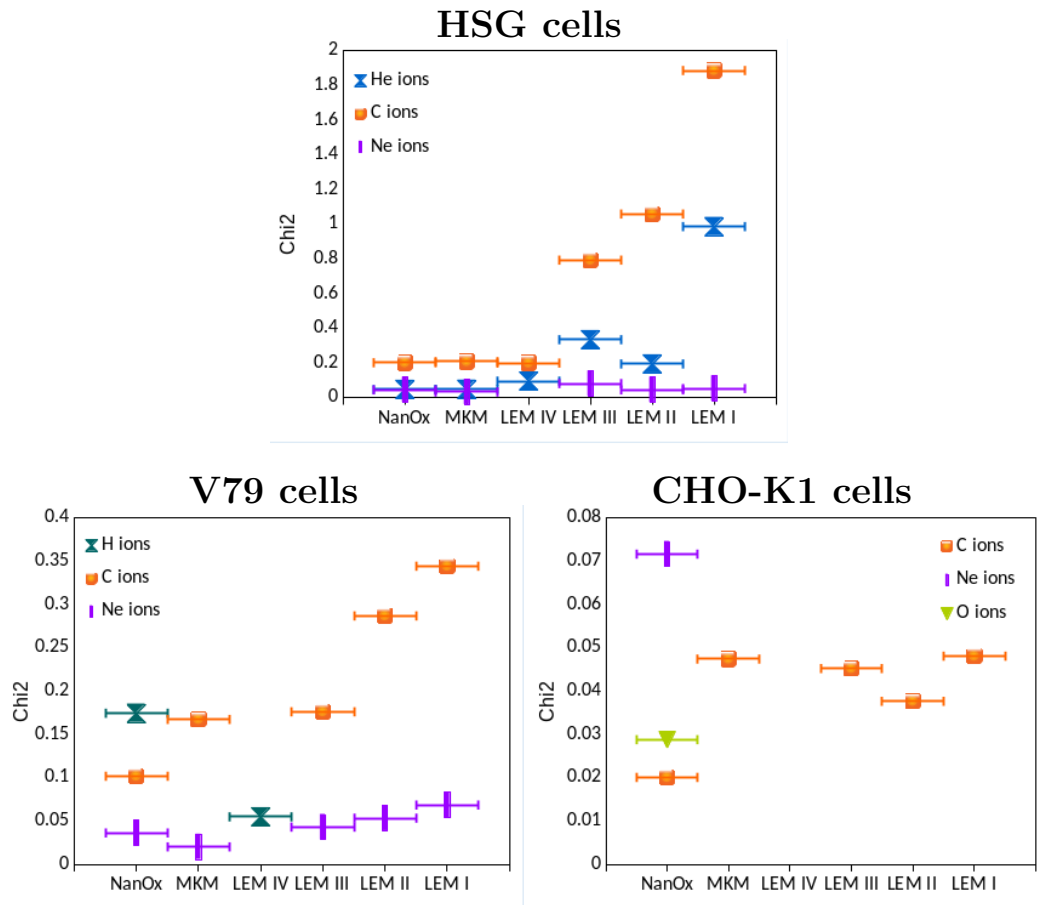

Figure 2: χ^2 associated to each radiobiological model on the basis of the experimental and predicted points of Figure 1. The symbols represent the values computed separately for HSG, V79 and CHO-K1 cells irradiated by hydrogen, helium, carbon and neon ions. The solid lines, instead, are for visual guidance purposes only.

Cell line	Model parameters
