14 ABSTRACT

15

16 Croplands contribute to greenhouse gas emissions but also have the potential to mitigate climate change through
17 soil carbon storage. However, there is a lack of tools based on objective observations for assessing cropland C
18 budgets at the plot scale over large areas. Such tools would allow us to more precisely establish the contribution
19 of an agricultural plot to net CO₂ emissions according to the plot management and identify levers for improving
20 the C budget. In this study, we present a diagnostic regional modelling approach, called SAFY-CO₂, that
21 assimilates high spatial and temporal resolution (HSTR) optical remote sensing data in a simple crop model and
22 evaluate the performance of this approach in quantifying crop production and the main components of the annual
23 carbon budget for winter wheat.

24

25 The SAFY-CO₂ model simulates daily crop development (biomass, partition to leaves, etc.), the components of
26 net ecosystem CO₂ fluxes, and the annual yield and net ecosystem carbon budget (NECB).

27 Multi-temporal green area index (GAI) maps derived from HSTR data from the Formosat-2 and SPOT satellites
28 were used to calibrate the light-use efficiency and phenological parameters of the model. Data from the literature
29 were used to set a priori values for a set of model parameters, and a large dataset of in situ data was used for
30 model validation. This dataset includes 8 years of eddy-covariance net CO₂ flux measurements and GAI,
31 biomass and yield data acquired at 2 instrumented sites in southwest France. Biomass and yield data from 16
32 fields in the study area between 2005 and 2014 were also used for validation.

33 The SAFY-CO₂ model is able to reproduce both GAI dynamics (RRMSE=14%, R²=0.97) and biomass
34 production and yield (RRMSE of 27% and 21%, respectively) with high precisions under contrasting climatic,
35 environmental and management conditions. Additionally, the net CO₂ flux components estimated by the model
36 generally agreed well with in situ data and presented very good and significant correlations (RMSE of 1.74, 1.13
37 and 1.29 gC.m⁻².d⁻¹ for GPP, R_{eco} and NEE, respectively; R² of 0.90, 0.75 and 0.85 for GPP, R_{eco} and NEE,
38 respectively) over the 8 studied years. This study also highlights the importance of accounting for post-harvest
39 vegetative events (spontaneous re-growth, weed development and cover crops) for an accurate calculation of the
40 annual net CO₂ flux. This approach requires a limited number of input parameters for estimating yield and net

41 CO₂ flux components, which is promising for regional/global-scale applications based on Sentinel 2-like data;
42 however, the approach requires plot-scale data concerning organic amendments and straw management
43 (exportation) in animal farming systems to calculate field C budgets.

44

45 **1. INTRODUCTION**

46 Agricultural lands occupy nearly 12% of Earth's terrestrial surface. They not only contribute to but also affect
47 climate change because climatic conditions and water resources affect crop production (Smith et al., 2005).
48 Additionally, the global food demand is increasing and may continue to increase for decades, driven by the
49 increasing global population and per capita income that are anticipated through the middle of the next century
50 (Tilman et al., 2011).

51 It is in this context that the '4 per mille Soils for Food Security and Climate' initiative was launched at COP21,
52 with the aspiration to increase global soil organic matter stocks by 4 per 1000 (or 0.4%) per year as a
53 compensation for part of the global emissions of greenhouse gases by anthropogenic sources and to increase
54 food security (Chabbi et al., 2017; Minasny et al., 2017). Since then, this initiative has induced a wide debate in
55 the scientific community concerning its feasibility (Baveye et al., 2018; Poulton et al., 2018), and it has been
56 recognized that such an increase in soil organic carbon (SOC) is likely achievable in soils that are being actively
57 managed for agriculture at a rate of increase that may not be achievable everywhere (Chabbi et al., 2017; Lal,
58 2016; Minasny et al., 2017; Pellerin et al., 2019). This debate illustrates the need for tools that can estimate
59 changes in cropland SOC and identify potential levers to increase it. Currently, quantifying the net ecosystem
60 carbon budgets (NECB) of croplands at regional or global scales remains difficult because of the heterogeneous
61 character of agricultural landscapes, which have numerous plots with varied management practices and
62 environmental conditions. This character results in uncertainties when assessing the impacts of specific
63 management practices on the cropland NECB (Osborne et al., 2010) and when determining whether croplands
64 are carbon sinks or sources (Ciais et al., 2010; West et al., 2010).

65 Indeed, the general biogeochemical models (such as SPA (Williams et al., 1996), Ecosys (Grant et al., 2007),
66 Isba-Ags (Calvet et al., 1998), ORCHIDEE (Krinner et al., 2005), and ORCHIDEE-STICS (Gervois et al.,
67 2008)) that are commonly used to simulate the carbon cycle in terrestrial ecosystems are not suited to account for
68 the specificities and complexities of agro-ecosystems, particularly the effect of management practices. In
69 contrast, the agronomic models or so-called crop models (*e.g.*, CERES (Gabrielle et al., 1998) or STICS (Brisson
70 et al., 1998)) that account for management and pedoclimatic effects are primarily designed for simulating crop
71 development and production (net primary production (NPP), yield) at the plot scale. However, unlike our
72 approach, these models require information regarding management practices, which makes them less suitable for
73 large spatial scale applications.

74 Several studies have demonstrated the benefit of assimilating remote sensing data into regional-scale crop
75 models (Sus et al., 2013; Wu et al., 2012). In particular, the combination of high spatial and temporal resolution
76 (HSTR) remote sensing data with crop models can provide, at the field scale over large areas, a timely and
77 accurate picture of crop development (Claverie et al., 2012; Hadria et al., 2010), cropland photosynthesis (Wang
78 et al., 2012; Wolanin et al., 2019) and net CO₂ fluxes (Reville et al., 2013; Sus et al., 2013). Among others, the
79 SAFY (Duchemin et al., 2008; Claverie et al., 2012) and SAFY-WB (Battude et al., 2017; Duchemin et al.,
80 2015) crop models constitute coherent frameworks for estimating biomass, yield production and water

81 requirements. These models describe the main biophysical processes underlying crop production by using
82 climatic data and assimilate green area index (GAI) dynamic maps derived from remote sensing to avoid the
83 need for management data, which makes them well suited for large-scale studies. In this work, we modified the
84 SAFY model to simulate the components of the net ecosystem exchange (NEE) and to evaluate the potential of
85 this approach for calculating cropland annual carbon budgets. The resulting model, called SAFY-CO₂, is
86 described and evaluated against in situ data. The objectives of this study are as follows:

- 87 1- To assess the potential of an approach combining HSTR remote sensing data and a simple crop model
88 to quantify the components of the NEE and of the annual NECB for winter wheat plots in contrasting
89 climatic and management conditions.
- 90 2- To address the potentialities and limitations of such an approach in the perspective of future regional- or
91 global-scale applications.

92 To fulfil our objectives, GAI maps derived from HSTR optical data (Formosat-2 and SPOT satellites) from 2006
93 to 2014 in southwestern France were used to constrain the photosynthetic light-use efficiency and phenological
94 parameters of the model. Consequently, the simulated crop phenology agreed well with the satellite observations,
95 which is essential for correctly estimating CO₂ fluxes and carbon budgets (Grant et al., 2007; Huang et al., 2009;
96 Wattenbach et al., 2010).

97 A validation of the simulated CO₂ fluxes (photosynthesis, ecosystem respiration and NEE) was performed
98 against eddy-covariance flux measurements that were carried out over two flux sites (Béziat, 2009) in the study
99 area.

100 In the next section of the manuscript, the study area, experimental datasets and satellite database are presented.
101 The following section describes the SAFY-CO₂ mathematical formulations, the parameterization and calibration
102 procedure and the method for computing the annual NECB. The inputs required to run the model as well as the
103 validation procedure are also detailed. Section 4 is dedicated to the results. The biomass and yield results are
104 presented first, followed by the flux estimate results and finally the annual C budgets. Section five discusses the
105 potentialities, the limitations and potential improvements of such an approach in the perspective of future
106 regional- or global-scale applications. The paper ends with a conclusion concerning the main results, limitations
107 and insights into future developments.

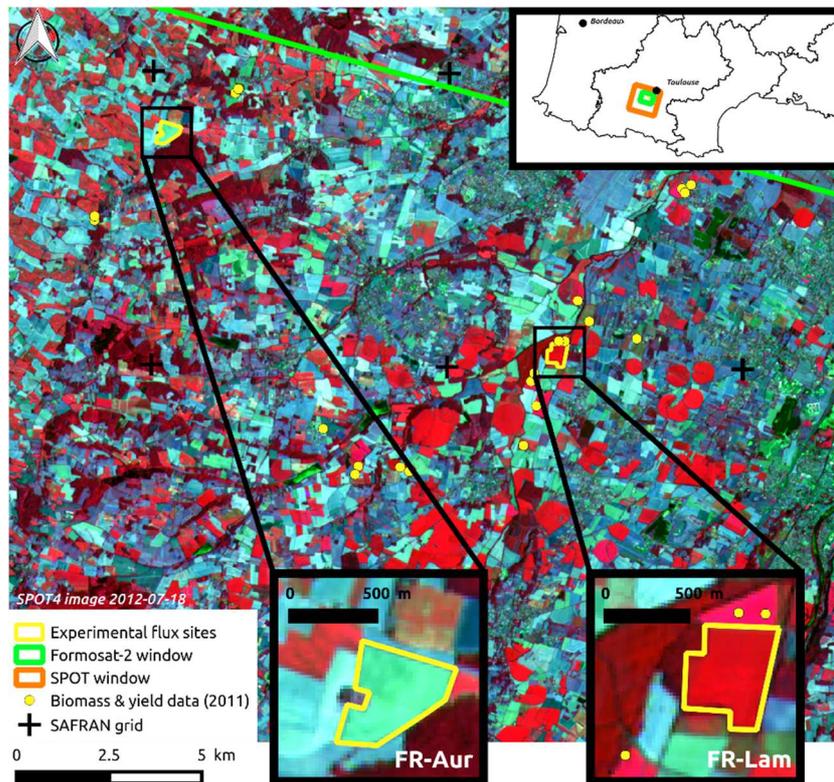

108

109 **2. MATERIALS**

110 **2.1. Study area**

111 The study area is part of the Regional Spatial Observatory [<http://www.cesbio.ups-tlse.fr/fr/osr.html>] located
112 next to Toulouse in southwest France which includes 2 instrumented agricultural sites, Auradé (FR-Aur) and
113 Lamasquère (FR-Lam) (Figure 1). Those two sites belong to the Integrated Carbon Observation System (ICOS)
114 network [<https://www.icos-ri.eu/>] for observations of surface fluxes (CO₂, latent and sensible heat fluxes). The
115 region has a temperate climate, with an annual mean precipitation of approximately 655 mm and an annual mean
116 temperature of 12.9°C (measured by Météo France at the Toulouse-Blagnac station between 1961 and 1990; see
117 <http://www.infoclimat.fr/climatologie/index.php>). Agricultural activity occupies almost 90% of the landscape,
118 and winter wheat is the main cultivated crop (covering approximately 20% of the total surface area). Sown from
119 mid-October until the beginning of December, winter wheat is harvested from mid-June until the end of July,
120 and straw is usually incorporated into the soil.

