### Abstract

Organic-inorganic hybrid halide perovskites are promising semiconductors with tailorable optical and electronic properties. The choice of A-site cation to support a three-dimensional (3D) perovskite structure  $AMX_3$  (where M is a metal, and X is a halide) is limited by the geometric Goldschmidt tolerance factor. However, this geometric constraint can be relaxed in two-dimensional (2D) perovskites, providing us an opportunity to understand how various the A-site cations modulate the structural properties and thereby the optoelectronic properties. Here, we report the synthesis and structures of single-crystals  $(BA)_2(A)Pb_2I_7$  where BA = butylammonium, and A = methylammonium (MA), formamidinium (FA), dimethylammonium (DMA) or guanidinium (GA), a series of A-site cation varied in size. Single-crystal X-ray diffraction reveals that the MA, FA, and GA structures crystallize in the same  $Cmcm$  space group, while the DMA imposes the  $Ccmb$  space group. We observe that as the A-site cation becomes larger, the Pb–I bond continuously elongates, expanding the volume of the perovskite cage, equivalent to exerting “negative pressure” on the perovskite structures. Optical studies and DFT calculations show the Pb–I bond length elongation reduces overlap of the Pb s- and I p-orbitals and increases the optical bandgap, while Pb–I–Pb angles play a secondary role. Raman spectra show lattice softening with

1  
2  
3 increasing size of the A-site cation. These structural changes with enlarged A cations result in  
4 significant decreases in photoluminescence intensity and lifetime, consistent with a more  
5 pronounced nonradiative decay. Transient absorption microscopy (TAM) results suggest that the  
6 PL drop may derive from a higher concentration of traps or phonon-assisted nonradiative  
7 recombination. The results highlight that extending the range of Goldschmidt tolerance factors for  
8 2D perovskites is achievable, enabling further tuning of the structure-property relationships in 2D  
9 perovskites.

## Introduction

Hybrid halide perovskites are emerging semiconductors with high mobility, long carrier lifetime and low trap density.<sup>1-2</sup> The three-dimensional (3D) halide perovskites with corner-sharing octahedra have a general formula of  $AMX_3$  [ $A = Cs^+$ ,  $CH_3NH_3^+$  (MA), or  $HC(NH_2)_2^+$  (FA);  $M = Ge^{2+}$ ,  $Sn^{2+}$ ,  $Pb^{2+}$ ;  $X = Cl^-$ ,  $Br^-$ ,  $I^-$ ].<sup>3-4</sup> The A-site cation occupying/templating the cuboctahedral cages defined by the eight adjacent Pb atoms can be seen as “perovskitizers”, and their choice is limited by the Goldschmidt tolerance factor,  $t = (r_A + r_X)/[\sqrt{2}(r_M + r_X)]$ , where  $r_A$ ,  $r_M$  and  $r_X$  are the effective radii of  $A^+$ ,  $M^{2+}$  and  $X^-$  ions, respectively.<sup>5-6</sup> It is only when the  $t$  value is between 0.8 and 1 that perovskite phases are mostly observed. Cations giving  $t$  larger than 1 or smaller than 0.8 are “forbidden” and instead stabilize non-perovskite phases.<sup>7</sup> When  $M = Pb^{2+}$  and  $X = I^-$ , the  $t$  values of  $Cs^+$  and FA are near the lower and upper limits of the ideal range, perovskite structures of  $CsPbI_3$  and  $FAPbI_3$  are metastable at room temperature. However for  $M = Sn^{2+}$ ,  $t$  values are closer to ideality, hence  $CsSnI_3$  and  $FASnI_3$  form stable perovskite structures.<sup>8</sup>

The equally important class of two-dimensional (2D) perovskites forms by incorporating an additional but larger organic cation which serve as spacers between the inorganic sheets.<sup>9-12</sup> The most prominent are the Ruddlesden-Popper (RP) and Dion-Jacobson (DJ) phases with the formulas  $(A')_2(A)_{n-1}Pb_nI_{3n+1}$  and  $A'A_{n-1}Pb_nI_{3n+1}$ , respectively, where A, A' are cations (A' defining the organic spacers) and  $n$  can reach values of up to 7.<sup>13-14</sup> In this way, tremendous structural diversity can be rationally achieved in 2D perovskites especially in the thickness of the inorganic layers, providing materials which have properties of quantum well structures.<sup>9-12</sup> The flexible spacer cations can also tolerate strain induced by the A-site cations larger than MA,<sup>15-16</sup> as in  $(BA)_2(FA)Pb_2I_7$  and  $(BA)_2(FA)Pb_2Br_7$  (BA = butylammonium).<sup>17-18</sup> Furthermore, it is possible for some 2D perovskites to incorporate larger cation, such as  $(EA)_2(EA)_2Pb_3X_{10}$  (EA = ethylammonium) ( $X = Br$  or  $Cl$ ),<sup>19</sup>  $(IPA)_2(IPA)Sn_2I_7$  (IPA = isopropylammonium)<sup>20</sup> and  $(BA)_2(EA)_2Pb_3I_{10}$ .<sup>21-22</sup> Fu *et al.*<sup>16</sup> reported the extension of Goldschmidt tolerance factor concept to 2D perovskites using hexylammonium (HA) as the spacer and formamidinium (FA), dimethylammonium (DMA), guanidinium (GA) and acetamidinium (AA) as A-site cations. However, among these compounds, only the single-crystal structure of  $(HA)_2(GA)Pb_2I_7$  was determined and a systematic study on how exactly the A-site cation affects the inorganic lattice and thus the optical properties of the 2D perovskites is still lacking. In order to better understand

1  
2  
3 the structure-property relationship in 2D perovskites, especially optoelectronic properties such as  
4 the electronic bandgap and photoluminescence quantum yield (PLQY), it is crucial to solve and  
5 refine the precise single-crystal structure for all the compounds.  
6  
7

