Abstract

Fast detection of bacteria in samples presumed to be un-contaminated, such as blood, is of great importance. Indeed, rapid diagnosis allows the set-up of appropriate antibiotic treatment. Besides clinical issues, there are many other domains, such as food processing or drug manufacturing, where the strict absence of any bacteria has to be assessed. Because the bacterial load found in most contaminated samples is often below the limit of detection for currently validated assays, a preliminary enrichment step is required to allow bacterial multiplication before proceeding to the analysis step, whatever it might be – cultural, immunological or molecular methods. In this study, we describe the use of a biosensor for single-step bacteria detection. The whole analysis is performed in less than 20 hours, during the growth phase of the micro-organisms, using an array of antimicrobial peptides (AMPs) coupled with a surface plasmon resonance imager (SPRI). A wide range of bacterial strains are assayed, showing differentiated affinity patterns with the immobilized peptides, which are confirmed by multivariate analysis. This work establishes the evidence that antimicrobial peptides, mostly used so far in the antibiotic drug industry, are suited for the wide-spectrum detection of unknown bacteria in samples, even at very low initial loads. Moreover, the small set of AMPs that were assayed provided a specific affinity profile for each pathogen, as confirmed by multivariate analyses. Furthermore, this work opens up the possibility of applying this method in more complex and relevant samples such as foodstuff, urine or blood.

Antimicrobial Peptides; Bacteria Detection; Pathogens; Surface Plasmon Resonance imaging

33 Introduction

34 The presence of bacteria in a normally sterile environment is a huge issue for human health,
35 since it can cause severe infections. Whether they originate in foodstuffs or bodily fluids such as
36 blood or urine, the rapid and sensitive detection of pathogenic microorganisms is thus of great
37 importance. Although fast diagnosis is vital during an infection, the early detection of pathogens
38 is made difficult because of their low concentrations. For this reason, all samples drawn from
39 patients are first diluted and cultured in a liquid medium to increase the bacterial concentration,
40 before proceeding to the analysis of the enriched samples. So far, culture-based techniques
41 have remained the gold standard in the process of diagnosing bacterial infections, though
42 several alternative methods have emerged in recent decades to devise faster and more
43 sensitive ways to achieve bacterial detection [1]. Assays based on DNA amplification have
44 paved their way to a large use in clinics [2]. In spite of their faster response, these assays are
45 still time-consuming, quite expensive, and require a high level of skills. Moreover, such methods
46 may give false-positive results due to the presence of residual DNA, released from killed
47 pathogenic bacteria in some samples, for instance after antibiotic treatment. Mass spectrometry
48 has also become widely used for the precise identification of strains [3]. However, it requires
49 isolated colonies of the pathogen to be grown on a solid medium and thus can only be
50 performed several days after enrichment of the sample. Owing to these considerations, new
51 technologies enabling faster diagnostics are still emerging, promising simple and low-cost on-
52 field implementation [4,5]. Amongst other alternatives under research, biosensors able to detect
53 whole viable cells directly from a suspect sample are very promising. Nevertheless, each of
54 these exciting alternatives still require a preliminary enrichment step to increase the initial
55 bacterial concentration above their limit of detection (10^3 to 10^6 CFU.ml⁻¹, depending on the
56 method). Surprisingly, only a few approaches couple the enrichment step with the detection
57 step. From this perspective, surface plasmon resonance imaging (SPRI) is a promising method.
58 Indeed, this technique is based on the optical detection of interactions at the surface of a
59 metallic layer, thus enabling the monitoring of molecular interactions without labels. Although
60 SPRI-based molecular detections are less sensitive than ELISA for biomolecular interaction
61 studies, SPRI has been used in versatile applications from molecular studies to whole cell or
62 living bacteria detection, taking advantage of its real-time and label-free multiplexing abilities
63 [6,7]. This optical method has already proven its ability to successfully detect and identify
64 pathogens starting from food matrices or blood spiked with low bacterial concentrations (few
65 CFU.ml⁻¹), using arrays of proteins and antibodies [8–11]. Such one-step approach enables
66 sensitive detection during the enrichment phase, with a wide range of probes used in parallel
67 that hence allow a high selectivity. However, although antibodies or other protein probes have
68 been proven to have high efficiency as ligands (enabling strain or even serotype identification)
69 they are known to present several difficulties such poor stability, difficulty of production, high
70 cost, and/or burdensome handling. It is the reason why new sets of probes have been benched
71 by researchers, the most prominent being aptamers, molecularly imprinted polymers, and
72 peptides [12]. Aptamers and molecularly imprinted polymers usually show high specificity and
73 reliability [13,14]. Nevertheless, to achieve wide spectrum detection, the multiplexing of large
74 series of probing ligands remains an issue, which limits the extent of wide spectrum detection.

75 Antimicrobial peptides (AMPs) are a subset of peptides presenting outstanding bactericidal
 76 activity [15,16]. Their binding to bacteria mainly relies on physico-chemical interactions, due to
 77 their polycationic or amphiphilic characteristics. Hence, they can easily attach to negatively
 78 charged lipopolysaccharides (LPS) anchored in the membrane of Gram-negative bacteria via
 79 electrostatic interactions [17,18]. Conformational changes of their structure can also mediate the
 80 attachment to bacterial outer walls [19]. Although AMPs have so far mainly been investigated to
 81 design new drugs or antimicrobial applications [20], they are also promising ligands as potential
 82 alternatives to antibodies as large spectrum recognition elements towards bacteria [21,22].
 83 Indeed, they have naturally evolved to interact with a wide range of pathogenic bacteria and they
 84 are not only easy to synthesize but also easier to handle than antibodies for instance, since they
 85 can resist harsh chemical conditions and air-drying for storage.

86 Surprisingly, the use of AMPs as recognition elements has only rarely been commented on in
 87 the literature [23–26]. Those studies relied on the specific recognition of particular groups of
 88 bacteria, for instance targeting either a bacterial genus or a Gram class. Herein, we demonstrate
 89 the use of AMPs in a multiplexed fashion, with several different peptidic probes exposed to a
 90 contaminated sample. Thanks to the development of antimicrobial peptides arrays, we expand
 91 the spectrum of detectable bacterial strains in a single one-step assay. Wide-spectrum sensing
 92 of bacterial pathogens would hence be achieved. A set of AMPs inspired by previous works on
 93 biosensors (see *Table 1*), has been produced by solid-phase synthesis and arrayed on the gold
 94 surface of SPRI prisms. Such arrays were then assayed with a series of samples spiked with
 95 pathogenic bacteria at low levels. Those strains are representative of major species encountered
 96 in both foodborne infections and bacteremia. We were thus able to assess the performance of
 97 such peptide-based sensors for wide-spectrum detection of bacteria.

98 Material and methods

99 Reagents

100 Phosphate Buffered Saline (PBS), Dimethyl Sulfoxide (DMSO), Bovine Serum Albumin (BSA),
 101 glycerol and Tryptic Soy Broth (TSB) culture medium were purchased from Sigma-Aldrich (Saint
 102 Quentin Fallavier, France). The solid culture medium Tryptone Soy Agar (TSA) was bought from
 103 bioMérieux (Lyon, France). Ultra-pure water (18,2 M Ω of resistivity) was obtained from an ELGA
 104 PURELAB flex dispenser (Veolia Water, France).