Figure 1: The upper right corner shows the location of the study site in southwestern France, as well as the footprint of Formosat-2 (green square) and Spot (orange square) images (in 2014 and 2012, respectively). The SPOT-4 false color image used as the background shows the flux sites of FR-Aur and FR-Lam (zoomed areas), the network of fields sampled for biomass and yield during the 2011 field campaign (yellow points), and the SAFRAN meteorological grid (black crosses).

121 *2.1.1 Soil characteristics*

122 The nature of the soils of the study area is shaped by
 123 the Garonne River. The Garonne River flows from the
 124 South to the North on the east side of the study area. It
 125 has spread sediments over a 15 km wide area along its
 126 western side resulting in vast terraces of heterogeneous
 127 soils called “boulbènes” and “terrefort” characterized
 128 by low-permeability and composed of a silt layer of
 129 variable thickness over stony clay soils. The geology is
 130 old quaternary and the main lithology is old alluviums.
 131 The area west of the terraces is characterized by a hilly
 132 landscape, consisting of hills and slopes resulting from
 133 the erosion of the oldest terraces. Further west the
 134 landscape is hilly over hundreds of kilometres and the
 135 soils become more calcareous with deposits formed of
 136 marl and clayey molasses with limestone.

137 The heterogeneous character of the soils of the study
 138 area is illustrated (Figure 2) by the texture
 139 measurements (fractions of clay, silt and sand)
 140 collected on the flux sites and on a network of fields
 141 within the footprint of the satellite images during the
 142 year 2018 (see also <https://soilgrids.org/> for predicted soil classification of the study area). The texture

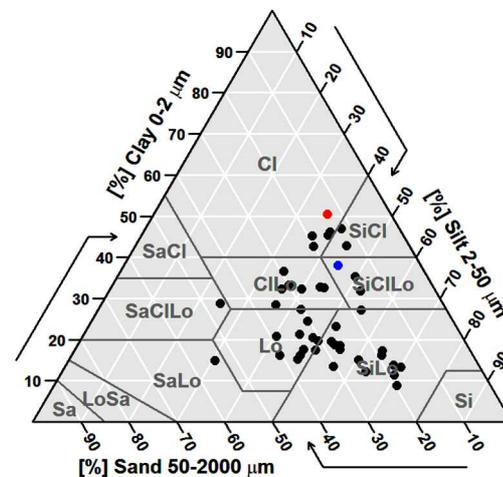

Figure 2: Surface texture measurements (FR-Lam in red, FR-Aur in blue and field campaign in black) displayed on USDA classification, with the following classes: clay (CI), silty clay (SiCl), sandy clay (SaCl), clay loam (CiLo), silty clay loam (SiCiLo), sandy clay loam (SaCiLo), loam (Lo), silty loam (SiLo), sandy loam (SaLo), silt (Si), loamy sand (LoSa), sand (Sa).

142 year 2018 (see also <https://soilgrids.org/> for predicted soil classification of the study area). The texture

143 measurements are presented within the USDA triangle (United States Department of Agriculture, Figure 2).
 144 With fractions between 9 and 50% for the clay, between 25 and 72% for the silt and between 12 and 55% for the
 145 sand, the observed contents cover wide ranges of each component. On average, the texture is composed of 48%
 146 of silt and 26% of clay and sand, illustrating the dominance of silt fraction within the study area. FR-Lam soil is
 147 more clayey than the FR-Aur one and thus less permeable. As FR-Lam is located on the terraces near a river
 148 flood can occur after heavy rainfall. As the FR-Aur site is located on a hillside, its soil is heterogeneous and its
 149 depth vary from 1 to more than 2 m.

150

151 2.2. In situ data

152 The FR-Aur and FR-Lam sites have been intensively monitored since 2005. Micrometeorological,
 153 meteorological, soil and vegetation measurements are performed since then (see Béziat et al., 2009 for more
 154 details). Both sites have similar climatic conditions but different soil properties (see 2.1.1), topography and
 155 agricultural management practices. Winter wheat was cultivated throughout 8 cropping years, 2005-2006, 2009-
 156 2010, 2011-2012 and 2013-2014 at FR-Aur and 2006-2007, 2008-2009, 2010-2011 and 2012-2013 at FR-Lam.
 157 To facilitate the reading of this paper, we will identify each site-year by the three first letters of the site followed
 158 by the harvest year (*e.g.*, AUR2006 for the site-year 2005-2006 at Auradé).

159 The FR-Aur field (23.5 ha) is located on a hillside area near the Garonne River terraces and is characterized by a
 160 rapeseed/winter-wheat/sunflower/winter-wheat rainfed rotation that only receives mineral fertilizers. Only the
 161 grain is exported. The FR-Lam field (23.8 ha) is part of an experimental farm for milk and chicken production
 162 owned by the Purpan engineering school EIP (Ecole d'Ingénieurs de Purpan). It is characterized by a
 163 maize/winter-wheat rotation that is used to feed livestock and provide litter. Therefore, nearly all aboveground
 164 biomass is exported as grain and straw for winter wheat, and irrigated maize is harvested when it is still green for
 165 silage. Both organic and mineral fertilizers are applied.

166 A field campaign was conducted in June-July 2011 in 16 winter wheat fields to obtain spatially distributed in situ
 167 biomass and yield data (referred to as the '2011 field campaign'). The selection of fields was based on the
 168 analysis of the intra- and inter-field variability of the Normalized Difference Vegetation Index (NDVI derived
 169 from the Formosat-2 and SPOT optical images of April) to monitor a wide range of vegetation development.
 170 Crop biomass and yield measurements were performed just before the harvest.

171

172 2.2.1. GAI, biomass and yield data

| Year | Site/ESU | Date of sowing | Date of harvest | Vegetation after harvest (nature) | GAI | Biomass | Grain yield | Flux and meteorological measurements |
|------|----------------|----------------|-----------------|-----------------------------------|-----|---------|-------------|--------------------------------------|
| 2006 | AUR | 27/10/2005 | 29/06/2006 | Yes (weeds/re-growth) | 9 | 9 | F | Yes |
| 2007 | LAM | 18/10/2006 | 15/07/2007 | No | 11 | 11 | F | Yes |
| 2009 | LAM | 19/11/2008 | 13/07/2009 | Yes (weeds) | 8 | 8 | F | Yes |
| 2010 | AUR | 19/11/2009 | 12/07/2010 | No | 5 | 5 | F | Yes |
| 2011 | LAM | 03/11/2010 | 02/07/2011 | Yes (re-growth) | 5 | 5 | F | Yes |
| | Field Campaign | - | - | - | - | 16 | D | No |
| 2012 | AUR | 21/10/2011 | 14/07/2012 | No | 5 | 5 | F | Yes |
| 2013 | LAM | 29/10/2012 | 22/07/2013 | Yes (cover-crop) | 5 | 5 | F | Yes |
| 2014 | AUR | 26/10/2013 | 10/07/2014 | No | 5 | 5 | F | Yes |

Table 1: Overview of the in situ data collected from 2005 until 2014, agricultural practices (dates of sowing harvest, etc.), and presence and type of vegetation during the fallow period. F: provided by farmer, D: destructive measurements.

173 During the vegetative cycle, the crop development at the experimental sites was regularly monitored using
174 destructive measurements of GAI and dry aboveground mass (DAM) (see Béziat, 2009 for protocol), while yield
175 data were provided by the farmers that cultivate the two flux sites. Farmer's data are often a mean of the yield at
176 several fields surrounding the instrumented sites.

177 During the 2011 field campaign, biomass and yield data were collected from 16 fields according to the VALERI
178 sampling protocol [<http://w3.avignon.inra.fr/valeri/>]. The samples were collected from five homogeneous square
179 subplots inside the 16 Elementary Sampling Units (ESUs) of 20×20 m². The subplots sampled in each ESU were
180 located in the ESU centre and corners. For each subplot, 4 rows with lengths of 50 cm and an inter-row distance
181 of 13 cm were collected, which resulted in a sampling surface area of 0.25 m². The samples were dried and
182 weighed, and the destructive grain yield was measured after threshing. The mean and associated standard
183 deviations of the five subplots were calculated for each ESU.

184 Table 1 summarizes, for each year, the number and the kind of data that were acquired and it specifies if
185 spontaneous regrowth, cover crop or weed development occurred or not after harvest for each year.

186

187 2.2.2. Flux and meteorological measurements

188 Turbulent fluxes of CO₂, water vapor (evapotranspiration and latent heat), sensible heat and momentum were
189 measured continuously using the eddy-covariance (EC) method (Aubinet et al., 1999; Baldocchi, 2003;
190 Moncrieff et al., 1997). The EdiRe software (Robert Clement, © 1999, University of Edinburgh, UK) was used
191 to calculate the turbulent fluxes. The NEE was calculated as the sum of turbulent CO₂ fluxes and changes in CO₂
192 storage under the EC devices. Flux filtering, quality controls and gap filling were performed following the
193 CarboEurope-IP recommendations ([www.carboeurope.org], see Béziat et al., (2009) for more details). The NEE
194 was partitioned into gross primary production (GPP) and ecosystem respiration (R_{eco}) components according to
195 the method proposed by Reichstein et al., (2005) and adapted by Béziat et al., (2009) for croplands (a process
196 that could lead to over- or underestimations of the two components of the NEE). During the periods of bare soil,
197 the GPP was set to 0, and the measured NEE fluxes only represented the R_{eco} component. Finally, the net
198 ecosystem production (NEP) was derived from the annual integration of the NEE values. Synchronously, the
199 standard meteorological variables were recorded at each experimental site and included different radiation
200 components (*i.e.*, direct and diffuse components of incoming global radiation). After pre-processing, the semi-
201 hourly fluxes and meteorological data were integrated or averaged at a daily time scale to be consistent with the
202 model time step. Note that because of instrument failure, there was a 3-month gap in the flux measurements at
203 the beginning of 2011 at FR-Lam.