8  
9 Here, we report the detailed structural evolution of the series  $(\text{BA})_2(\text{A})\text{Pb}_2\text{I}_7$  (A = FA, DMA and  
10 GA) as a function of A cation size. Single-crystal X-ray diffraction shows elongation of the Pb–I  
11 bonds with increasing the size of the A-site cation, which reduces the orbital overlap between Pb  
12 and I atoms and increases the optical bandgaps. This lattice expansion is a form of “negative  
13 pressure” exerted by the larger A-site cations. As the perovskite cages expand, the PL intensities  
14 and lifetimes decrease because of increased trap or phonon-mediated nonradiative recombination  
15 caused by lattice softening, as supported by the more diffuse low frequency Raman spectra. Our  
16 results highlight the remarkably soft and elastic nature of the 2D inorganic perovskite networks,  
17 which can respond continually to size changes in the A cation thereby extending the range of  
18 achievable Goldschmidt tolerance factor, rather than undergoing the dramatic structural transitions  
19 observed in the 3D perovskites.

## 28 **Experimental Section**

29  
30  
31 **Starting Materials** PbO (99.9%), methylammonium chloride (98%), formamidinium acetate  
32 (99%), dimethylammonium chloride (99%), guanidinium chloride (99%) , hydroiodic acid (57 wt  
33 % in H<sub>2</sub>O, distilled, stabilized, 99.95%), and hypophosphorous acid solution (50 wt % in H<sub>2</sub>O)  
34 were purchased from Sigma-Aldrich and used as received.  
35  
36  
37

### 38 **Synthesis.**

39  
40  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$  was synthesized as previously reported.<sup>23</sup> The other three compounds were  
41 synthesized in a similar way with step-cooling to avoid the formation of light-yellow color non-  
42 perovskite phase.  
43  
44

45  
46  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$ . An amount of 1 mmol PbO (223 mg) and 0.5 mmol formamidinium (FA) acetate  
47 (52.1 mg) was dissolved in 1.5 mL concentrated HI solution under heating and stirring until boiling.  
48 0.9 mmol (89.1  $\mu\text{L}$ ) butylamine (BA) was added to 0.25 mL of concentrated aqueous H<sub>3</sub>PO<sub>2</sub>  
49 solution in a separate vial under stirring. The neutralized BA solution was added to the boiling HI  
50 solution under stirring until a clear yellow solution was obtained. Then the temperature was  
51 lowered to 125 °C until red plate-shaped crystals started to precipitate out. Further decrease of the

2  
3 temperature to 80 °C resulted in precipitation of most of the crystals within an hour. Then the hot  
4 plate was turned off and the solution was cooled to room temperature. After 30 min, the product  
5 settled in the bottom of the vial and was isolated by suction filtration followed by drying on the  
6 filtration funnel for a further 30 min. Yield: 228.5 mg, 29.1% based on total Pb.  
7  
8  
9

10  
11 **(BA)<sub>2</sub>(DMA)Pb<sub>2</sub>I<sub>7</sub>.** An amount of 1 mmol PbO (223 mg) and 0.5 mmol dimethylammonium  
12 (DMA) chloride (40.8 mg) was dissolved in 1.75 mL concentrated HI solution under heating and  
13 stirring until boiling. 0.5 mmol (49.6 μL) BA was added to 0.25 mL of concentrated aqueous  
14 H<sub>3</sub>PO<sub>2</sub> solution in a separate vial under stirring. The neutralized BA solution was added to the  
15 boiling HI solution under stirring until a clear yellow solution was obtained. Then the temperature  
16 was lowered to 125 °C until red plate-shaped crystals started to precipitate out. Further decrease  
17 of the temperature to 80 °C resulted in precipitation of most of the crystals within an hour. Then  
18 the hot plate was turned off and the solution was cooled to room temperature. After 30 min, the  
19 product settled in the bottom of the vial and was isolated by suction filtration followed by drying  
20 on the filtration funnel for a further 30 min. Yield: 165.4 mg, 21.1% based on total Pb.  
21

1  
2  
3 a BBO crystal. A 435 nm long pass filter was used before the detection to block the excitation  
4 light.  
5

6 **Raman Spectroscopy.** Low frequency Raman spectra were acquired using 660 nm laser excitation  
7 and the Raman signals were detected with a CCD camera. The measurements were performed in  
8 ambient conditions. The Raman spectra were acquired using a 20× objective under the parallel  
9 configuration (polarizations of the excitation laser and Raman scattered light are kept the same).  
10 Two notch filters were used to suppress the Rayleigh scattering, enabling the collection of Raman  
11 signals with wavenumber down to 10 cm<sup>-1</sup>. Details of the Raman setup used for the measurements  
12 have been reported elsewhere.<sup>24</sup> The spectra were collected from -150 cm<sup>-1</sup> to 200 cm<sup>-1</sup>, and the  
13 samples were stable throughout the measurement.