107 *Table 1. Set of arrayed antimicrobial peptides. Sequences are listed along with the bacteria they*
 108 *can detect, the detection techniques that they were used in and literature references for each.*
 109 *Spacer is corresponding to AEEA.*

110

111 All peptides were synthesized by Smart Bioscience (Saint Égrève, France) through standard
 112 Fmoc solid-phase method. A (2-(2-(amino)ethoxy)ethoxy)acetic acid (AEEA) spacer was
 113 inserted between the peptide sequence and the additional terminal cysteine. When this cysteine
 114 amino acid was added at the C-terminus, the supplier amidated this latter to achieve higher
 115 synthesis yields, otherwise the terminal amino acid was left free. The sequences of the chosen
 116 peptides are listed in *Table 1*. The certificates of analysis furnished by Smart Bioscience are
 117 given in the Electronic Supplementary Information to confirm peptide purities and molecular
 118 weights.

119 Bacterial strains

120 The *Salmonella enterica* subspecies *enterica* serovar Typhimurium (*S. Typhimurium*),
 121 CIP104474, was obtained from the Pasteur Institute (Paris, France). *Listeria monocytogenes*
 122 strain belonging to the molecular serotype IVc was acquired from the Institut Scientifique
 123 d'Hygiène et d'Analyse (ISHA, Massy, France). It had been isolated from chicken meat. The
 124 methicillin-resistant *Staphylococcus aureus* subspecies *aureus* (MRSA), ATCC43300, the
 125 *Staphylococcus epidermidis* strain, ATCC12228, and the *Escherichia coli* serovar O1:K1:H7
 126 (isolated from urine), ATCC11775, were all purchased from the American Type Culture
 127 Collection (Manassas, Virginia, USA).

128 Culture conditions

129 Prior to each experiment, an individual bacterial colony was isolated on a TSA plate and
 130 resuspended in 4 mL of sterile TSB. This bacterial culture was then incubated for 18 hours at
 131 37°C under constant agitation (180 rpm). Ten-fold serial dilutions of the bacterial suspension
 132 were then performed in TSB. 100 μL of one of the ten-fold dilution series was used for sample
 133 spiking. The 10^{-5} and 10^{-6} dilutions were plated (100 μL on TSA plates, in triplicates) to
 134 determine the initial bacterial concentration through manual colony counting. For each assay,
 135 sterility controls were performed.

136 Peptide arraying

137 Lyophilized peptides were resuspended in DMSO at 1 $\text{mg}\cdot\text{mL}^{-1}$ and stored at -80°C. Each
 138 peptide sequence was diluted at 100 μM in PBS 1x, with 5% (v/v) of glycerol ahead of arraying
 139 biochips. SPRI-biochips bought from Horiba Scientific (Palaiseau, France) consisted of glass
 140 prisms coated with a thin gold layer for direct functionalization using thiol moieties (see fig. S1 in
 141 the Electronic Supplementary Information for more details). Peptide biochips were prepared

142 using a sciFLEXARRAYER (Scienion, Berlin, Germany), a piezo-dispenser allowing arraying of
143 4 *nL* droplets per spot. Each array resulted in 12 spots with a 450 μm diameter, and a 800 μm
144 pitch between each spot. All peptides were systematically arrayed in duplicate. This step was
145 performed at room temperature under a humid atmosphere (75% relative humidity). After
146 arraying, prisms were incubated for 18 hours at 25°C, under 94% humidity, to allow the
147 complete formation of self-assembled monolayers of peptides onto gold. Chips were then rinsed
148 with ultra-pure water, dried under an argon flow for a few seconds, and stored up to several
149 weeks at +4°C until experiments. Effective surface functionalization was assessed by AFM
150 comparison with bare gold surfaces (supplemental figure S2).

151 Biochip conditioning and sample processing

152 Prisms were systematically incubated with a sterile solution of PBS+1% BSA before each
153 experiment to mimic interfering proteins of complex media such as blood, and to block non-
154 specific interactions with gold. The surface of the prism was then rinsed with 3 mL of sterile PBS,
155 before loading the biochip in the Surface Plasmon Resonance imager. 900 μL of sterile TSB
156 were then injected in the culture chamber containing the AMP-array, followed by 100 μL of the
157 bacterial dilution used for spiking. Interactions of bacteria on the surface of the prisms were
158 observed in real-time with the SPRi-Lab+ system (Horiba Scientific, Palaiseau, France), at 37°C.
159 The AMP-array was positioned so that its surface was vertical, on the sidewall of the culture
160 chamber. This avoids any non-specific signal from sedimenting bacteria. Sensors were
161 systematically discarded after use.

162 SPR data analysis

163 Real-time monitoring of the SPR signal began when the bacteria were spiked into the sample.
164 Regions of interest (ROI) were defined on each duplicate of AMP spots, in order to monitor the
165 temporal change of reflectivity. Kinetics data were directly collected and processed in R
166 programming language. Duplicate spots of each peptide were averaged, corrected with respect
167 to the reference signal, and plotted. Peptide-free gold ROIs, coated with BSA, were chosen as
168 reference signals for non-specific interactions. Reflectivity shifts as a function of time for each
169 ROI allowed the assessment of the presence of bacteria in samples without further processing of
170 the data, by the observation of a temporal response shift. Kinetics data were used to generate a
171 database of interaction patterns between peptides and bacteria. For each spot, the first
172 derivative of the smoothed temporal data was calculated. The maximum value of this derivative,
173 as well as the corresponding smoothed reflectivity shift, were recorded. Unsupervised
174 multivariate analysis was performed on this database thanks to the FactomineR package,
175 embedded in the R software [34]. Names of targeted bacteria were used as a descriptive
176 variable, and therefore did not affect the results of the Principal Components Analysis (PCA). As
177 data were heterogeneous, they were centered and reduced. On one hand, PCA score plots were
178 used to distinguish results from one bacterial strain to another. On the other hand, they also
179 permitted a high level of repeatability of the process from different duplicates of the same assay.
180 Hierarchical Clustering on Principal Components (HCPC) was also performed on the outcome of
181 the PCA. This statistical method ensured that targeted bacteria were indeed discriminated from
182 each other, based on the Euclidean distance separating the replicates in the PCA results.

183

184

Results and discussion

185

Bacterial growth monitoring by SPRI

186

The set of five bacterial strains to be detected with the peptide array has been chosen to represent the diversity of pathogens frequently involved in bloodstream or urinary tract infections, as well as food poisoning. The set also reflects microbial morphological diversity, with both Gram-positive and negative species, including bacilli and cocci.

187

188

Growth kinetics monitored by SPRI of the bacteria are depicted in fig. 1, datasets retrieved from those results allow defining characteristic detection times of bacteria (Supplemental Table S1) and affinity patterns with the peptides.