204 For the '2011 field campaign' simulations, the SAFRAN meteorological data produced by Météo-France (Durand
205 et al., 1993) are used. The SAFRAN data provide the air temperature, incoming global radiation, precipitation,
206 and relative air humidity 2 m above the ground and the wind speed 10 m above the ground based on weather
207 station measurements and modelling. The data are available every 6 h over an 8 km spatial resolution grid. The
208 daily means of these climatic variables are calculated for each 2011 campaign field using bilinear interpolation.
209 The other simulations are performed using the climatic data recorded at the instrumented sites.

210 During the studied years, the climatic conditions were very contrasted. The 2006-2007 cropping year was
211 characterized by a mild winter resulting in strong vegetation developments while water stress occurred at the end
212 of the 2005-2006 cropping season due to very low spring rainfall (86 mm at FR-Aur compared to 197 mm on

213 average over all studied years, see Béziat et al., 2009). The 2008-2009 autumn was characterized by heavy
 214 rainfall (cumulated precipitation of 192 mm during 2009 fall at FR-Lam compared to 154 mm in average
 215 between 2006 and 2014 at the same site) following the sowing, delaying crop emergence and resulting in very
 216 low biomass and yield production. The 2009-2010 cropping year was close to average in terms of precipitations
 217 and temperatures except during winter as temperatures were below the average (5.1°C at FR-Aur compared to
 218 6.6°C on average) and were negative during several days resulting in two cumulated weeks delaying the crop
 219 development. In 2010-2011, the winter and spring were very dry (precipitation of 93 and 103 mm at FR-Lam in
 220 winter and spring respectively compared to 169 and 208 mm on average) delaying, crop development while hot
 221 temperatures in spring (average temperature of 16.5°C at FR-Lam during 2011 spring compared to 15.7°C on
 222 average during this period between 2006 and 2014) accelerated the development and the senescence. The
 223 cropping season 2011-2012 was characterized by a cold winter (mean temperature of 5.9°C at FR-Aur compared
 224 to an average of 6.6°C) during which low precipitations occurred (86 mm instead of 162 mm on average). In
 225 2012-2013 heavy rainfall during winter and spring (323 and 296 mm at FR-Lam in winter and spring) coupled
 226 with hot temperatures in summer (21.1°C compared to a mean of 20.5°C) led to high biomass production.
 227 Finally, the cropping year 2013-2014 was characterized by its warm winter (8.1°C against 6.6°C on average)
 228 allowing the crop to start early in the season.

2.3. Satellite data and products

2.3.1. Multi-satellite optical images

231 This study uses an extensive dataset of HSTR from several satellites. Because of the spatial and temporal
 232 resolution of this dataset, and also as the bands necessary for this study are available from Sentinel-2 we consider
 233 that their combined use in this modelling exercise is representative of what could be achieved with Sentinel 2.
 234 Figure 3 presents a chronogram of the satellite images used in this study between 2006 and 2014. The images
 235 from those different satellites were combined to better monitor crop development and to reduce the gaps between
 236 successive observations. Nevertheless, the presence of clouds and/or shadows reduced the number of useful
 237 images. For instance, only one cloud-free SPOT image (April 26th) was available from mid-February until mid-
 238 June 2008; consequently, this site-year was not processed in the present study.

240 The high spatial resolution images provided by Formosat-2 (F2, 155 images) and Spot-2/4/5 (80 images) were in

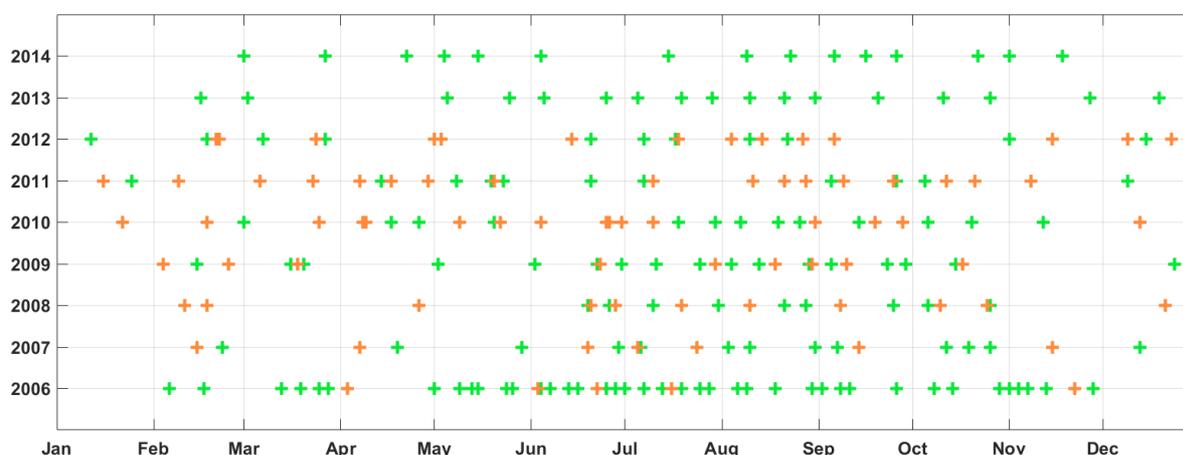

Figure 3: Timeline of the images acquired by Formosat-2 (green) and SPOT-2/4/5 (orange)

241 the optical domain (multispectral mode). The F2 images were characterized by a spatial resolution of 8 m
242 (footprint of 24×24 km²) and were acquired at the same viewing angle ($\pm 45^\circ$) in four narrow wavelengths (blue,
243 green, red and near-infrared) (Chern et al., 2008). The SPOT images were characterized by spatial resolutions of
244 20 m (Spot-2/4) and 10 m (Spot-5) covering an area of 60 × 60 km². The images were acquired at two incidence
245 angles (75° and 102°) in at least three wavelengths (green, red, and near-infrared), with the medium-infrared
246 wavelength for SPOT-4/5 (Arnaud and Leroy, 1991).

247 Surface reflectances were derived from the satellite data using the KALIDEOS processing chain
248 [<http://kalideos.cnes.fr>] for atmospheric, radiometric and geometric corrections. The mean geometric correction
249 accuracy was close to 0.2 pixels (LaFrance, Lenot, Ruffel, Cao, & Rabaute, 2012), which is satisfactory for the
250 surface area of the studied fields.

251 The combined use of images acquired by different satellites was important to increase the number observations
252 per cropping year (see Figure 3). The comparison of the reflectances or of the NDVIs derived from different
253 sensors, including Formosat-2 and SPOT, acquired at close dates over various crops, had highlighted the good
254 performances of the processing chain and the limited effect of the sensor type (Battude et al., 2016; R. Fieuzal et
255 al., 2017).

256

257 *2.3.2. From image reflectance to GAI estimates*

258 The seasonal dynamic maps of GAI were derived from the surface reflectances using the BV-NNET tool
259 (Biophysical Variables Neural NETWORK, Baret et al., (2007)), which consists of a trained artificial neural
260 network (ANN) using the outputs of a radiative transfer model (PROSAIL Jacquemoud et al., (2009)). ANNs
261 were first trained with the wide range of conditions estimated by the radiative transfer model. Then, the trained
262 network was used to predict the GAI from satellite reflectances. The GAI estimates derived from F2 and SPOT
263 reflectances were compared to non-destructive measurements based on digital hemispherical photographs
264 collected over a range of crops (Demarez et al., 2008) and showed a determination coefficient of $R^2 = 0.86$ and
265 an absolute root mean square error (RMSE) of approximately 0.5 m².m⁻² (Veloso, 2014). Battude et al., (2016)
266 also compared BV-NNET derived GAI from several satellites, including SPOT and Formosat-2. They showed
267 very good correlation ($R=0.92$ and $RRMSE=23\%$) and performances that were similar to the ones found in the
268 literature (Berjón et al., 2013; Bsaibes et al., 2009; Duan et al., 2014). The BV-NNET procedure did not include
269 the aggregation of the leaves, which can lead to the underestimation of GAI during periods of strong vegetation
270 development (Claverie et al., 2012). GAI estimates were finally averaged considering all the pixels of the studied
271 plots after the application of an offset of 10 m to avoid edge effects and to consider only the GAI of the
272 considered crop.