## 21 **Results and Discussion**

### 22 **Synthesis**

23  
24 We used the step-cooling method reported previously to grow red-color single crystals of  
25 (BA)<sub>2</sub>(A)Pb<sub>2</sub>I<sub>7</sub> [A = formamidinium (FA), dimethylammonium (DMA) and guanidinium (GA)].<sup>25-</sup>  
26  
27 <sup>27</sup> A 2:1 ratio of PbO and A cations was dissolved in concentrated HI solution under stirring and  
28 heated to a boil. In the case of (BA)<sub>2</sub>(DMA)Pb<sub>2</sub>I<sub>7</sub> and (BA)<sub>2</sub>(GA)Pb<sub>2</sub>I<sub>7</sub>, half-stoichiometric ratio  
29 of BA (1:1:2 for BA, A cation and PbO) was added to the solution to avoid formation of the *n* = 1  
30 phase (details in the Experimental Section), because the *n* = 1 phase has the highest fraction of  
31 organic spacer, and higher concentration of BA favors lower layer-numbers. We also observed  
32 that there was no evidence for the existence of higher layer-number than *n* = 2 when DMA and  
33 GA serve as A-site cations. For (BA)<sub>2</sub>(MA)Pb<sub>2</sub>I<sub>7</sub> and (BA)<sub>2</sub>(FA)Pb<sub>2</sub>I<sub>7</sub>, 70% and 90% of the  
34 stoichiometric ratio of BA was added, respectively. Using half-stoichiometric ratio (50%) of BA  
35 in these cases led to higher layer-number phases forming concurrently. It is worth mentioning that  
36 with FA, darker crystals formed with low-energy absorption peaks; however, they seemed to be  
37 unstable and dissociated to *n* = 2 and 3D phases within about half an hour, which suggests that the  
38 *n* = 2 is a more thermodynamically stable phase. Direct cooling the solution to room temperature  
39 can result in the precipitation of yellow non-perovskite phase. Therefore, after a clear yellow  
40 solution was obtained under heating and stirring, the temperature of the hot plate was set to 125 °C,  
41 which is right below the boiling point of HI (127 °C), so that the solution was still hot to prevent  
42 the formation of the yellow non-perovskite phases, while it was highly concentrated such that the  
43

1  
2  
3 red  $n = 2$  perovskite phases could still precipitate. Once the red crystals started to form, they served  
4 as seeds for further growth of the crystals until the precipitation was complete. We note that no  
5 crystals of other colors in the solution could be visually identified. The crystals were separated by  
6 vacuum filtration.  
7  
8  
9

10 From the powder X-ray diffraction (PXRD) patterns in Figure 1a, we can clearly observe two  
11 characteristic peaks at  $2\theta \sim 4.5^\circ$  and  $9^\circ$  that correspond to the  $n = 2$  phases. In the case of  
12  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$  and  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$ , there are additional peaks because of the precipitation of  
13 the orange  $n = 1$  phase during the vacuum filtration. Since the crystals are big and the color of the  
14  $n = 1$  (orange) and  $n = 2$  (red) phases are distinct from each other, they can be easily separated for  
15 further characterizations. The differential scanning calorimetry (DSC) measurements of all four  
16 samples are shown in Figure S1, which all exhibit distinctive phase transition(s) just below room  
17 temperature.

### 25 **Crystal structures.**

26 All structures were refined in both centrosymmetric and noncentrosymmetric space groups. As  
27 discussed previously, the structure of  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$  has been solved in both *Cmcm* and *Cc2m*  
28 space groups.<sup>23</sup> The noncentrosymmetric space group is known to better reflect the local structure  
29 (e.g. configuration of the organic cation and hydrogen bonding) whereas the centrosymmetric  
30 space group better represents the averaged structure. Here, we want to focus on the average  
31 structure and how the A-site cation influences the inorganic part. Therefore, centrosymmetric  
32 space groups are used for all the discussions in the main text, and results for noncentrosymmetric  
33 space groups are shown in SI (Table S1, S2, S4 and Figure S3) for comparison purposes. It is  
34 worth noting that even though the noncentrosymmetric space groups give better refinement in  
35 terms of R values, the centrosymmetric ones result in significantly smaller estimated standard  
36 deviations (ESDs), thus believed to better represent the average structures. All the trends remain  
37 the same, however, regardless of the space group chosen. Both  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$  and  
38  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$  crystallize in the same *Cmcm* space group (no 63) as  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ , while  
39  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  adopts the *Ccmb* space group, which is equivalent to the space group of  
40  $(\text{BA})_2(\text{MA})_2\text{Pb}_3\text{I}_{10}$  (*Cmca*, no 64) and can be transferred to *Cmca* by symmetry operations (Table  
41 1). The difference in space group (*Cmcm* and *Ccmb*) comes from the different symmetry elements,  
42 which is a glide plane between the two octahedral layers for  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$ , but a mirror plane  
43

crossing the spacer cation for  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$  and the other two structures (Figure 1b, c). The organic spacer BA is restricted to the mirror plane parallel to the stacking direction in all the compounds. The  $b$  and  $c$  lattice parameters of the unit cell increase with larger A-site cation, however, the stacking  $a$  axis does not follow the same trend, which will be discussed below.

The effective radius of the A-site cation increases as  $\text{MA} < \text{FA} < \text{DMA} < \text{GA}$ , as shown in Table 2. The unit cell strain for the structures with larger A-site cation than MA originates from the significant variance in the Pb–I bond lengths. As the effective radius of the A-site cation increases, the Pb–I bonds in both the equatorial and axial directions become longer (Table 3), which is also reflected in the average Pb–I bond lengths. The axial Pb–I bond (denoted as Pb–I<sub>ax</sub> bond) can be further divided into the external Pb–I<sub>ax</sub> bond close to the spacer cation, and the internal Pb–I<sub>ax</sub> bond next to the A-site cation (Figure 1d). The internal Pb–I<sub>ax</sub> bond is the longest for all the structures, while the external ones are the shortest. Both the internal Pb–I<sub>ax</sub> and the equatorial Pb–I bond (denoted as Pb–I<sub>eq</sub> bond) lengths increase with the larger A-site cation (Figure 1, Table 3), which suggests that the perovskite cage expands to accommodate the large A-site cation. The cage expansion can be seen as a form of “negative chemical pressure” being exerted on the structure, in contrast to the studies under high-pressure, where there is cage contraction and the Pb–I bond lengths decrease when increasing the pressure.<sup>28</sup>