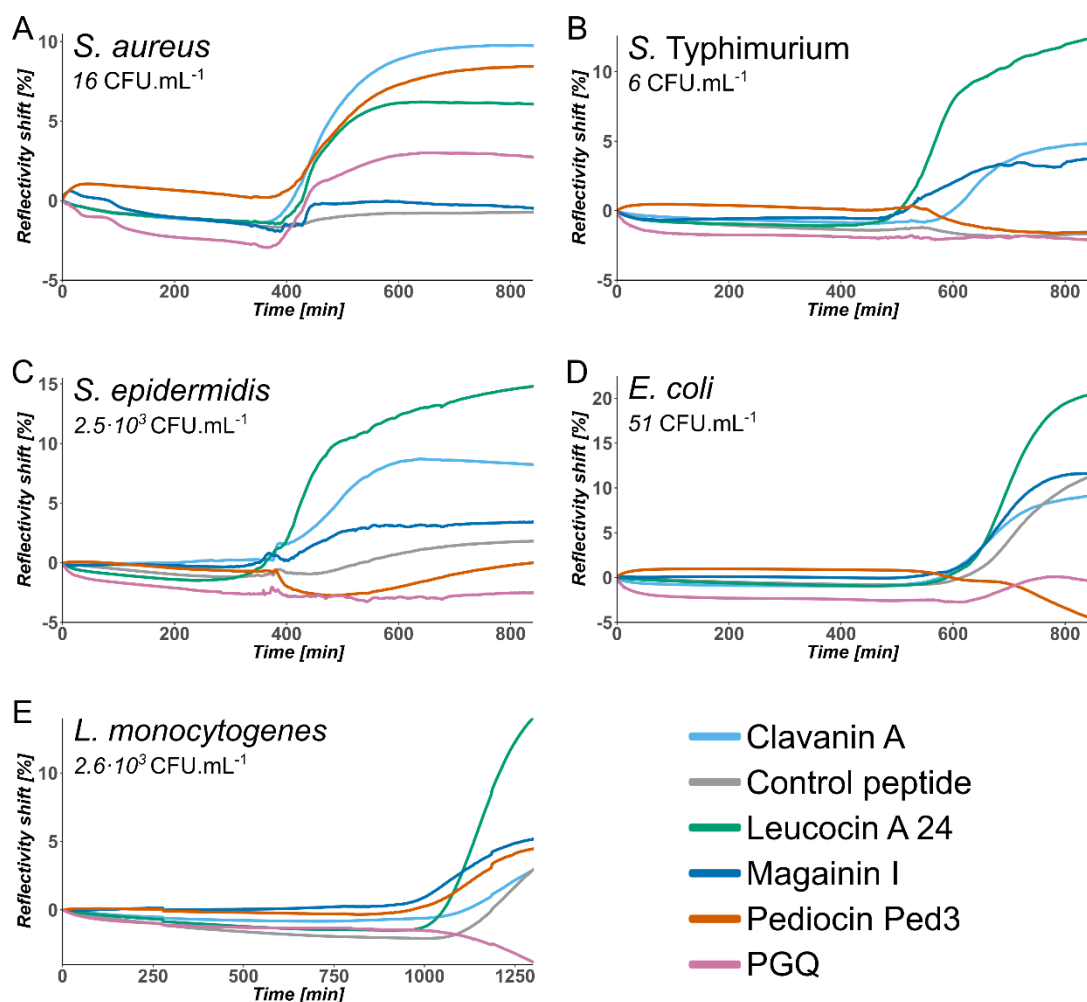

189

190

191

192

193

194

195

Figure 1. SPR kinetic data of the bacterial growth for five different bacterial strains cultured in tryptic soy broth at 37°C. Each curve is the average of duplicate spots for a given peptide arrayed on the sensor, with subtraction of the reference signal taken on peptide free gold.

196

197

198 AMP-based arrays have permitted the detection of pathogens present at low initial concentration
199 in all samples, at most in 19 hours, and in even less than 12 hours in the majority of cases. All
200 culture conditions being the same, variations of detection signal can come from dissimilarities in
201 generation times of the different strains. Shortest detection times were for *S. aureus* and *S.*
202 *epidermidis*, in about 6 to 7 hours. Similar conclusions with solid based culture methods are
203 hitherto obtained in at least 24 hours. Compared to other biosensing methods using AMPs to
204 analyze pre-enriched samples, we obtained a very low limit of detection of virtually one live
205 bacterium per sample. The coupling of the enrichment step in our one-step process, not only
206 improved the safety for the operator, but also significantly improved both the overall processing
207 time and the limit of detection, by comparison to the two-steps methods described so far.
208 Naturally, the lower limit of detection comes with a longer detection time to get bacterial
209 concentrations sufficient for SPRI detection.

210 Individual peptide responses for bacterial pathogens detection

211 Peptides showed very distinct profiles of response depending on the targeted bacterial strains.
212 Individual examination of their performances is thus interesting to understand underlying
213 interactions with bacteria. Interestingly, Leucocin A 24 interacted strongly with all tested bacterial
214 strains. Nonetheless, the scrambled version of Leucocin A 24, here used as a control peptide,
215 displayed only weak to no interactions at all with any bacterial pathogen, suggesting that
216 interactions of bacteria with tethered peptides are not only governed by physico-chemical
217 mechanisms but more probably by structural interactions between peptides and bacterial
218 membranes. Such observation has already been described for therapeutic peptides [35].
219 Clavanin A functionalized surfaces exhibited stronger SPRI responses with *Staphylococci spp.*,
220 which are Gram-positive bacteria, although this peptide also enabled to successfully detect
221 *Salmonella Typhimurium* and *E. coli*, although with weaker interactions. With our method,
222 Magainin I only displayed mild interactions with all the tested bacteria, whatever their Gram
223 coloration (except for *S. aureus* which gave a very low shift). On the contrary, Ped3, a Pediocin
224 fragment, exhibited a moderate ability to detect *Listeria monocytogenes*, as previously described
225 [31], but surprisingly Ped3 also displayed a potent interaction with MRSA in our assay. In the
226 meantime it did not interact with *S. epidermidis*, although they belong to the same *genus*. This
227 selective response might be caused by an association of the peptide with a peculiar receptor
228 specific to the membrane of MRSA. PGQ displayed interactions with *E. coli*, which is consistent
229 with the literature [32]. However it detected *S. aureus*, which is a Gram-positive strain, and had
230 no apparent interactions with *Salmonella*, another Gram-negative bacterium, that also displays
231 LPS, which is a hint that the interactions between PGQ and bacteria is not only mediated by
232 interacting with the latter.

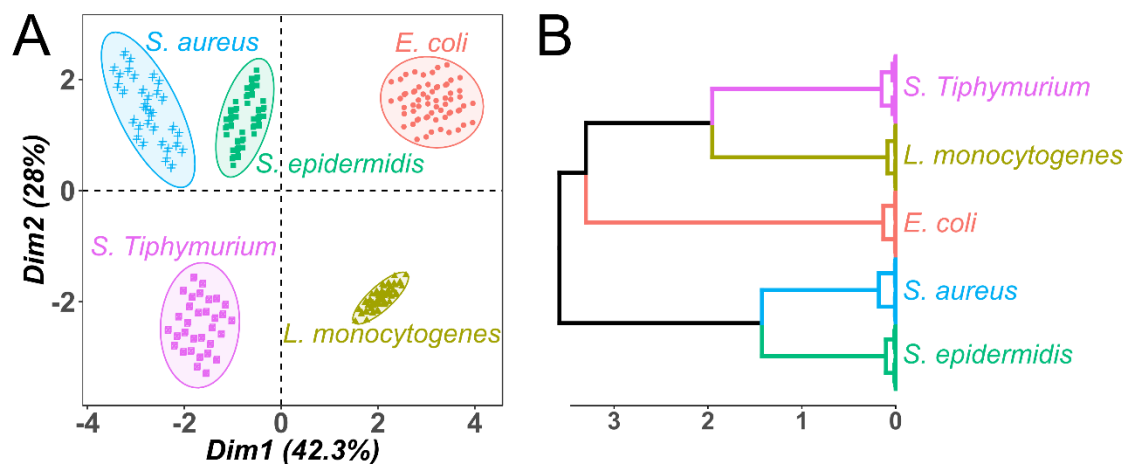

233 These results tend to show that AMPs keep a wide spectrum of affinity towards bacteria after
234 tethering on a surface. Moreover, association of AMPs enabled to obtain various kinetic profiles
235 depending on the bacterial strain. Interestingly, our SPRI detection method allowed to unravel
236 interactions which remained unobserved with other methods [25]. This could be explained by the
237 establishment of weaker interactions between bacteria and AMPs thanks to their longer
238 exposure time to the cultured bacteria.