273

274 **3. METHODOLOGY**

275 **3.1. The SAFY-CO₂ model**

276 The SAFY-CO₂ model (Figure 4) was adapted from the SAFY model (Simple Algorithm for Yield Estimates;
277 Duchemin et al., 2008) to simulate the components of the net CO₂ fluxes and the cropland annual carbon budget.
278 SAFY is a daily time step crop model that simulates the temporal evolution of GAI, DAM and final grain yield
279 (YLD) by considering two climatic input variables: incoming global radiation and mean temperature. This
280 approach is based on Monteith and Moss's (1977) light-use efficiency theory, which links the production of the

281 total DAM with the photosynthetically active portion of the solar radiation (PAR) absorbed by the plant. In
 282 SAFY, the ratio of photosynthesis to autotrophic respiration is assumed to be constant when estimating the DAM
 283 from the absorbed PAR (APAR). The SAFY model has been extensively used for the estimation of biomass and
 284 yield in contrasting climatic conditions and crop types (Battude et al., 2016; Claverie et al., 2012; Duchemin et
 285 al., 2015, 2008; Fieuzal et al., 2011).
 286 Conversely, in SAFY-CO₂, the GPP is first estimated as a function of the APAR. Then, the components of the
 287 biomass (above and below ground) and the corresponding components of the net CO₂ fluxes and annual carbon
 288 budget are calculated. In this section, the main formalisms and equations of the model are presented and the
 289 parameters are detailed in the tables. Each table summarized the notations, the values or the ranges and the
 290 methods for estimating the parameters for the winter wheat crop and the post-harvest vegetative events.
 291 First, the model computes photosynthesis (GPP) [eq.1] as a function of the incoming global radiation (R_g), the
 292 climatic efficiency (ϵ_c), the fraction of APAR by the plant (fAPAR) [eq.1.1], the temperature stress function (f_T)
 293 [eq.1.2], the effective efficiency of the conversion of absorbed radiation to fixed CO₂ through plant

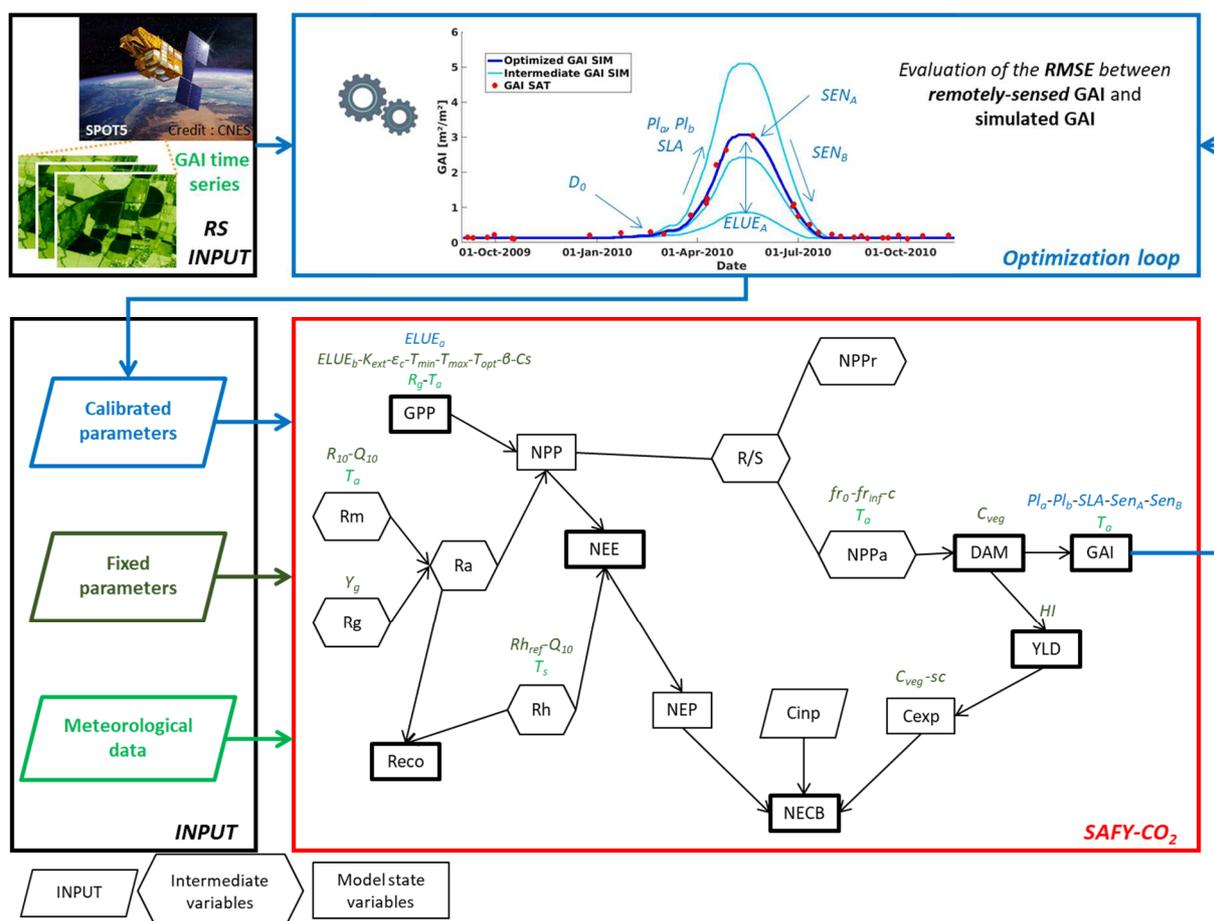

Figure 4: Schematic representation of the assimilation procedure of GAI derived from high resolution satellite optical images for the calibration of the agro-meteorological model SAFY-CO₂ by minimizing difference between satellite derived (SAT) and simulated (SIM) GAI. Also the figure shows the procedure for estimating the crop biomass, the components of the net CO₂ fluxes (GPP, RECO, NEE) and the annual carbon budgets (NECB) over a cropping season (see Tables 2 to 6 and equations 1 to 11.3.1 for more details concerning the processes simulated and the parameters).

294 photosynthesis (fELUE) [eq.1.3], and a multiplicative coefficient (sR10) [eq.1.4.1 and 1.4.2], which takes into
 295 account the decline in canopy photosynthetic capacity during the senescence phase (see Béziat, 2009). sR10 is
 296 set to 1 until senescence begins [eq.1.4.1] and then defined as the ratio between the GAI of the previous day and
 297 the maximum seasonal GAI value multiplied by the corrective factor C_s . The senescence phase first acts on the
 298 lower portion of the plant (closer to the soil) and then acts on the higher canopy elements. Thus, the actual
 299 phenological senescence may be greater than the phenological senescence detected by satellite observations,
 300 which thus requires a corrective factor. Therefore, the C_s coefficient is included in the computation of sR10 to
 301 correct for the effects of senescence over simulated fluxes. The effects of diffuse global radiation over canopy
 302 photosynthesis are not always considered in crop models when estimating crop productivity. However,
 303 measurements, including the measurements at our flux sites, have indicated that the efficiency is very sensitive
 304 to the diffuse components of incoming global radiation (Béziat, 2009; Hollinger et al., 1998; Roderick et al.,
 305 2001). An effective light-use efficiency function is thus defined to account for the fraction of diffuse global
 306 radiation (see 3.2). Because diffuse incoming radiation R_{df} is not often measured in the field, the De Jong (1980)
 307 approach was used to estimate the R_{df}/R_g ratio over the study area from the top of the canopy and the top of the
 308 atmosphere radiation data.

$$GPP = R_g * \varepsilon_c * fAPAR * f_T(T_a) * fELUE * sR10 \quad 1$$

$$fAPAR = 1 - \exp(-K_{ext} * GAI) \quad 1.1$$

$$f_T(T_a) = 1 - \left(\frac{T_{opt} - T_a}{T_{opt} - T_{min}} \right)^\beta \text{ for } T_{min} < T_a < T_{opt} \quad 1.2.1$$

$$f_T(T_a) = 1 - \left(\frac{T_{opt} - T_a}{T_{opt} - T_{max}} \right)^\beta \text{ for } T_{opt} < T_a < T_{max} \quad 1.2.2$$

$$f_T(T_a) = 0 \text{ for } T_a < T_{min} \text{ or } T_{max} < T_a \quad 1.2.3$$

$$fELUE = ELUE_a * \exp\left(ELUE_b * \frac{R_{df}}{R_g}\right) \quad 1.3$$

$$sR10 = 1 \text{ from sowing to senescence} \quad 1.4.1$$

$$sR10 = \frac{GAI}{GAI_{max} * C_s} \text{ from senescence to harvest} \quad 1.4.2$$

Table 2. List of SAFY-CO₂ model parameters for calculating the GPP

309 The NPP is then derived from the difference between the GPP and the autotrophic respiration (R_a) [eq.2], which
 310 was separated into two components: maintenance respiration (R_m) and growth respiration (R_{gr}) (McCree, 1974)
 311 [eq.3]. R_m is calculated from the NPP of the previous day and a maintenance coefficient m_R [eq.3.1], which
 312 corresponds to the fraction of maintenance respiration per NPP unit. Because R_m responds strongly to the
 313 temperature (Amthor, 2000), it was estimated using a “ Q_{10} type” equation (Van’t Hoff, 1898) [eq.3.1.1]. In this
 314 equation, R_{10} is the reference respiration at 10°C. R_{gr} is calculated using the method described by Amthor (1989)
 315 and improved by Choudhury (2000), as shown in eq.3.2. The constant Y_g is the growth conversion efficiency.

$$\begin{aligned} NPP &= GPP - R_a & 2 \\ R_a &= R_m + R_{gr} & 3 \\ R_m &= NPP * m_R * sR10 & 3.1 \\ m_R &= R_{10} * Q_{10}^{\left(\frac{T_a-10}{10}\right)} & 3.1.1 \\ R_{gr} &= (1 - Y_g) * (GPP - R_m) & 3.2 \end{aligned}$$

Table 3. List of SAFY-CO₂ model parameters for calculating autotrophic respiration

317 Finally, the total NPP is divided into root (NPP_r , [eq.4.1]) and aerial (NPP_a , [eq.4.2]) components, estimated by
 318 considering a root-to-shoot ratio (RtS) in accordance with the method proposed by Baret et al., (1992) [eq.5]. In
 319 this equation, SMT is the sum of temperature, D_0 is the emergence date and D_s is the first day of the spiking
 320 stage. fr_0 is the extrapolated value of the root fraction fr at emergence, fr_∞ is the asymptotic value of fr , and c
 321 is the relative rate of decrease. The DAM is estimated by dividing the NPP_a by the coefficient C_{veg} , which
 322 represents the plant carbon content [eq.6].

$$\begin{aligned} NPP_r &= NPP * RtS & 4.1 \\ NPP_a &= NPP * (1 - RtS) & 4.2 \\ RtS &= fr = fr_\infty + (fr_0 - fr_\infty) * \exp\left(-c \left(\frac{SMT_{D_s}^{D_s} - SMT_{D_0}}{SMT_{D_s} - SMT_{D_0}}\right)\right) & 5 \\ DAM &= \frac{NPP_a}{C_{veg}} & 6 \end{aligned}$$

Table 4. List of SAFY-CO₂ model parameters for calculating the aboveground and the belowground mass

323 Once the biomass computed, the grain yield and GAI can be estimated, as in the SAFY version. The GAI is the
 324 sum of the GAI of the previous day and the positive and negative change in GAI of the current day [eq.7]. Leaf
 325 production and leaf senescence are controlled by a growing degree-day approach. The positive increment
 326 [eq.7.1] is the product of a function of leaf partitioning [eq.7.1.1], the specific leaf area parameter and the daily

327 DAM production. The negative increment, which is only evaluated from the beginning of senescence, depends
 328 on the two senescence parameters Sen_a and Sen_b [eq.7.2]. The grain yield estimation [eq.8] depends on the total
 329 biomass production at the end of the vegetative period (DAM_{max}) and a constant harvest index HI (see 3.2).

$$\begin{aligned} \Delta GAI &= GAI + \Delta GAI^+ - \Delta GAI^- & 7 \\ \Delta GAI^+ &= \Delta DAM * Pl * SLA & 7.1 \\ Pl &= 1 - Pl_a * \exp^{(Pl_b * SMT)} & 7.1.1 \\ \Delta GAI^- &= GAI * \frac{SMT - Sen_a}{Sen_b} & 7.2 \\ Yield &= DAM_{max} * HI & 8 \end{aligned}$$

Table 5. List of SAFY-CO₂ model parameters for calculating the leaf biomass production, the yield and the senescence

330
 331 The NEE is calculated as the difference between the NPP and the carbon losses due to heterotrophic respiration
 332 (R_h) [eq.8]. R_h is calculated using a Q_{10} first-order exponential equation (Delogu, 2013). R_{href} is the reference
 333 respiration at $0^{\circ}C$, and \exp^{b*10} is equal to Q_{10} .