The interlayer distance between the perovskite  $[\text{Pb}_2\text{I}_7]^{3-}$  slabs as defined by planes crossing terminal iodine atoms is not a constant. In fact, the spacer cation is more compressed (interlayer d-spacing is smaller) in the cases of the larger A-site cations (Table 2). It is believed that by applying opposite compressive strain the spacer cations can balance the expansion of the perovskite cage and reduce the accumulated strain energy,<sup>15-16</sup> leading to the an increase of the Goldschmidt tolerance factor range in 2D perovskites.<sup>16,29</sup> Taking these factors into consideration, even though the unit cell volume (Table 1) varies only marginally with increasing size of A-site cation, the volume defined by eight adjacent Pb atoms does increase with the size of the A-site cation (Table 2), consistent with the exertion of negative pressure induced by the A cation size. The level of distortion for each individual octahedron can be defined by the distortion index (D) and bond angle variance ( $\sigma^2$ ) as calculated by the Vesta software<sup>30-31</sup>. The D and  $\sigma^2$  are defined by equation (1) and (2), where  $l_{\text{av}}$  is the average Pb–I bond distance and  $l_i$  are the six individual bond distances, and  $\theta_i$  is the individual I–Pb–I angle.

$$D = \frac{1}{6} \sum_i \frac{6|l_i - l_{av}|}{l_{av}} \quad (1)$$

$$\sigma^2 = \sum_{i=1}^{12} (\theta_i - 90)^2 / 11 \quad (2)$$

The distortion index increases as the size of A-site cation becomes larger, with the DMA and GA compounds showing the largest distortion index. The MA compound has the smallest bond angle variance, followed by the FA and GA compounds, while the DMA compound has the largest bond angle variance (Table 2). The DMA structure has a different space group and symmetry elements than the other three. Instead of the mirror plane crossing the MA, FA and GA cations, the DMA cations are related via a glide plane (Figure 1b, c). The axial Pb–I bonds in the same octahedra tilt in opposite directions (left and right, Figure 1d) for MA, FA and GA, while they tilt in the same direction (both left or both right, Figure 1f) for DMA. Therefore, the I–Pb–I bond angles in the axial direction are smallest for DMA (Figure 1d–g), and that is the reason why the DMA structure has a larger bond angle variance.

The Pb–I–Pb angles (Table 4) are similar for the four compounds. The MA compound has the smallest average Pb–I–Pb angle (166.7°), followed by the GA (169.3°) and FA (170.0°) compounds, while the DMA compound has the largest average Pb–I–Pb angle (171.1°). The Pb–I–Pb angle can be further categorized into equatorial angle, which is parallel to the inorganic layer, and axial angle perpendicular to the layer. The large average Pb–I–Pb angle of the DMA compound originates mainly from the large axial angle, while the equatorial Pb–I–Pb angle, which may be more relevant to the charge transport direction in 2D perovskites, is the smallest.

**Impact of increasing A-site cations on bandgap.** The optical absorption spectra of the four compounds exhibit a high-energy absorption edge and a lower-energy exciton peak, Figure 2. The bandgaps are estimated by extrapolating the high-energy slope to the imaginary axis parallel to the  $x$  axis where the absorption edge is interrupted by the exciton peak.<sup>23, 25</sup> The corresponding optical bandgap energies are shown in Table 2, following the trend  $E_{g,DMA} > E_{g,GA} > E_{g,FA} > E_{g,MA}$ .

It is well known from previous studies, that Pb–I–Pb angle variation related to in-plane and out-of-plane octahedra tilts are of prime importance to rationalize the bandgap energy in metal halide perovskites by changing the metal  $s$ - and halogen  $p$ -orbital overlap<sup>19, 32-33</sup>. However, the bond stretching and especially the variations of the Pb–I distances also affect orbital overlap. To

1  
2  
3 evaluate the influence of Pb–I bond length on the electronic bandgap, we conducted density  
4 function theory (DFT) calculations for the structures reported here. Electronic structure  
5 calculations were performed using the experimental crystallographic structures except that  
6 hydrogen atom positions have been optimized. All compounds are direct bandgap semiconductors  
7 at the  $\Gamma$  point (Figure 3). The dispersion along the  $\Gamma$ -R direction in the Brillouin zone is flat, which  
8 corresponds to the stacking direction ( $a$ ) in real space, indicative of 2D-like electronic structures.  
9  
10 Regardless of the level of theory in use, the calculated electronic bandgaps follow the same trend  
11 with  $E_{g,DMA} > E_{g,GA} > E_{g,FA} > E_{g,MA}$ . The calculated bandgaps are 2.60 eV, 2.55 eV, 2.54 eV and  
12 2.48 eV, respectively, at the Heyd, Scuseria and Ernzerhof + spin-orbit coupling level of theory  
13 with 73% of Fock exchange.<sup>34</sup> We further checked the partial density of states (PDOS) using DFT  
14 calculations, that intrinsic band structures are not deeply modified by A-site cations (Figure S2).  
15 In particular, the respective weights of Pb s- and I p-orbitals at the top of the valence band are only  
16 slightly modified by the substitution.

23  
24  
25

26 The band structure calculations for the noncentrosymmetric space groups are also shown in SI  
27 (Table S4, Figure S3). The bandgaps show the same trend as those calculated in the  
28 centrosymmetric space groups (Table S3, S4).  
29  
30  
31