239 Multivariate analyses of kinetic results

240 Multivariate analyses were performed to objectively assess the discrimination values of our
241 method. To do so, PCA was performed based on reflectivity shift and sensitivity values at the

242 maximum of the first derivative for each peptide (Figure 2A). Each bacterial strain was
 243 processed once on an AMP micro-array, giving 64 sets of values, from all possible combinations
 244 of peptide duplicates responses at the surface. This combinatorial analyzing method ensured
 245 that statistical variability of the overall response was totally represented, and that cherry picking
 246 of data was avoided. Experiments on different bacterial strains with the same set of AMPs gave
 247 clustered results in the PCA 2D-score plot. Moreover, those clusters of data points were well
 248 segregated from each other according to the monitored pathogen: results were repeatable
 249 regardless of the set of replicates in the same monitoring. The first two principal components
 250 represented only 70.3% of the total variance. This meant that the data were of high
 251 dimensionality, thus explaining why such a good discrimination between bacterial strains could
 252 be obtained. However, those first two components were sufficient in our case to clearly
 253 distinguish between distinct bacterial strains. Such results underlined potential identification
 254 ability of the method, although more experiments would be required to create an even more
 255 exhaustive database. Results of the PCA were also used to perform a Hierarchical Clustering on
 256 Principal Components (fig. 2B), leading again to a satisfying separation of the different strains in
 257 separate clusters. Such discriminated profiles came from the variety of affinities displayed by the
 258 peptides towards the tested bacteria. Due to different physicochemical properties and structures,
 259 each peptide interacted differently to Gram or genera, hence the overall combination
 260 discriminated the tested strains. Multivariate analyses with appropriate databases thus allow
 261 pathogen identification methods to be derived from the usual key-lock principle and enable
 262 cross-reactivity sensors as demonstrated by [36].

270

271 In this work, we demonstrated the suitability of AMP-arrays as powerful ligands of bacterial
 272 pathogens. Traditionally studied in the field of pharmacology and antimicrobial applications,
 273 AMPs were revealed to be potent ligands for pathogens in biosensing applications. Not only they
 274 are well-adapted for the detection of bacteria in a standard culture medium such as tryptic soy

275 broth, but compared to antibodies, the biochip functionalization and operation were less tedious,
276 thanks to peptide resistance to air-drying without loss of activity in the process.

277 The use of AMPs in a multiplexed fashion allowed a fast and simple assessment of the presence
278 of pathogens even at low concentrations. Detection times ranged from 6 to 19 hours, in a one-
279 step assay. This is shorter than standard methods in blood or foodstuffs, which require
280 enrichment times of usually 24 hours before confirmation of the culture positivity. Each tested
281 bacterial strain resulted in different kinetic responses on the part of the AMP-array. Ped3 even
282 exhibited a near-specific behavior, interacting almost uniquely with MRSA. Further studies could
283 assess this point, which would be of importance in the detection of this prominent pathogen. Our
284 results, for instance for Leucocin A24 and its scrambled version, showed that the recognition of
285 bacteria by AMPs is not uniquely driven by physico-chemical interactions, but also by their
286 secondary structuration. Moreover, tethering of the AMPs on the surface of our sensor did not
287 seem to alter this interaction with bacteria in solution. The study of the whole set of AMPs
288 interacting with live bacteria gave clearly different affinity profiles. This combined approach was
289 preferred to a biomolecular study to enable the identification of several bacterial pathogens, with
290 a single AMP set. The response to polymicrobial infections, which represent only 10% of
291 bloodstream infections [37,38], is still to be investigated to check how AMPs responses might be
292 deciphered to identify two, or more, pathogenic strains present in the same sample.

293 Furthermore, the small set of AMPs we used provided very distinct affinity profiles towards
294 different pathogens, as multivariate analysis confirmed. Arrays presenting a larger collection of
295 peptides could hence enable the possibility to create interaction profile libraries and therefore the
296 identification of bacterial genus, species or strain of the infecting pathogen in a sample.

297 To the extent of our knowledge, the system we described is the first one-step biosensor assay
298 using different multiplexed AMPs and enabling detection of several viable bacterial strains in
299 biomedically relevant concentrations along with a discrimination capacity in a label-free assay. In
300 the near future, this approach could be applied for the detection of any pathogen in samples
301 such as foodstuff, urine or blood without any pre-requisite knowledge of the threat.

302 If these auspicious results are confirmed on a larger scale, it could permit the development of a
303 one-step assay – not only able to detect common pathogens overnight – but also to identify
304 them in reference to a database of affinity patterns.

Table S1. Detection times of the presence of the different bacterial strains are determined by the timestamp of the kinetics first derivative highest value. It thus corresponds to the middle of the jump between the baseline signal and the plateau. It is given for the shortest time for each bacterial strain, associated with the peptide giving this result. Only peptides giving a strong positive signal are included in the analysis. Times are given as the average over duplicates of each peptide.

Bacterial strain	Initial concentration (CFU.mL⁻¹)	Shortest detection time (min)	Peptide
<i>E. coli</i> ATCC11775	51	677	Clavanin A
<i>S. Typhimurium</i> CIP104474	6	537	Magainin I
<i>S. aureus</i> ATCC43300	16	433	Leucocin A 24
<i>S. epidermidis</i> ATCC12228	2.5 · 10 ³	374	Leucocin A 24
<i>L. monocytogenes</i> IVc	2.6 · 10 ³	1160	Leucocin A 24

Figure S1. (A) Scaled scheme showing characteristic dimensions of the SPRi-biochip, including a representation of the observable field of view with the SPRi-Lab+. (B) Picture of a SPRi-biochip right after a spotting.