334 The ecosystem respiration is defined as the sum of R_a and R_h [eq.10].

$$\begin{aligned} NEE &= NPP - R_h & 8 \\ R_h &= a * \exp^{b*T_s} & 9 \\ a &= R_{h_{ref}} & 9.1 \\ Q_{10} &= \frac{Rh(T_s + 10)}{Rh(T_s)} = \frac{a * \exp^{b*(T_s+10)}}{a * \exp^{b*(T_s)}} = \exp^{b*10} & 9.2 \\ R_{eco} &= R_a + R_h & 10 \end{aligned}$$

Table 6. List of SAFY-CO₂ model parameters for calculating the heterotrophic respiration

336 3.2. Model parameterization and calibration

337 The parameters of the SAFY-CO₂ model are set using one of the following three options: i) literature
 338 sources, ii) multi-site in situ measurements and iii) optimization using the time series of satellite-derived GAI.
 339 The parameters in the first two categories are set as equal for all of the investigated fields and years of study (see
 340 equations 1 to 10 and Tables 2 to 6), while the parameter of the third category are optimized. Parameter b of the
 341 exponential function in the relationships between ELUE and R_{df}/R_g [eq.1.3] is fixed to 1.34 based on field data
 342 (*i.e.*, CO₂ fluxes and meteorological data) acquired over several years for contrasting climatic, soils, and
 343 management conditions at 5 European instrumented sites, including ours (Lonze, BE; Auradé, FR; Grignon,

344 FR; Lamasquère, FR; Oensingen, CH; see Supplementary Material). This parameter is set to a generic value to
345 facilitate the large-scale application of the approach.

346 The parameters in the third category are set using an iterative minimizing method with a RMSE
347 objective function between satellite-based GAI and SAFY-CO₂ GAI estimates. This procedure aims at
348 determining the values of parameter “a” of the fELUE function [eq.1.3] and 6 phenological parameters, *i.e.*, the
349 day of plant emergence (D_0), the specific leaf area (SLA), the two parameters of the partition-to-leave function
350 (Pl_a , Pl_b), the sum temperature for senescence (Sen_a) and the rate of senescence (Sen_b).

351 The minimization procedure, applied to each simulations (*i.e.* each cropping year and each field), is
352 based on an adapted version of the Nelder-Mead simplex method (Lagarias et al., 1998), which considers a priori
353 boundaries for each parameter to constrain the solutions within realistic parameter intervals. The minimization
354 process runs the model, computes a cost function (in this case the RMSE derived from the comparison between
355 the estimated and the remote sensed GAI) and iteratively updates the values of parameters to converge to the
356 best parameter combination, coinciding with the lowest cost function value. To reduce the probability of local
357 minima, a global approach is applied that runs the optimization process 30 times, with different *a priori*
358 conditions for each parameter. A set of the parameters with the best solution is considered (*i.e.*, lower RMSE for
359 the GAI estimates). The number of optimization runs is set to 30, based on a sensibility analysis, so that the best
360 combination of parameters is always retrieved, while avoiding unnecessary runs.

361 The optimization process requires boundaries for the parameters to calibrate (Pl_a , Pl_b , Sen_a , Sen_b , SLA,
362 $ELUE_a$, D_0). These boundaries are first estimated based on a literature review. Then, a sensitivity analysis of the
363 model is conducted to adjust these boundaries using a grid search. The ranges of the parameters are discretized,
364 and all possible combinations are simulated (more than 3 million simulations). Then, the outputs are compared to
365 the outputs obtained by optimizations performed using the adapted simplex method described above and the
366 same parameter boundaries. This comparison allows us to do the following.

- 367 1- Verify that the adjusted boundaries reproduce all plant development conditions, with the constraint
368 of a limited dispersion in the outputs.
- 369 2- Validate the efficiency of the adapted version of the simplex in retrieving the best set of parameters.

370 Compared to SAFY, the SAFY-CO₂ version considers the biomass production of re-growth, weeds and
371 cover crops (hereafter called post-harvest vegetative events) and their effect on the CO₂ fluxes and annual C
372 budgets. Indeed, these post-harvest events can have an important impact on the NEE (Béziat et al., 2009; Ceschia
373 et al., 2010; Poepflau and Don, 2015) and thus on the NECB. Therefore, the model is adapted to simulate these
374 events without the distinction of their nature (*i.e.*, spontaneous re-growth, weeds or cover crop).

375 In a first attempt to estimate the effects of post-harvest vegetative events on the net CO₂ flux
376 components and ultimately on the annual NECB, the same parameterization considered for winter wheat is also
377 considered for all post-harvest vegetative events. For the studied years, when the satellite-derived GAI indicates
378 the presence of vegetation on the field after harvest (*i.e.*, AUR2006, LAM2009, LAM2011, and LAM2013), the
379 model is first run to simulate the main crop. Then, a second optimization is performed on the vegetation
380 following the main crop, optimizing $ELUE_a$ and the 6 phenological parameters. The boundaries of parameters
381 Sen_a , D_0 and $ELUE_a$ are changed compared to those fixed for winter wheat, while the ranges of the 4 other
382 parameters remain the same.

383

3.3. From daily net ecosystem CO₂ fluxes, NEE to the annual net ecosystem carbon budget, NECB

To compute the annual NECB [eq.11], carbon input (C_{inp}) and export (C_{exp}) terms are added to the annual cumulated NEE (*i.e.*, the NEP) [eq.11.1]. The NEP is the carbon absorbed or released by the field (through photosynthesis and respiration processes) over a cultural year, a positive NEP indicates that cumulated soil and autotrophic respiration are higher than cumulated photosynthesis, meaning that the field loses carbon towards the atmosphere and vice versa. The value of NEP is computed from October 1st to September 30th because this period usually corresponds to the agricultural cropping year in Europe (Ceschia et al., 2010). The term C_{inp} represents the amount of C that is brought to the field as organic fertilizer (only at FR-Lam in this study) and as seeds. Since C_{inp} could not be simulated, the C_{inp} values provided by the farmer as well as analysis of the organic fertilizer C content (Béziat et al., 2009), were used to calculate the NECB at LAM. C_{exp} generally corresponds to the yield [eq.11.2] in the study area, as typically, only grain is exported from the field (*e.g.*, FR-Aur). However, in some cases, straws are also exported from the field (*e.g.*, FR-Lam). From the perspective of regional-scale applications, this term ($straw_{exp}$) is estimated as a function of the total straw biomass ($straw_{tot}$), which corresponds to the final aboveground biomass (DAM_{max}) minus the final grain yield [eq.11.3]. The sc parameter [eq.11.3.1] is estimated from in situ data during the 2011 field campaign and set to 0.3.

$$NECB = NEP + C_{exp} - C_{inp} \quad 11$$

$$NEP = \int_{1^{st} Oct}^{30^{th} Sept} NEE \quad 11.1$$

$$C_{exp} = Yield * C_{veg} \quad 11.2$$

$$C_{exp} = C_{veg} * (Yield + (DAM_{max} - Yield) * sc) \quad 11.3$$

$$sc = \frac{straw_{exp}}{straw_{tot}} = \frac{straw_{exp}}{DAM_{max} - Yield} \quad 11.3.1$$

400

3.4. Model implementation and validation strategy

The proposed approach requires several types of input data, which are taken into account at different stages of the modelling process or during the calculation of the carbon budgets. To run the model, meteorological data (R_g and T_{air}), soil parameters (heterotrophic respiration parameters) and plant parameters (some being fixed and some being calibrated (see Table 2 to 6 for more details) are needed. The model can simulate the output variables only with those information, however, in the absence of calibration process, the estimates are very likely to be erroneous. To correctly simulate the crop development and thus get meaningful outputs, the satellite derived GAI is used to calibrate Pl_a , Pl_b , Sen_a , Sen_b , $ELUE_a$, SLA and D_o . Once the calibration process achieved, the parameters are set for each field and climatic year allowing to reproduce the vegetation dynamic (GAI, DAM, YLD) as well as the CO₂ fluxes (GPP, R_{eco} , NEE). Because at this stage, only remote sensing data and crop maps are needed, the approach can be up-scaled easily. Nevertheless assessing carbon budgets demand additional data that are not easily available at plot scale over large areas yet. The two additional input data needed are: the amount of C imported (C_{inp}) to the plot (as seeds and eventually as organic amendments), and an information on whether straw are exported from the plot or not. These two inputs allow to estimate the NECB [eq. 11].

The validation strategy relies on different types of datasets. Concerning the GAI, the comparison of the model output with the satellite derived GAI is not really a validation since the later is used to calibrate the model but

417

418 rather a verification of the model's ability to reproduce vegetation dynamic. To evaluate the performances of the
 419 model to simulate biomass, data from the instrumented ICOS flux sites and from the 2011 field campaign are
 420 considered. For yield validation, only the results from the 2011 field campaigns are presented (covering a range
 421 of values from 1.87 to 8.93 t.ha⁻¹) as the annual yields provided by the farmer at the two instrumented sites may
 422 be averages of several fields from the farm and therefore present high uncertainties (see Béziat et al., 2009).
 423 These validations are presented in section 4.1.1.