32 By inspecting the crystal structure, we can see that in the present series the octahedral tilts  
33 (Pb–I–Pb angle) remain similar whereas the Pb–I bonds undergo significant length variations,  
34 depending on the A-site cation. To focus on the impact of bond length variation on the electronic  
35 bandgap energy, we built a simplified model structure “ $\text{Cs}_3\text{Pb}_2\text{I}_7$ ” (Figure 4a) and computed the  
36 bandgap energies considering a range of bond lengths consistent with the present crystal structures.  
37 In order to isolate the effect of Pb–I bond lengths, all octahedral connections were kept as  
38 undistorted with  $180^\circ$  Pb–I–Pb angles. As discussed in the crystal structure part, the axial Pb–I  
39 bond can be further divided into external and internal ones. Since the external Pb– $\text{I}_{\text{ax}}$  contributes  
40 less to the VBM and CBM spinor densities,<sup>35</sup> we only consider the equatorial Pb–I ( $d_{\text{Pb}-\text{I}_{\text{eq}}}$ ) and  
41 the internal Pb– $\text{I}_{\text{ax}}$  ( $d_{\text{Pb}-\text{I}_{\text{ax-int}}}$ ) bond lengths, all external Pb– $\text{I}_{\text{ax}}$  ( $d_{\text{Pb}-\text{I}_{\text{ax-ext}}}$ ) bond lengths have  
42 been fixed at 3.1 Å (Figure 4a). A vacuum slab of 25 Å was introduced between the layers. To  
43 obtain a mapping of the electronic bandgap, the  $d_{\text{Pb}-\text{I}_{\text{ax-int}}}$  and  $d_{\text{Pb}-\text{I}_{\text{eq}}}$  bond lengths were varied  
44 from 3.1 to 3.4 Å (0.1 Å steps) and 3.1 to 3.3 Å (0.025 Å steps), respectively, and the  
45 corresponding bandgap vs bond length map is shown in Figure 4b.

As shown in Figure 4b, the bandgaps increase with increasing Pb–I bond lengths, following the experimental trend that  $E_{g,GA} > E_{g,FA} > E_{g,MA}$ . This simplified model predicts that  $(BA)_2(GA)Pb_2I_7$  has the widest bandgap among the four compounds, while DFT calculations on the real structures (Figure 3) leads to  $E_{g,DMA} > E_{g,GA}$  (also confirmed experimentally, Figure 2). This is because the 2D mapping does not take into consideration additional octahedral distortions and deviation of Pb–I–Pb angles from  $180^\circ$ . When the bond lengths are similar, the Pb–I–Pb angles still play the role in affecting the bandgaps. It turns out that  $(BA)_2(DMA)Pb_2I_7$  has the smallest equatorial Pb–I–Pb angle among the series (Table 4), which means the octahedra are more significantly tilted in the planes of the 2D layer that in turn increases the bandgap energy. This suggests that for this series of layered perovskites the Pb–I bond lengths are the main factors tuning the bandgap energy and the equatorial Pb–I–Pb angles exert a secondary effect. Meanwhile, both these structural components cooperate to minimize the strain energy in layered perovskites.<sup>15</sup> Other researchers have observed similar trend of bandgap blueshift for larger A-site cations in the colloidal nanoplates.<sup>36</sup> It is worth mentioning that the trend of the bulk and colloidal systems is slightly different. The size dependence of absorption peak for the 2D perovskite nanoplates follows the same trend as the 3D bulk perovskites  $APbI_3$  ( $A = Cs^+$ , MA and FA) that  $E_{g,Cs^+} > E_{g,MA} > E_{g,FA}$ , while for the 2D bulk perovskites,  $E_{g,MA} < E_{g,FA} < E_{g,GA}$ .

**Trends in PL and lattice softening.** All compounds exhibit photoluminescence at room temperature, with the PL peak positions following the same trend as the bandgap (Figure 5a), consistent with the trends derived from electronic band structure calculations and the optical absorption spectra. It is worth noting that the intensity of the PL peaks drops as the size of the A-site cation increases (Figure 5b). The PL quantum yield (PLQY,  $\phi$ ) is defined by the equation  $\phi = \frac{k_r}{k_r + k_n}$ , where  $k_r$  and  $k_n$  are the rate constant of the radiative and nonradiative decay, respectively.<sup>37-</sup>  
<sup>39</sup> Because of the similar dielectric environments of the compounds, the exciton binding energy and the radiative decay rate are generally expected to be similar. The observed decrease of the PL intensity, however, suggests a higher nonradiative decay rate in the larger A-site cation compounds, which is also confirmed by the time-resolved PL (TRPL) measurement (Figure 5c). The TRPL plots are fitted with two exponential decays, and the PL lifetime values summarized in Table S5. The timescale of the PL lifetimes varies as  $\tau_{avg, MA} > \tau_{avg, FA} > \tau_{avg, DMA} > \tau_{avg, GA}$  which shows that as the size of the A-site cation increases, the PL lifetime decreases, matching the trend of the PL

1  
2  
3 intensity. We note that we measured the TRPL using the 2 ns window of a streak camera, which  
4 focuses on the intrinsic exciton recombination. Longer-lived processes which are caused by  
5 extrinsic effects may also exist based on the long tail of the PL decay curve, but the work aimed  
6 at understanding the origins of this is outside the scope of the manuscript.  
7  
8  
9

10  
11 The decreasing trend in PL lifetime may come from more defect states that trap the excitons in  
12 perovskites incorporating larger A-site cations, which can serve as recombination centers and  
13 quench the PL.<sup>40</sup> At low photon fluence, the PLQY is limited by the charge trapping pathway,<sup>41</sup>  
14 which is the process discussed here. It has been reported that 2D perovskite with larger A-site  
15 cation, (BA)<sub>2</sub>(EA)<sub>2</sub>Pb<sub>3</sub>I<sub>10</sub>, exhibits higher defect densities than (BA)<sub>2</sub>(MA)<sub>2</sub>Pb<sub>3</sub>I<sub>10</sub>, and shorter PL  
16 lifetime.<sup>42</sup> At high fluence, the trap states are predominantly filled and Auger recombination or  
17 exciton-exciton annihilation is the dominant channel for the nonradiative loss.<sup>41, 43-44</sup> The exciton-  
18 exciton annihilation is expected to be enhanced in the 2D perovskites. Nevertheless, our transient  
19 absorption measurements reveal that the exciton-exciton annihilation rates appear slower in the  
20 structures with large A cations, as will be discussed later.  
21  
22