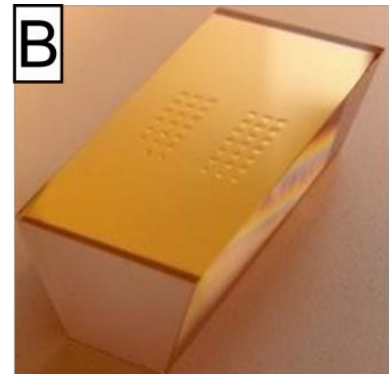

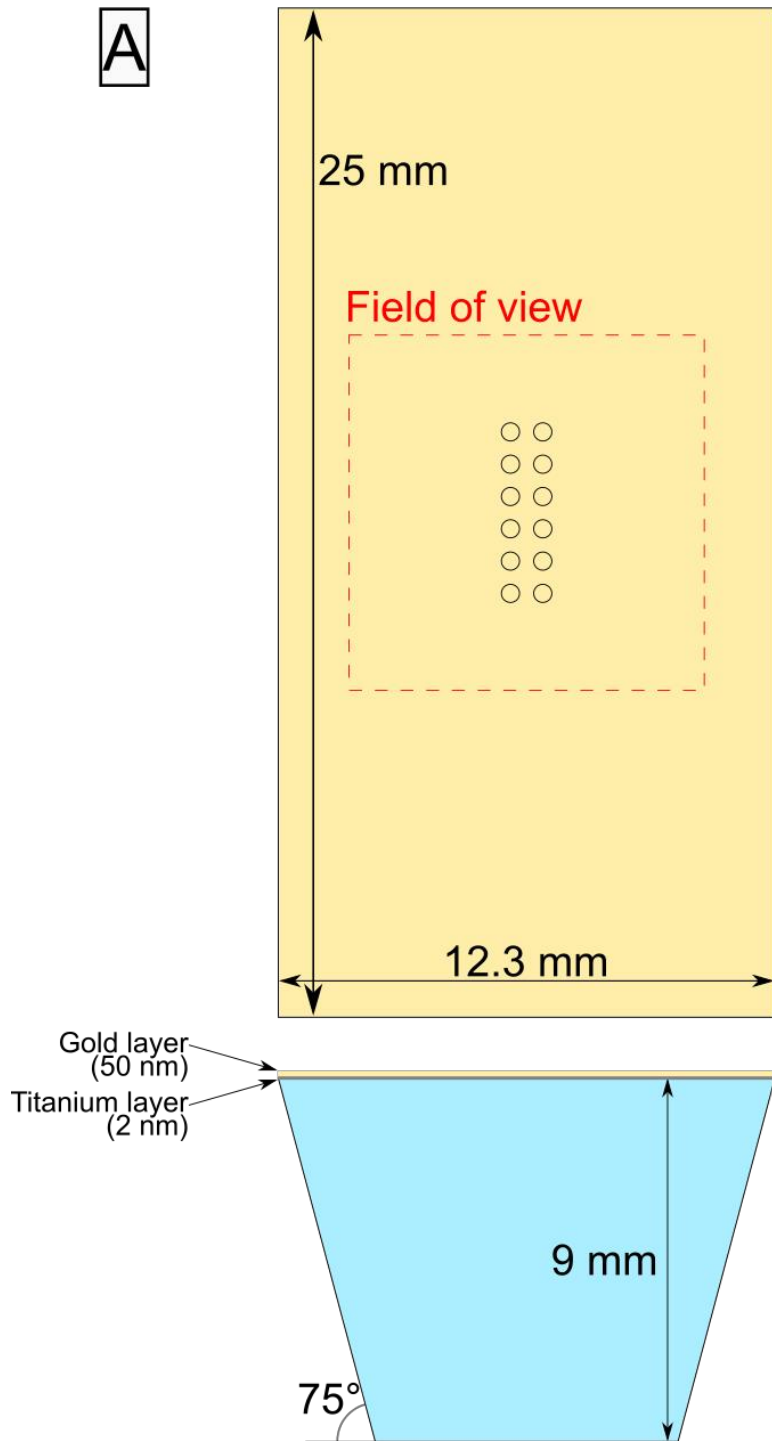

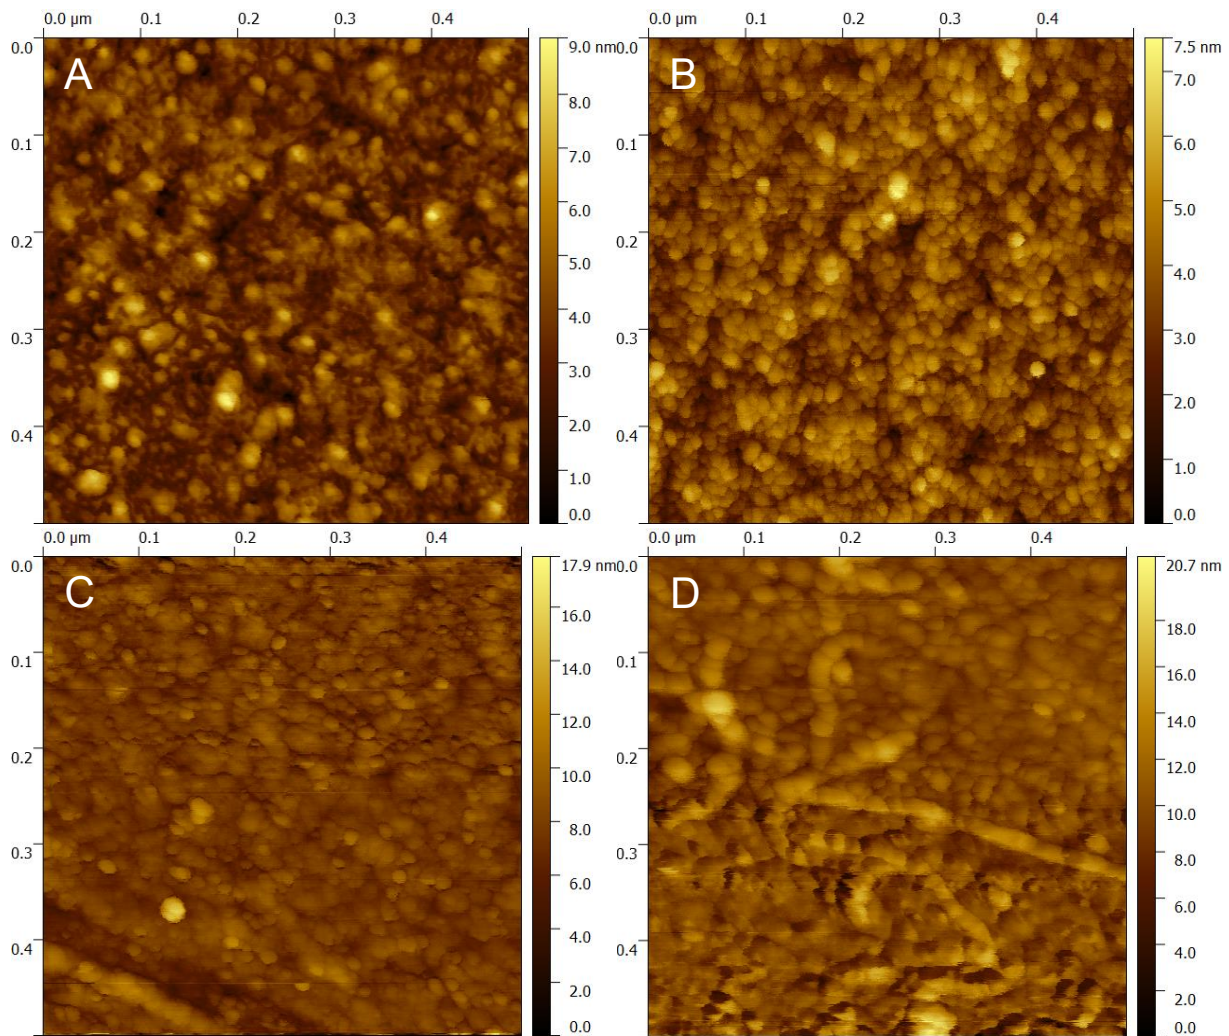

Figure S2. AFM images of monolayers of peptides prepared in the same conditions as SPRI biochips: (A) bare gold as a reference; (B) Magainin I; (C) Leucocin A 24; (D) Control peptide. They were recorded in air using the peak force mode of a Dimension Icon AFM (from Bruker, Santa Barbara, CA). The cantilevers were triangular and using a force contact of 0.1 N/m at a 70 kHz frequency and a 0.5 Hz scan rate. Image processing was performed using the Gwyddion microscopy software.