424 To evaluate the performance of the model in terms of CO₂ flux simulations we used the data from the two ICOS
 425 sites (FR-Lam and FR-Aur). The use of very contrasted climatic years and management regimes at FR-Lam and
 426 FR-Aur (see section 2.2.2) makes our validation approach more robust. Those results are presented in section
 427 4.1.2.

428 Among the objectives of the present study, assessing annual carbon budget is the most challenging. Indeed, the
 429 performances of the model to simulate both the NEP and the amount of biomass exported at harvest must be
 430 quite high to compute NECB as those two terms are usually of opposite sign and partly compensate each other.
 431 A small absolute error on one of those two terms will end up in a large absolute error on the NECB. Section
 432 4.2.1 presents the ability of the model to reproduce the cumulated NEE, which leads to the NEP. Then sections
 433 4.2.2 and 5 present and discuss, respectively, the capability of the model to assess the NECB.

434

435 4. RESULTS

436 4.1. Evaluation of the overall model performances

437 4.1.1. GAI, DAM and yield estimates

438 Figure 5 shows an overview of the statistical performances of the model in estimating GAI and DAM by

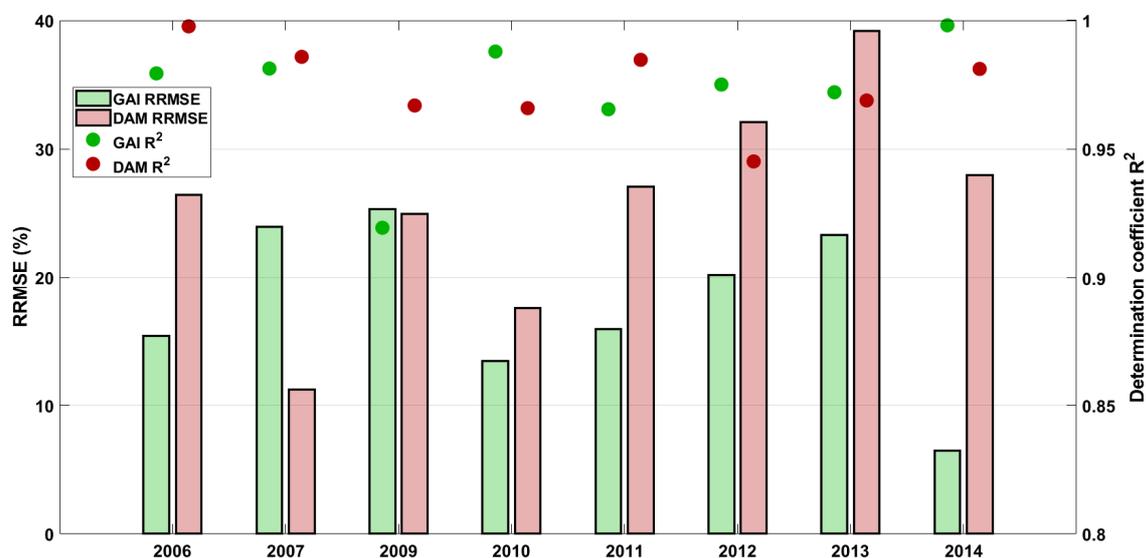

Figure 5: Statistical performances (relative root mean square errors and coefficients of determination correspond to the bars and dots, respectively) associated with the estimation of the GAI (green) and DAM (red) for winter wheat at the Auradé (even-numbered years) and Lamasquère (odd-numbered years) sites.

439 comparing the estimates with
 440 satellite-derived GAI and
 441 destructive biomass
 442 measurements for the FR-Aur
 443 (even-numbered years) and
 444 FR-Lam (odd-numbered
 445 years) sites in the 8
 446 cultivation years. In addition,
 447 Figures 6a and 6b present
 448 scatter plots of these two
 449 variables, distinguishing
 450 observations performed
 451 during the entire studied
 452 period (2006-2014) at the two
 453 flux sites and measurements
 454 collected during the 2011
 455 field campaign. At the flux

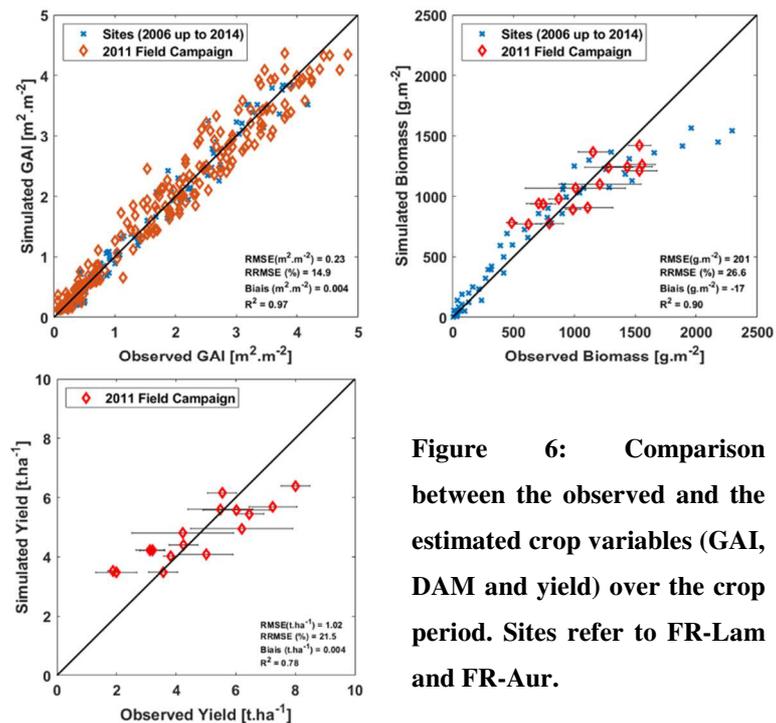

Figure 6: Comparison between the observed and the estimated crop variables (GAI, DAM and yield) over the crop period. Sites refer to FR-Lam and FR-Aur.

456 sites, the GAI relative root mean square errors (RRMSEs, *i.e.*, RMSE normalized by the mean observed value)
 457 range between 6 and 24% (for the years 2014 and 2007, respectively), while the determination coefficients (R²)
 458 are between 0.919 and 0.998 (for the years 2009 and 2014, respectively, Figure 5). When also considering fields
 459 from the 2011 campaign (Figure 6a), the GAI is reproduced by the model with a very high R² (0.97) and with
 460 almost no bias (0.004 m².m⁻²). The magnitude of this performance confirms that the model allows the correct
 461 interpolation of the GAI derived from remote sensing, as has already been demonstrated in previous studies
 462 (Duchemin et al., 2015; Fieuzal et al., 2011; Hadria et al., 2010).

463 On average, the model also reproduces the DAM with good precision. When considering all investigated fields
 464 across the studied years (Figure 6b), the RMSE, RRMSE and R² were 201 g.m⁻², 26.6% and 0.90, respectively.
 465 These performances are consistent with those achieved using the SAFY model (maize and sunflower had
 466 RMSEs of 252 and 145 g.m⁻², respectively, and RRMSEs of 24.7 and 39.1%, respectively, in Claverie et al.,
 467 2012), as well as the performances of other models such as the APSIM-wheat model (Asseng et al., 1998) and
 468 STICS (Brisson et al., 2002), which estimated winter wheat biomass with R² of 0.90 and 0.78, respectively, and
 469 RMSEs of 0.101 and 0.266 kg.m⁻², respectively. Nevertheless, the performances are more scattered when
 470 analysing annual statistics (Figure 5). Indeed, the DAM RRMSE values are between 11 and 39.2% (for the years
 471 2007 and 2013, respectively), while the R² values are between 0.945 and 0.998 (for the years 2012 and 2006,
 472 respectively). In general, the modelling approach tends to underestimate the highest biomass values at the end of
 473 the season (observed at LAM2011, AUR2012, LAM2013 and AUR2014). The highest levels of errors, for the
 474 DAM in 2012 and 2013, correspond to the strongest vegetation developments of 1960 g.m⁻² and 2298 g.m⁻²,
 475 respectively, reached at the end of the crop season. Those DAM underestimations are caused by the
 476 underestimation of the effective GAI produced by BV-NNET for the highest values since the clumping effect is
 477 not accounted for (Claverie et al., 2012). This issue will be further discussed in Section 5.2.

478 On average, yields (only data from the 2011 field campaign are analysed here, see 2.2.1) are estimated with good

479 precision (RMSE=1.02 t.ha⁻¹, RRMSE=21.5%, R²=0.78), but underestimations are observed for the highest
 480 observed values. These underestimations are directly related to the DAM underestimations described above, as
 481 yield is estimated as a fraction of the final biomass. Nevertheless, the yield-estimation performances of SAFY-
 482 CO₂ are similar to those of SAFY (Duchemin et al., 2008) and STICS (Brisson et al., 2002) for wheat, with R²
 483 values of 0.64 and 0.65, respectively, and RMSEs of 0.5 and 1.6 t.ha⁻¹, respectively.