24  
25  
26  
27  
28

29 The 6s<sup>2</sup> lone pairs that dominate the top of the VBM play an important role in physical properties  
30 of halide perovskites. These lone pairs are crystallographically hidden (delocalized) in 3D  
31 perovskites, and only exhibit local distortion upon thermal expansion as they struggle to achieve  
32 stereochemical expression.<sup>45</sup> This distorts the octahedral coordination geometry as the Pb atoms  
33 move slightly off-center possibly in random directions and in a dynamic way. Therefore, these  
34 lone pairs may be more localized in these 2D perovskites at room temperature because of the  
35 expansion of Pb–I bonds. The stereochemical activity can be characterized by the large distortion  
36 index and bond angle variance as discussed above. Our hypothesis is that as the size of the A-site  
37 cation increases, the Pb-I bonds get elongated and the inorganic framework becomes “loose” and  
38 more deformable. Thus, the lone pairs are more statically expressed and result in stronger lattice  
39 anharmonicity. A less rigid structure is easier to form defects and the optical phonon frequency is  
40 expected to decrease since it is directly proportional to the chemical bond strength, and this trend  
41 is associated with lattice “softness”.  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51

52 The lattice anharmonicity and softness can be probed via the low-frequency Raman spectral  
53 characterization (Figure 6). We used a laser with 660 nm wavelength, which is below the bandgaps  
54 of the compounds, to excite the materials in the transparency region and avoid undesirable PL  
55  
56  
57

1  
2  
3 background. As shown in Figure 6, the Raman spectra of all four compounds consist of broad  
4 quasielastic central peaks around  $0\text{ cm}^{-1}$ , which are diffuse, and composed of spectral continuum  
5 underlying broad Raman transitions. The broad central peaks are signatures of anharmonic, highly  
6 dynamic and fluctuating structures.<sup>46-49</sup> Also seen in  $\text{MAPbI}_3$ ,  $\text{MAPbBr}_3$  and  $\text{CsPbBr}_3$  perovskites,  
7 this type of room temperature Raman spectra is known to be associated with soft distortive lattices  
8 and interestingly similar to those of fluids.<sup>46-47</sup> Besides the broad peaks, there are also some distinct  
9 low-frequency peaks at  $25\text{ cm}^{-1}$  and  $45\text{ cm}^{-1}$  for  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ , which may correspond to the  
10 bending modes of  $[\text{PbI}_6]^{4-}$  octahedra.<sup>47, 50-51</sup> As the size of the A-site cation increases, there are two  
11 clear observations. First, the peak positions in the spectra shift to lower frequency (Figure 6). Since  
12 the frequency is directly proportional to the bond strength, it is expected that longer bonds result  
13 in lower energy for the optical phonons. Second, the spectra become more diffuse since the broad  
14 background associated with dynamic disorder emerges, which suggests that the structure becomes  
15 more anharmonic as A-site cation size increases, indicating a softer lattice. This can be rationalized  
16 by the expression of the  $6s^2$  lone pair in the loosely connected structure, which tends to become  
17 localized, acting as a lever of perturbation of the octahedral coordination environment.<sup>45</sup> This  
18 perturbation is likely the origin of the enhanced disorder observed as the size of the A-site cation  
19 increases.

33 **Trend in Carrier Dynamics.** Many-body exciton–exciton annihilation in strongly excited low  
34 dimensional semiconductors represents an important nonradiative loss path that limits the  
35 efficiency in lasers and LEDs. The annihilation is a process when an exciton recombines  
36 nonradiatively and transfers the energy to another exciton, which is analogous to Auger  
37 recombination for free carriers. Exciton–exciton annihilation is expected to be efficient in 2D  
38 perovskites due to the strong many-body interactions and large exciton binding energies (for  
39 example up to 200 meV in  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ ) at room temperature. Under low excitation power  
40 density at which the TRPL is measured, there are still trap states so that the PL decays are  
41 nonexponential because of trap-assisted recombination, whereas under high excitation power  
42 density, the exciton–exciton annihilation dominates recombination dynamics.<sup>43-44</sup>  
43  
44  
45  
46  
47  
48  
49  
50

51 To better understand the exciton annihilation dynamics in these materials, we performed ultrafast  
52 transient absorption microscopy measurements on exfoliated crystals under a high excitation  
53 power density. The pump fluence was  $\sim 120\text{ }\mu\text{J cm}^{-2}$ , corresponding to a carrier density of  $\sim 10^{12}$   
54  
55  
56  
57  
58  
59  
60

1  
2  
3  $\text{cm}^{-2}$ , below the Mott density ( $\sim 10^{14} \text{ cm}^{-2}$ ).<sup>44</sup> The absorption spectra of the exfoliated crystals  
4 (Figure S4) match well the ones of bulk crystals obtained by the diffuse reflectance UV-vis  
5 measurements. As shown in Figure 7, the 2D transient absorption (TA) map exhibits a ground-  
6 state bleaching (GSB) feature (blue color) at the optical bandgap and two photo-induced absorption  
7 (PIA) (red colors) above and below the optical bandgap. There are also weak bleaching features  
8 (light-blue color) below the optical bandgap for the MA, FA and GA compounds (purple decay  
9 trace in Figure S5). The dynamics of the four features for the first 6 ps is shown in Figure S5. The  
10 GSB rises at sub-picosecond timescale due to the fast band-edge population<sup>52</sup> and then goes  
11 through a slow decay process, lasting in the hundreds of ps, which is associated with the exciton-  
12 exciton annihilation given the high fluence used in the measurement.<sup>39</sup>