Certificate of analysis

Date	14/03/2016	Batch	849_s1p4f2
Product name	Magainin 1-Ncys	Catalog #	

Product specifications

AA sequence	C-AEEA-GIGKFLHSAGKFGKAFVGEIMKS-OH		
Disulfide bond	0		
Formula	$C_{121}H_{193}N_{31}O_{32}S_2$		
Appearance	White powder		
Theoretical average weight	2658,14 g/mol		
CAS number			
Source	Synthetic		
Counterion	TFA		
Solubility (recommendation)	10% acetonrile solution		1 mg/mL

Handling & Storage

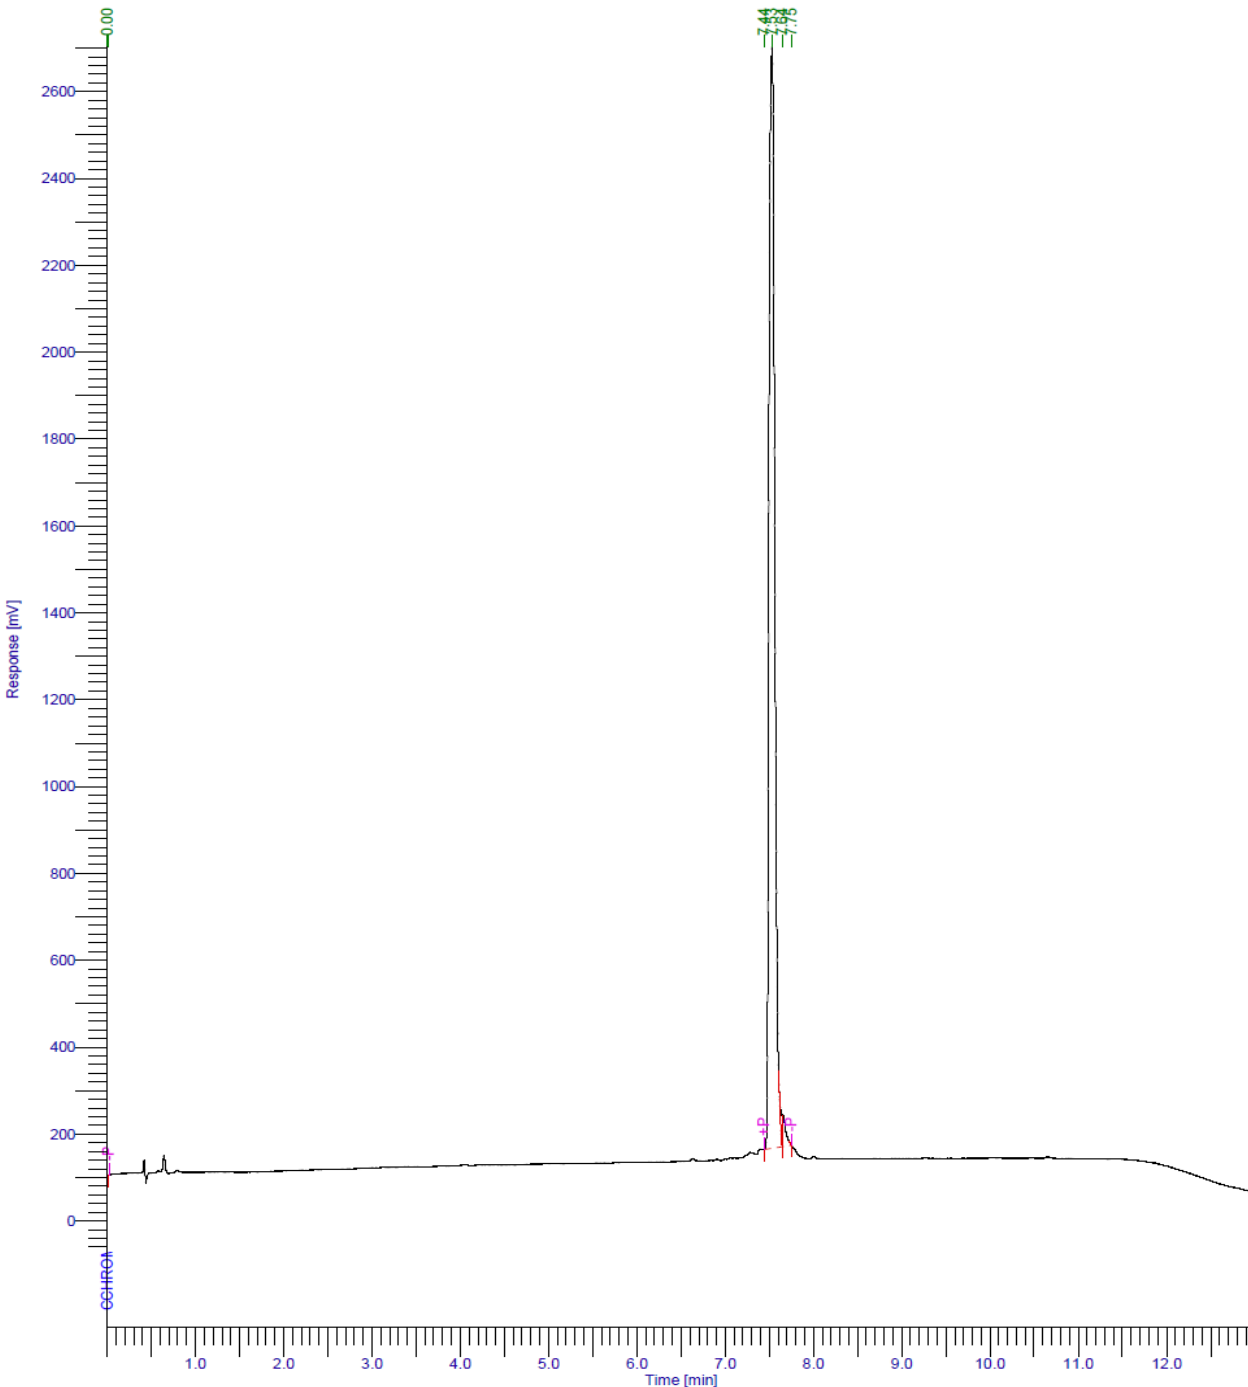

Storage	Shipped at ambient temperature under lyophilized powder. Store at -20°C (-4°F). Do not freeze-thaw. Aliquot sample if required and store at -80°C (-112°F).		
Expiry date	Not defined		
Handling and use restriction	Use with caution. Might be toxic. Product intended for research use only, not for use in diagnostic or therapeutic procedures.		