484

485 4.1.2. Components of the net CO₂ fluxes: daily GPP, R_{eco} and NEE

486 In this section, the components of the net CO₂ fluxes simulated by SAFY-CO₂ are compared to the measured
 487 NEE at the FR-Aur and FR-Lam flux sites and with the GPP and R_{eco} estimated following the partitioning of
 488 NEE. For the 8 investigated cropping years, the model performances are evaluated in terms of the error (RMSE)
 489 and correlation (R²) (see Figure 7). These statistical parameters are also calculated for the following periods of
 490 each cropping year (see Figure 8):

- 491 1- From the beginning of the cropping year (October 1st) until the emergence of the crop
- 492 2- From the emergence of the crop until the maximum vegetation
- 493 3- From the maximum vegetation until harvest
- 494 4- From harvest until the end of the cropping year (September 30th)

495 4.1.2.1 GPP estimates

496 When considering the whole vegetative periods (*i.e.*, crop development and post-harvest vegetative events) of
 497 the 8 site-years, the simulated GPP dynamics agree well with the measurements, showing R² values between
 498 0.82 (LAM2011) and 0.94 (LAM2007) and RMSEs between 1.34 (LAM2009) and 2.39 (LAM2011) gC.m⁻².d⁻¹.
 499 In 2011, however, the simulated GPP during crop development showed poor statistics. A strong development of

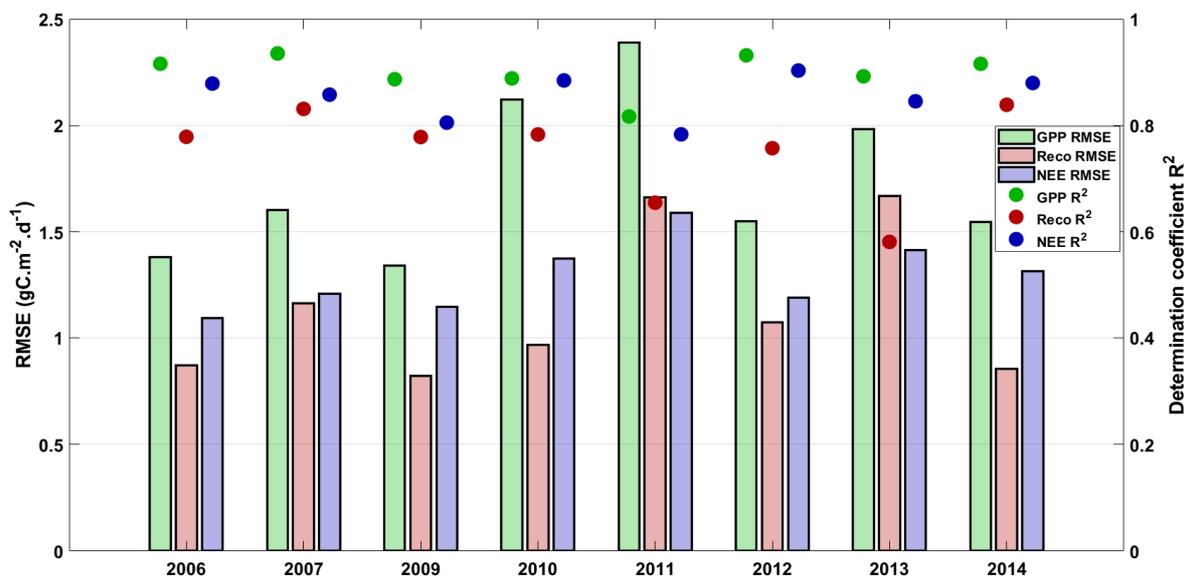

Figure 7: Statistical performances (root mean square errors and coefficients of determination are bars and dots, respectively) associated with the estimations of the daily GPP, R_{eco} and NEE for the 8 winter wheat cropping years (October 1st to September 30th) at FR-Aur (even-numbered years) and FR-Lam (odd-numbered years).

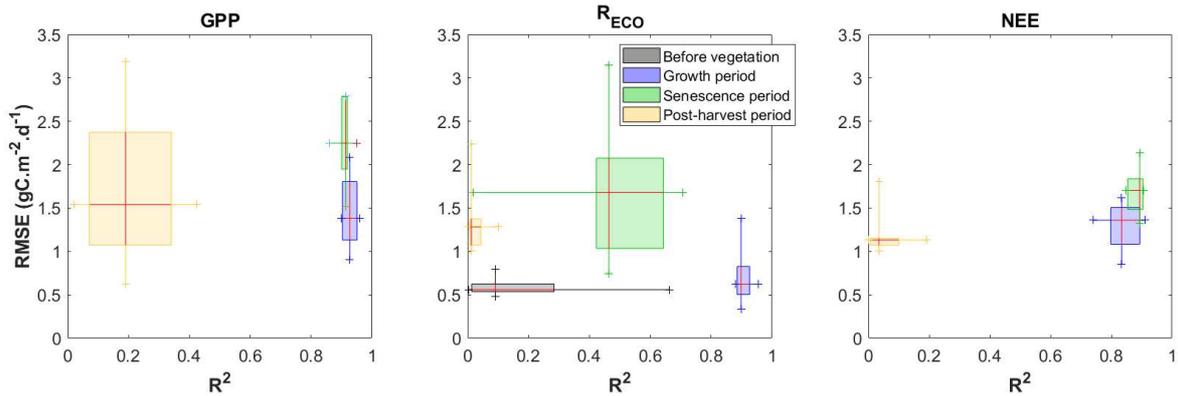

Figure 8: Boxplot of the pluriannual determination coefficients (R^2) and the pluriannual root mean square errors (RMSEs) of the simulated GPP, R_{eco} and NEE in the before-crop, crop-growth, crop-senescence, and post-harvest periods for the 8 cropping years of winter wheat at AUR and LAM. Only the years with post-harvest vegetative events (2006-2009-2011-2013) are considered for the boxplot of the post-harvest GPP.

500 vegetation occurred in early 2011, while no flux data were recorded between January 1st and March 31th.
 501 Consequently, the CO₂ fluxes were gap filled, and thus, the simulated GPP is underestimated over this period,
 502 leading to low R^2 and high RMSE values.

503 During crop development (growth and senescence, excluding post-harvest vegetative events), the simulated GPP
 504 shows R^2 values between 0.86 and 0.96 and RMSE values between 0.90 and 2.79 gC.m⁻².d⁻¹. These periods are
 505 well reproduced by the model, the growth period shows slightly better performances than the senescence period.
 506 This trend can be explained by two phenomena: i) the underestimation of the simulated GPP during senescence
 507 due to the abovementioned limits of remote-sensed GAI (underestimation due to saturation effects) coupled with
 508 the potential lack of remote sensing observations, which prevents the correct reproduction of GPP during the
 509 senescence phase and ii) the presence of weeds growing inside the senescent crop (the understorey vegetation
 510 often observed at FR-Lam), which are undetectable by the satellite but still impact the flux measurements (see
 511 *Temporal Evolution* of LAM2013 in section 4.1.2).

512 Considering the post-harvest period, only site-years with significant vegetative events are considered (*i.e.*, weeds
 513 for AUR2006 and LAM2009, spontaneous crop re-growth for LAM2011 and cover crops for LAM2013). The
 514 values of the R^2 between the simulated and observed GPP are lower during this period than during the crop
 515 development period for several reasons. First, at this stage, the same parameterization as the winter wheat
 516 parameterization is used for simulating the different types of post-harvest vegetative events (except concerning
 517 the parameters calibrated based on GAI satellite estimates – see section 3.2). Second the post-harvest vegetation
 518 is characterized by higher spatial heterogeneity than winter wheat, leading to likely divergence between observed
 519 and simulated CO₂ fluxes. Indeed the footprint of the EC system is probably not fully representative of the entire
 520 field simulated by the model. Nevertheless, the overall performances of the model always increase when post-
 521 harvest vegetative event are considered.

522

523 4.1.2.2 Reco estimates

524 Overall, the ecosystem respiration follows the same dynamics as the GPP but in an attenuated way (*i.e.*, the

525 differences between bare-soil and vegetative periods are smaller). The simulated R_{eco} dynamics are in good
526 agreement with the observations, as shown in Figure 7. The annual RMSE values range from 0.82 (LAM2009)
527 to 1.67 (LAM2013) $\text{gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$, and the R^2 values range from 0.58 (LAM2013) to 0.84 (LAM2014).

528 The mean annual performances of the model in estimating R_{eco} are lower than those in estimating GPP but are
529 consistent with other studies that aim to estimate ecosystem respiration in agricultural fields. Zhan et al. (2019)
530 found R^2 values between 0.84 and 0.87 and RMSEs between 1.52 and 1.65 $\text{gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$ for a maize-soybean
531 system, while Lohila et al., (2003) estimated the total ecosystem respiration of barley with a simple soil
532 temperature-dependent model with good precision (R^2 between 0.71 and 0.79). A more detailed analysis of our
533 results shows that the R_{eco} is always well estimated during the crop growing periods, showing R^2 values between
534 0.88 and 0.95, while the statistical performances are lower in other periods than in the crop growing period
535 (Figure 8). One explanation for this difference is that the formulation for estimating heterotrophic respiration is
536 too simplistic to reproduce some of the processes occurring in the soil, especially after harvest. This issue will be
537 further discussed in Section 5.2.

538 Additionally, for GPP, the presence of weeds growing inside the senescent crop, which is hardly detectable by
539 the considered satellite but still impacts flux measurements (see the temporal evolution of LAM2013 in section
540 4.1.2.4), cannot be considered in our modelling approach. On the other hand, the good performances during the
541 crop growing periods indicate that the model accurately reproduces autotrophic respiration, which can represent
542 80% of the R_{eco} during the crop season (Béziat, 2009). The modelled R_{eco} estimates are thus satisfactory
543 considering the simplicity of its representation as well as the limited number of inputs in this crop modelling
544 approach.

545 **4.1.2.3 NEE estimates**

546 The daily dynamics of the NEE are well reproduced by the SAFY-CO₂ model even when GPP and R_{eco} are
547 underestimated, since the errors of the two components compensate for each other (either because the
548 partitioning process overestimates the in situ data or because the model underestimates the crop development,
549 which affects both GPP and R_{eco}). The model that shows good performances over the cropping year in terms of
550 errors and correlations, with RMSEs between 1.09 (AUR2006) and 1.59 (LAM2011) $\text{gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$ and R^2 values
551 between 0.78 (LAM2011) and 0.90 (AUR2012). The model achieves better performances during the vegetative
552 stages than during fallow periods (as is the case for GPP and R_{eco} due to the reasons mentioned above).

553 In order to compare the performances of SAFY-CO₂ to simulate NEE with other agronomical or land surface
554 models, our results were confronted to those presented by Wattenbach et al., (2010). In their study, they
555 compared the performances of DNDC (Li et al., 2005, 1994, 1992), ORCHIDEE-STICS (de Noblet-Ducoudré et
556 al., 2004; Gervois et al., 2008), SPA (Williams et al., 1996) and CERES-EGC (Gabrielle et al., 2006; Lehuger et
557 al., 2009) in reproducing the GPP, R_{eco} and NEE for several site-years, including the AUR2006 crop season.
558 SPA and SAFY-CO₂ outperformed the other approaches by reproducing the dynamics of the cumulated NEE,
559 with R^2 values of 0.993 and 0.995, respectively. In terms of errors, SAFY-CO₂ and CERES-EGC showed the
560 lowest RMSEs, 33.6 $\text{gC}\cdot\text{m}^{-2}$ and 44.16 $\text{gC}\cdot\text{m}^{-2}$, respectively.