21 The TA features are markedly similar to those of previous studies under lower excitation power  
22 densities, confirming that the excitons remain the main excited-state species here (i.e. below the  
23 Mott transition). We then model the decay kinetics of the bleaching peak using the rate equation  
24  $\frac{dn(t)}{dt} = kn(t)^2$ , as expected for the exciton–exciton annihilation process, in which  $n(t)$  is the  
25 exciton density and  $k$  is the rate constant for the exciton annihilation. In the linear region we  
26 performed the measurement, the TA signal should be proportional to exciton density ( $\Delta T \propto n(t)$ ).  
27 Therefore, to fit the rate constant in  $\frac{1}{n(t)^2} \frac{dn(t)}{dt} = k$ , we plotted the  $1/\Delta T \sim t$  curve (Figure 7e), the  
28 slope divided by the initial carrier density (Table S6) gives the rate constant. The annihilation rate  
29 constants are calculated to be  $1.7 \times 10^{-2}$ ,  $3.5 \times 10^{-2}$ ,  $2.8 \times 10^{-3}$ , and  $4.4 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$  for  
30  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ ,  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$ ,  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  and  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$ , respectively. For  
31 comparison, the exciton annihilation rate is  $1.1 \times 10^{-4} \text{ cm}^2 \text{ s}^{-1}$  for  $(\text{PEA})_2(\text{MA})\text{Pb}_2\text{I}_7$  (PEA =  
32 phenethylammonium)<sup>43</sup> and  $\sim 2 \times 10^{-2} \text{ cm}^2 \text{ s}^{-1}$  for  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ .<sup>44</sup> Because the annihilation rate  
33 sets an upper limit on the density of injected charges, for the same spacer cation such as BA, the  
34 even smaller values in the structures with larger A-site cations than MA indicate they could be  
35 more promising candidates for lasing.<sup>53</sup> Moreover, the results further support that the PL drop is  
36 mainly due to the increased trap or phonon-assisted nonradiative recombination rather than the  
37 exciton–exciton annihilation that manifests in 2D perovskites. Even though the role of surface and  
38 edges have not been ruled out, they are less likely to be responsible for the PL quenching.

1  
2  
3 The main GSB peak becomes broader with increasing size of A-site cation (Figure 7f), and so are  
4 the absorption (Figure S4) and the emission peak (Figure 5a) (Table S7). The broadening originates  
5 from enhanced dynamic disorder, which can be correlated to the larger octahedral distortion of  
6 those structures. The below-bandgap bleaching was previously assigned to the trap states below  
7 the bandgap.<sup>54</sup> These traps may not come from common chemical defects, but from the trapping  
8 of the band-edge exciton through electron-phonon coupling.<sup>54</sup> Strong electron-phonon coupling  
9 has been assumed to play a role for the sub bandgap states in 2D perovskites.<sup>55</sup>

## 16 **Conclusions**

17  
18 In 2D perovskites, the choice of the A-site perovskitizer cations is not entirely limited by the so-  
19 called Goldschmidt tolerance factor. The stabilizing effect of the spacer cations makes it possible  
20 to tolerate larger A-site cations as perovskitizers. By solving the single-crystal structures of  
21 (BA)<sub>2</sub>(MA)Pb<sub>2</sub>I<sub>7</sub>, (BA)<sub>2</sub>(FA)Pb<sub>2</sub>I<sub>7</sub>, (BA)<sub>2</sub>(DMA)Pb<sub>2</sub>I<sub>7</sub> and (BA)<sub>2</sub>(GA)Pb<sub>2</sub>I<sub>7</sub>, we have proven that  
22 the relatively large DMA and GA can serve as the A-site cation of 2D perovskites despite the fact  
23 that they are too large to formally satisfy the Goldschmidt rule. As the size of the A-site cations  
24 across these compounds increases, the Pb–I bonds are elongated, which reduces the orbital overlap  
25 of Pb s- and I p-orbitals, thus decreasing the electronic bandwidths and increasing the bandgaps,  
26 as confirmed by DFT calculations. The expanded cage size essentially equals to a “negative  
27 chemical pressure” applied to the 2D perovskite structure. This increases the local distortions of  
28 the PbI<sub>6</sub> coordination environment and leads to a decrease of PL intensity and shortening of PL  
29 lifetime. The expanded cages also result in soft and anharmonic lattices, as supported by Raman  
30 spectra. Exciton-exciton annihilation processes occur in these systems with the rates being slower  
31 in the structures with larger A cations.

38  
39  
40  
41  
42

43 Our study suggests that increasing the size of the A-site cation can lead to Pb–I bond elongation,  
44 bandgap blueshift, lattice softening and PL quenching, showing that the A-site cation has powerful  
45 tunability over the property of 2D perovskites. Finally, there is a long-standing debate on the role  
46 of the A-site cations (organic vs inorganic, polar vs nonpolar) in the outstanding properties of  
47 halide perovskites.<sup>56-57</sup> While MA, FA and DMA are polar cations, the GA cation is nonpolar.  
48 There are many reports on how the A-site cation may influence the properties of the 3D  
49 perovskites,<sup>48-49, 56-57</sup> such as carrier dynamics,<sup>48, 57</sup> local ferroelectric domains,<sup>49, 56</sup> Rashba  
50 splitting,<sup>58</sup> and localizing conduction and valence band edges in spatially separated regions<sup>56</sup>.

1  
2  
3 However, agreement still has not been reached and very few studies have been done on 2D  
4 perovskites. Our work presents more choices of A-site cations for 2D perovskites with different  
5 dipole moments and provides a set of model systems to study the effect of A-site cation on the  
6 property of perovskites. This study improves our understanding of the structure-property  
7 relationship of 2D perovskites and could help future design of more optimal materials for specific  
8 optoelectronic applications.

Table 2. Effective Radii of A-site cations ( $R_{A,eff}$ ), Cage Volumes ( $V_{cage}$ ), Average Pb–I bond lengths ( $d_{avg}$ ), Distortion Index (D), Bond-angle Variance ( $\sigma^2$ ), Interlayer d-spacing, Bandgap and PL Peak of the Compounds Reported Here.