Analytical results

Observed purity rate	97,60%	Observed monoisotopic mass [M+H] ⁺	2657,407 Da
		Theoretical monoisotopic mass	2656,38 Da

Certificate of analysis

Date	22/03/2016	Batch	850_s2p1r1
Product name	peptide Contrôle	Catalog #	

Product specifications

AA sequence	C-AEEA-RGEWFWGNLVVSAASFGNHNAGG-OH		
Disulfide bond	0		
Formula	$C_{119}H_{194}N_{36}O_{34}S$		
Appearance	White powder		
Theoretical average weight	2681,89	g/mol	
CAS number			
Source	Synthetic		
Counterion	TFA		
Solubility (recommendation)	50 % of Acetonitrile solution		1 mg/mL

Handling & Storage

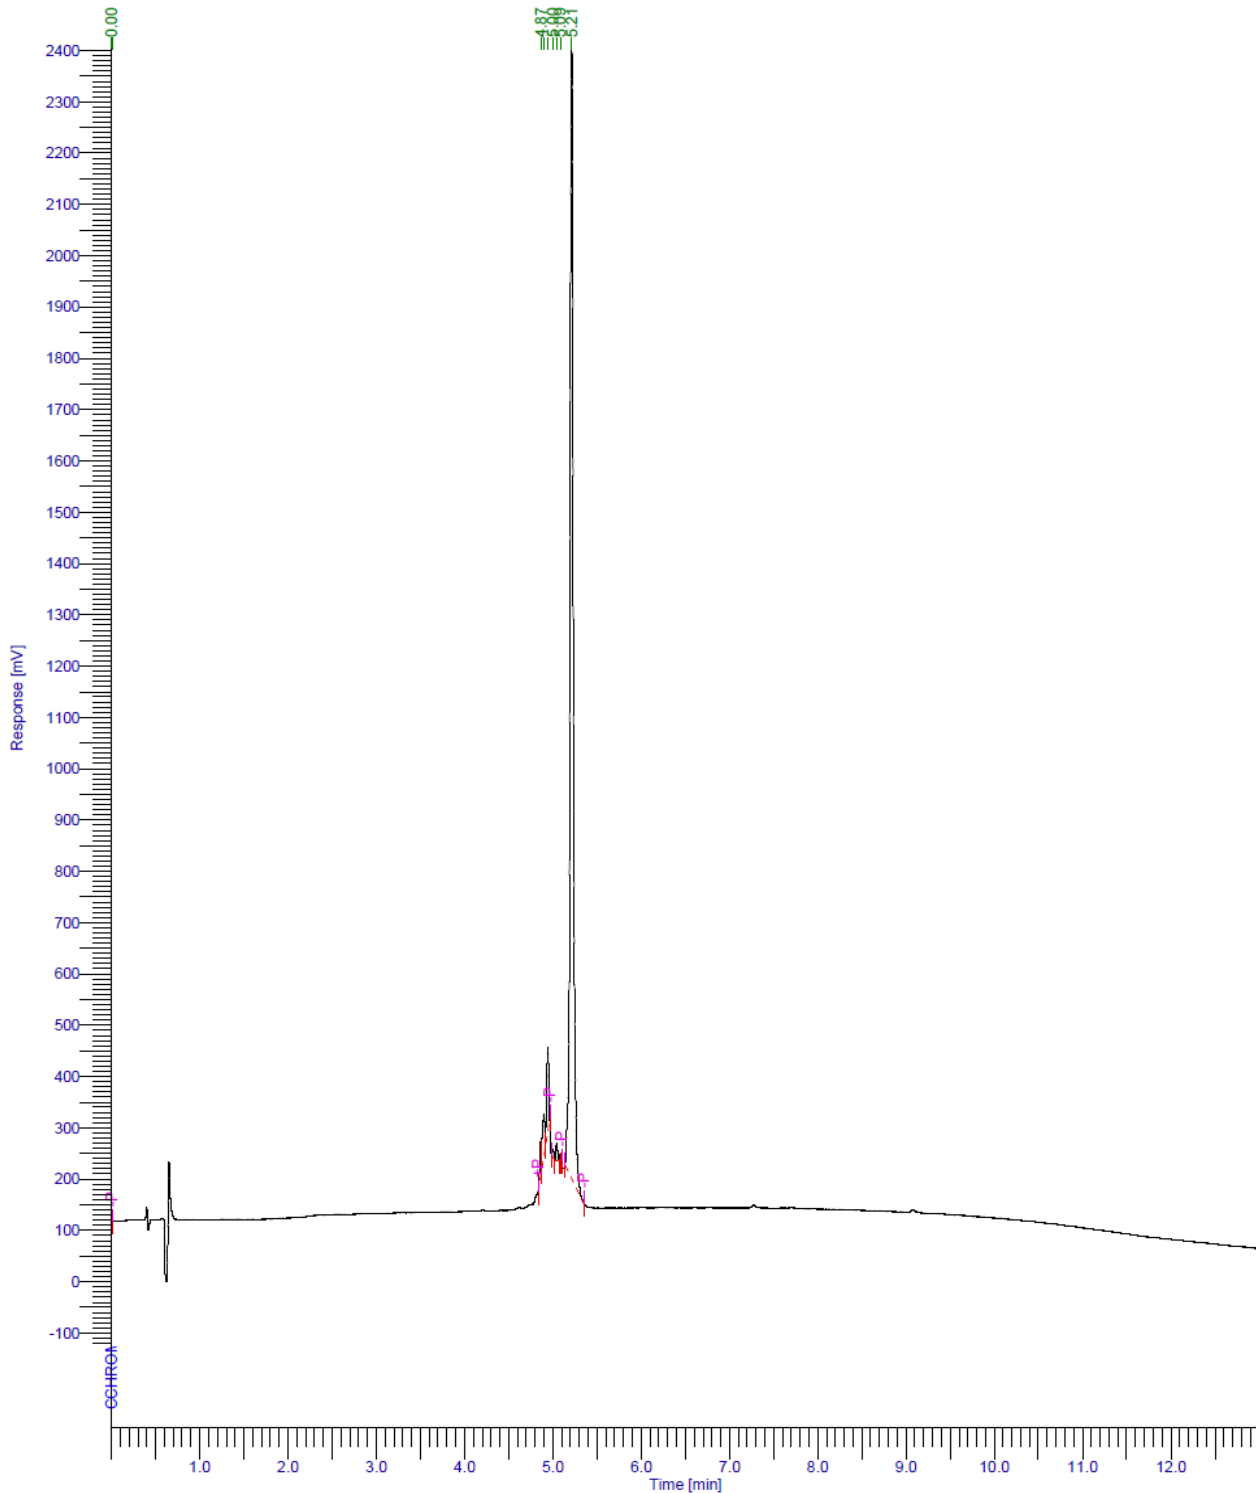

Storage	Shipped at ambient temperature under lyophilized powder. Store at -20°C (-4°F). Do not freeze-thaw. Aliquot sample if required and store at -80°C (-112°F).		
Expiry date	Not defined		
Handling and use restriction	Use with caution. Might be toxic. Product intended for research use only, not for use in diagnostic or therapeutic procedures.		