Compound	$(BA)_2(MA)Pb_2I_7$	$(BA)_2(FA)Pb_2I_7$	$(BA)_2(DMA)Pb_2I_7$	$(BA)_2(GA)Pb_2I_7$
$R_{A,eff}$	217	253	272	278
$V_{cage}$ ( $\text{\AA}^3$ )	248.6	256.0	256.9	258.7
$d_{avg}$ ( $\text{\AA}$ )	3.17	3.19	3.20	3.21
D ( $10^{-3}$ )	10.4	14.8	18.4	19.1
$\sigma^2$	2.7	5.2	17.5	5.0
Interlayer d-spacing ( $\text{\AA}$ )	7.13	7.03	7.09	6.91
Bandgap (eV)	2.16	2.18	2.22	2.20
PL peak (eV)	2.12	2.14	2.18	2.17

Table 3. Equatorial Pb–I Bond Lengths, Axial Pb–I Bond Lengths (internal and external), Average Equatorial Pb–I Bond Length and Average Axial Pb–I Bond Length of the Compounds Reported Here.

Compound	$(BA)_2(MA)Pb_2I_7$	$(BA)_2(FA)Pb_2I_7$	$(BA)_2(DMA)Pb_2I_7$	$(BA)_2(GA)Pb_2I_7$
Equatorial Pb–I ( $\text{\AA}$ )	3.1644(7)	3.1926(9)	3.2043(6)	3.2007(8)
	3.1644(7)	3.1926(9)	3.2043(6)	3.2007(8)
	3.1721(8)	3.1963(9)	3.1816(6)	3.2131(8)
	3.1721(8)	3.1963(9)	3.1816(6)	3.2131(8)
Axial Pb–I (internal) ( $\text{\AA}$ )	3.2633(10)	3.3312(13)	3.3699(10)	3.3788(14)
Axial Pb–I (external) ( $\text{\AA}$ )	3.081(2)	3.055(3)	3.0623(18)	3.037(3)
Ave eq Pb–I ( $\text{\AA}$ )	3.1683(7)	3.1945(9)	3.1930(6)	3.2069(8)
Ave ax Pb–I ( $\text{\AA}$ )	3.1722(15)	3.1931(22)	3.2161(14)	3.2079(22)

Table 4. Equatorial, Axial and Average Pb–I–Pb angles of the Compounds Reported Here

Compound	(BA) <sub>2</sub> (MA)Pb <sub>2</sub> I <sub>7</sub>	(BA) <sub>2</sub> (FA)Pb <sub>2</sub> I <sub>7</sub>	(BA) <sub>2</sub> (DMA)Pb <sub>2</sub> I <sub>7</sub>	(BA) <sub>2</sub> (GA)Pb <sub>2</sub> I <sub>7</sub>
<b>Equatorial</b>				
<b>Pb–I–Pb (°)</b>	164.5	172.9	165.2	169.1
<b>Axial Pb–I–Pb (°)</b>	165.6	171.3	180.0	171.8
<b>Ave equatorial</b>				
<b>Pb–I–Pb (°)</b>	167.2	169.4	166.6	168.1
<b>Ave Pb–I–Pb (°)</b>	166.7	170.0	171.1	169.3

**Figure 1.** (a) PXRD patterns of the compounds reported here. (b) Crystal structure of  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$  and (c)  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  from side view. The dash line represents the glide plane and the solid line indicates the mirror plane. Crystal structures of (d)  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ , (e)  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$ , (f)  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  and (g)  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$  emphasizing the cage defined by eight adjacent Pb atoms.

**Figure 2.** Optical absorption spectra of the 2D perovskite compounds reported here.

**Figure 3.** Computed electronic band structures for (a)  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ , (b)  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$ , (c)  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  and (d)  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$ . The DFT calculations have been performed at the HSE+SOC level of theory with 73% of Fock exchange.

**Figure 4.** (a) Schematic representation of the all inorganic 2D model compound ( $\text{Cs}_3\text{Pb}_2\text{I}_7$ ) showing three different types of bond lengths: equatorial ( $d_{\text{Pb-I}_{\text{eq}}}$ ), internal axial ( $d_{\text{Pb-I}_{\text{ax-int}}}$ ), and external axial ( $d_{\text{Pb-I}_{\text{ax-ext}}}$ ) lead-iodide bond lengths. (b) 2D color map of computed electronic bandgap energies ( $E_g$ ) for different values of equatorial ( $d_{\text{Pb-I}_{\text{eq}}}$ ) and internal axial ( $d_{\text{Pb-I}_{\text{ax-int}}}$ ) distances, setting  $d_{\text{Pb-I}_{\text{ax-ext}}}$  to 3.1 Å, overlaid by the experimental bond lengths extracted from single crystal structures for  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$  (MA),  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$  (FA),  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  (DMA) and  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$  (GA).

**Figure 5.** (a) normalized PL spectra, (b) unnormalized PL spectra and (c) normalized time-resolved PL decay of the 2D perovskite compounds reported here.

**Figure 6.** Raman spectra of 2D compounds reported here, the numbers indicate the peak positions in cm<sup>-1</sup>.

**Figure 7.** Two-dimensional pseudocolor ( $-\Delta T/T$ ) plots of TA spectra for (a)  $(\text{BA})_2(\text{MA})\text{Pb}_2\text{I}_7$ , (b)  $(\text{BA})_2(\text{FA})\text{Pb}_2\text{I}_7$ , (c)  $(\text{BA})_2(\text{DMA})\text{Pb}_2\text{I}_7$  and (d)  $(\text{BA})_2(\text{GA})\text{Pb}_2\text{I}_7$  at the first 6 ps. The blue areas represent bleaching and the red ones are photo-induced absorption. (e) Experimental (symbols) and fitted (lines)  $1/\Delta T \sim t$  plots of the ground-state bleaching peaks for compounds reported here. (f) TA spectra cuts at 10 ps for compounds reported here.