Analytical results

Observed purity rate	90,49%	Observed monoisotopic mass [M+H] ⁺	2681,17 Da
		Theoretical monoisotopic mass	2680,22 Da

MS Spectra

Certificate of analysis

Date	22/03/2016	Batch	853_s1p1r2
Product name	Leucocin A 24	Catalog #	

Product specifications

AA sequence	C-AEEA-SVNWGEAFSAGVHRLANGGNGFW-OH		
Disulfide bond	0		
Formula	$C_{119}H_{170}N_{36}O_{34}S$		
Appearance	White powder		
Theoretical average weight	2681,89	g/mol	
CAS number			
Source	Synthetic		
Counterion	TFA		
Solubility (recommendation)	50% of Acetonitrile solution		1 mg/mL

Handling & Storage

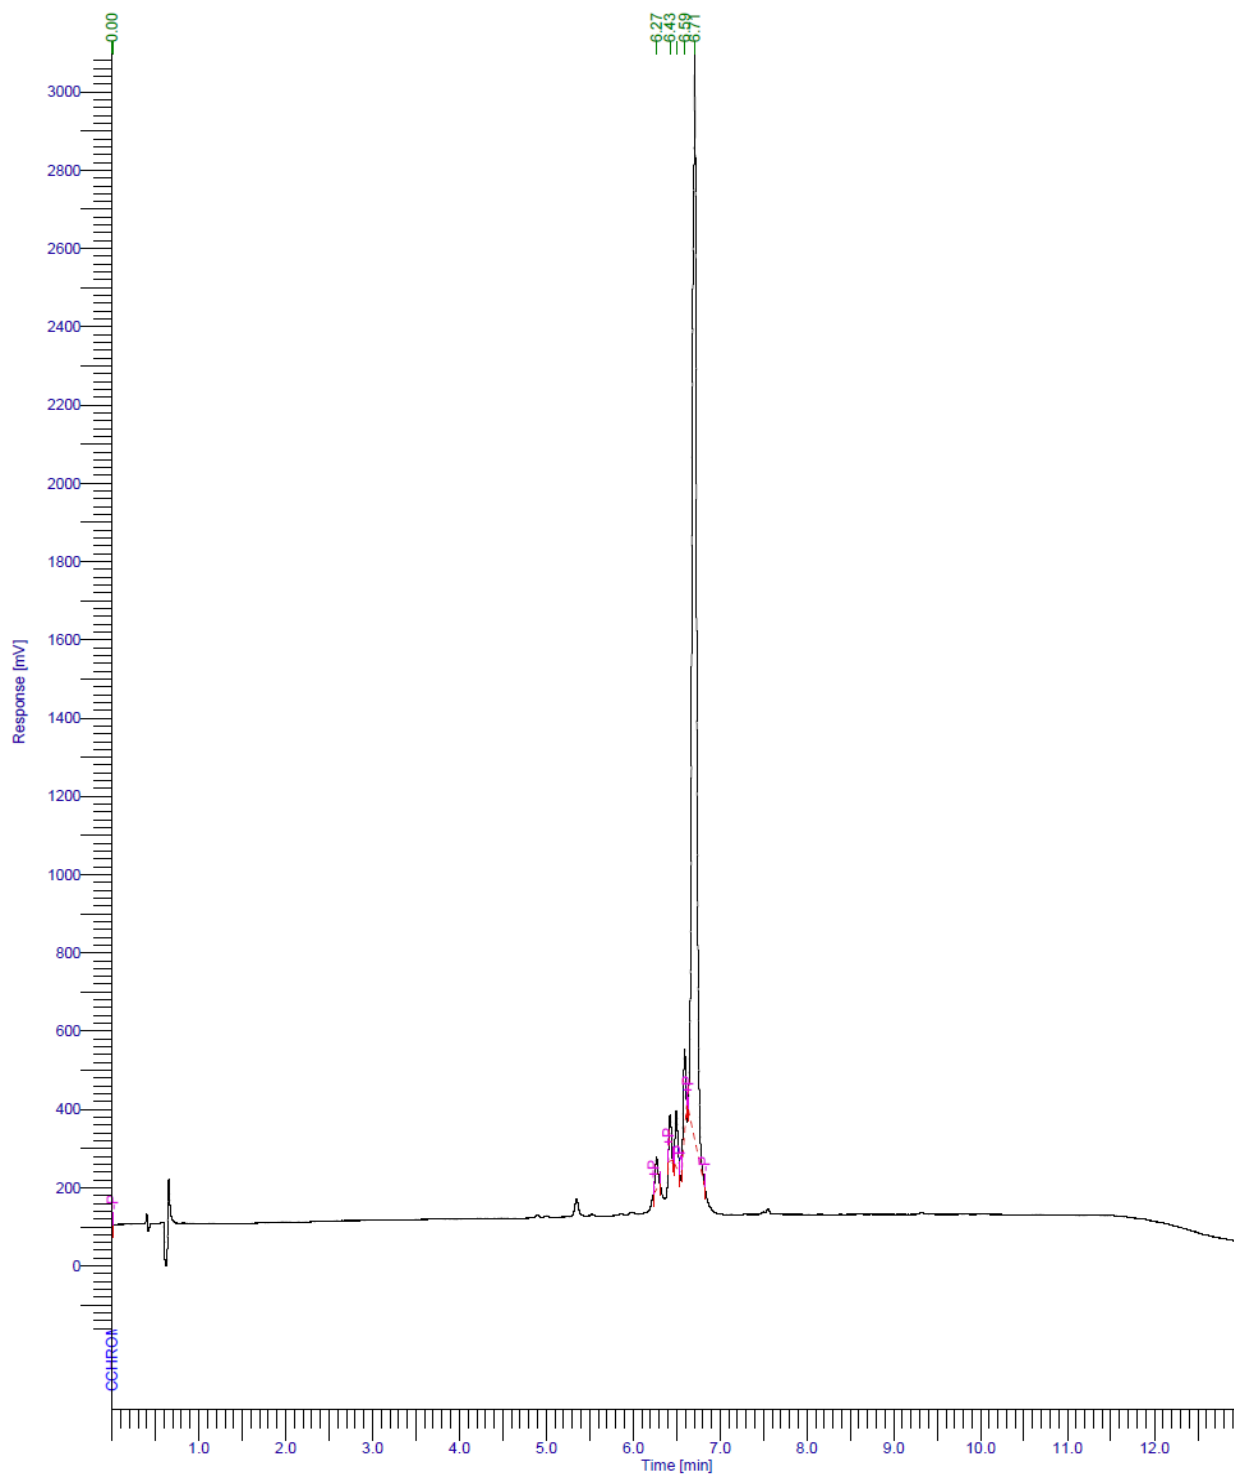

Storage	Shipped at ambient temperature under lyophilized powder. Store at -20°C (-4°F). Do not freeze-thaw. Aliquot sample if required and store at -80°C (-112°F).		
Expiry date	Not defined		
Handling and use restriction	Use with caution. Might be toxic. Product intended for research use only, not for use in diagnostic or therapeutic procedures.		

Analytical results

Observed purity rate	90,34%	Observed monoisotopic mass [M+H ⁺] ⁺	2681,12 Da
		Theoretical monoisotopic mass	2680,22 Da

Chromatogram

Sample Name : Sample #: 027 Page 1 of 1
FileName : C:\totalchrom\data\Peptide cealinjer AEEA fevrier 2016\160314 leucocin a24 aeea 853 s1p1r2.raw
Date : 3/21/2016 2:59:05 PM
Method : cchromolith 5-95 en 10 min.mth Time of Injection: 3/15/2016 1:53:49 AM
Start Time : 0.00 min End Time : 13.00 min Low Point : -162.95 mAU High Point : 3096.09 mAU
Plot Offset: -162.95 mAU Plot Scale: 3259.0 mAU