561 **4.1.2.4 Temporal evolution**

562 We decided to show the performances of SAFY-CO₂ in simulating the time courses of the GPP, R_{eco} and NEE
563 for three contrasting site-years (AUR2006, LAM2009 and LAM2013) among the eight cultivation years. The

564 objectives here are i) to identify potential sources of errors in the GPP and R_{eco} estimates that can affect the NEE
565 and the net annual CO_2 fluxes (NEP) and therefore the NECB estimates, ii) to verify whether the proposed
566 approach is robust for varying soils, management practices and climatic years and iii) to analyse the potential of
567 this approach to simulate contrasting post-harvest vegetative events.

568

569 • Auradé 2006

570 The 2006 cropping year at FR-Aur (grain farm) is characterized by very clear sky conditions and strong
571 radiation, little precipitation in spring (23.4, 29.7 and 32.8 mm of rain during April, May and June, respectively,
572 in 2006; in contrast, the monthly means in these months over the 8 years of the study and both sites are 64.1,
573 61.1 and 95.4 mm, respectively) and several re-growth/weed events occurring after harvest. For this site-year
574 (Figure 9a), the model correctly reproduces the GPP and the R_{eco} in terms of errors (RMSEs of 1.38 and 0.87
575 $\text{gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$, respectively) and dynamics (R^2 of 0.92 and 0.78, respectively). Consequently, the NEE for this year
576 is accurately estimated (RMSE and R^2 of 1.09 and 0.88, respectively). Nevertheless, the modelled GPP is
577 slightly overestimated after maximum development and at the beginning of senescence (Figure 9a). This
578 overestimation could be related to the water stress conditions observed after the maximum GAI was reached
579 (Béziat et al., 2013) that cannot be fully considered by the model. Moreover, spontaneous re-growth and weeds
580 developed twice after harvest. The first event led to increases in the observed GPP and R_{eco} just after harvest and
581 was interrupted by soil work on July 31. The second vegetative event occurred from mid-August until late
582 September 2006 and was interrupted by soil work on September 29. In a first attempt, we simulate only one
583 vegetation cycle after harvest, so the two events are simulated as one (see red dashed line in Figure 9a); as a
584 consequence, GPP and R_{eco} are overestimated. NEE estimates during this period are improved (RMSE from 1.22
585 to $0.93 \text{ gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$) by accounting for weed/re-growth development.

586

587 • Lamasquère 2009

588 The 2008-2009 cropping season at FR-Lam (milk and chicken production farm) was characterized by strong
589 rains in November and December that saturated the soil, causing poor emergence and late winter wheat
590 development. Additionally, weeds developed before harvest during the winter wheat senescence. The GPP
591 dynamics for LAM2009 are well reproduced, with an R^2 of 0.89. Additionally, R_{eco} and NEE present R^2 values
592 of 0.78 and 0.81, respectively, over the cultivation year. The errors of the GPP, R_{eco} and NEE are also low,
593 showing RMSE values of 1.34, 0.82 and $1.14 \text{ gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$, respectively. However, during May 4, peaks are
594 observed in measurements (13 days in total) that are not reproduced by the model. This divergence between
595 simulated and observed GPP comes from the underestimation of the fELUE for days with high radiation and
596 very clear sky conditions. After harvest (from mid-July to mid-September), the presence of weeds in the field is
597 highlighted by the measured GPP dynamics. As for 2006, the dynamics and the range of the simulated post-
598 harvest GPP and R_{eco} are not correctly reproduced by the model since the parameterization is the same as that for
599 winter wheat, and many phenomena are not considered (*i.e.*, priming effect, nitrogen or water stress, etc.).
600 Nevertheless, accounting for weeds in the model allows a better estimation of the NEE (RMSEs decreasing from
601 1.7 to $1.14 \text{ gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$).

602

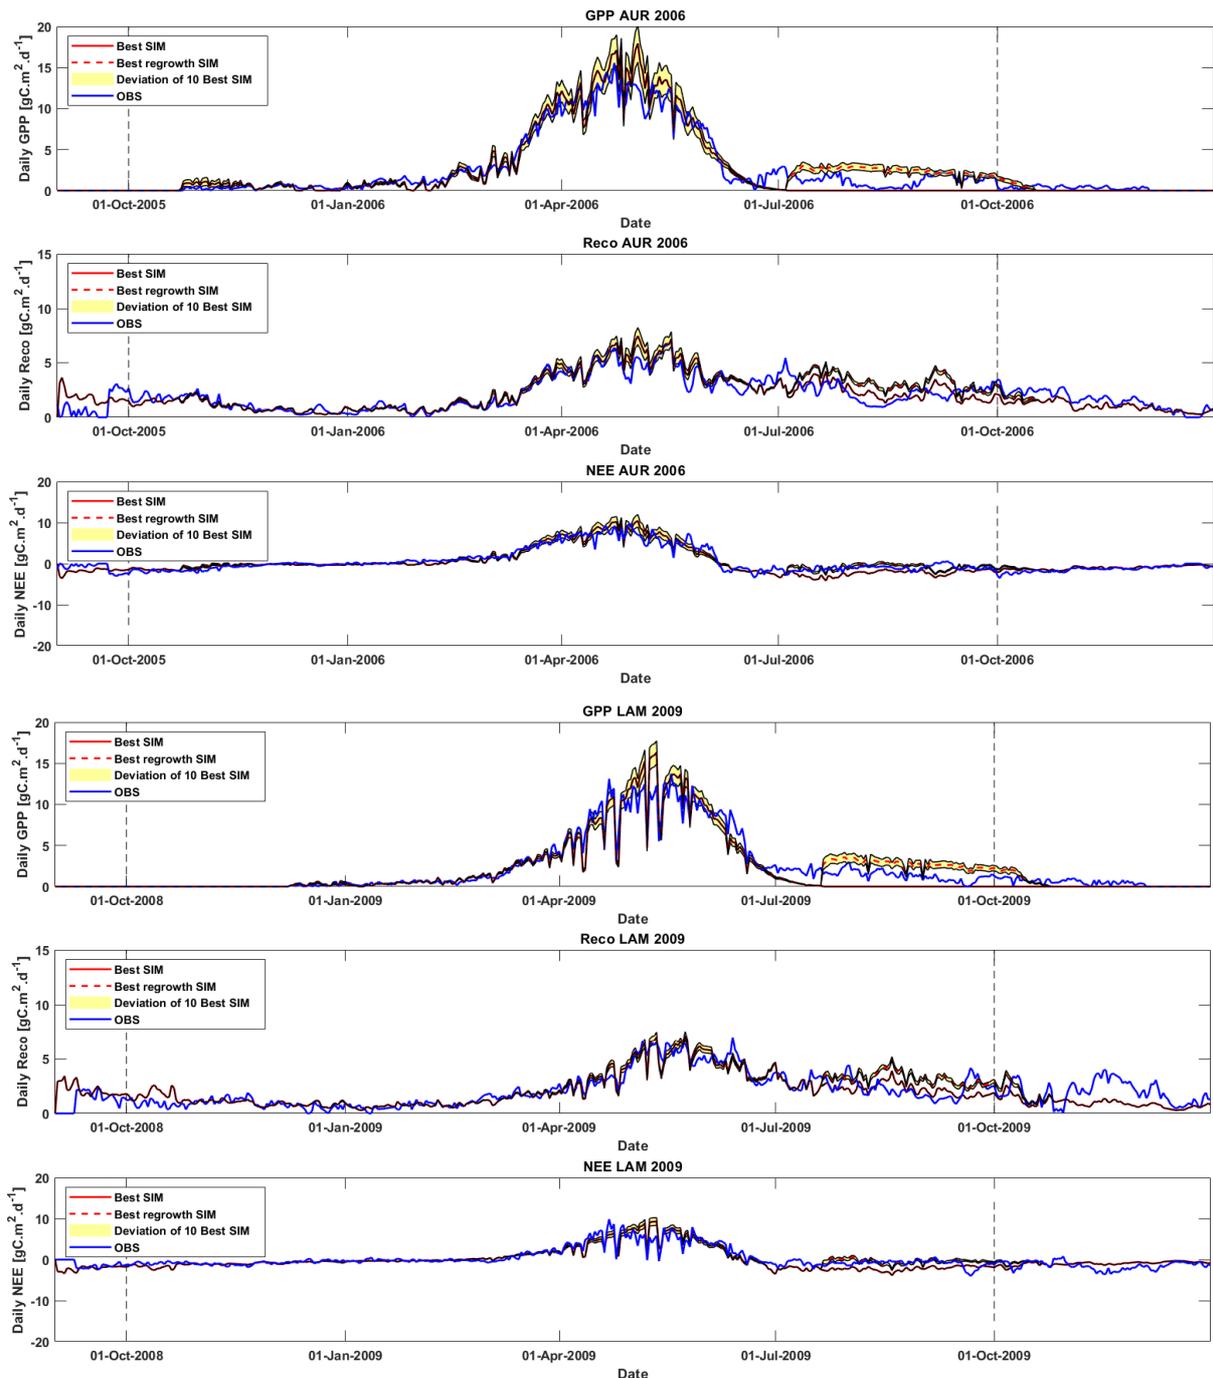

Figure 9a: Temporal evolution of the measured (in blue) and estimated (in red or red dashed lines) GPP, R_{eco} and NEE for 2 site-years (AUR2006 and LAM2009). The red/red dashed lines represent the simulations that do/do not account for re-growth and weed events. The yellow envelopes represent the daily standard deviation of the 10 (/30) best simulations (i.e. smaller RMSE GAI error). The vertical dashed lines define the cropping year.

603 • Lamasquère 2013

604 We present the results of FR-Lam over the LAM2013 cropping year because it is the only site-year during which
 605 a cover crop was grown. Indeed, in 2013 at FR-Lam, after the harvest of the winter wheat, white mustard was
 606 sown on the 21st of August and incorporated in the soil on the 4th of December. Unlike re-growth and weed
 607 development, the development of the cover crop is rather homogeneous in the field and follows a growing cycle

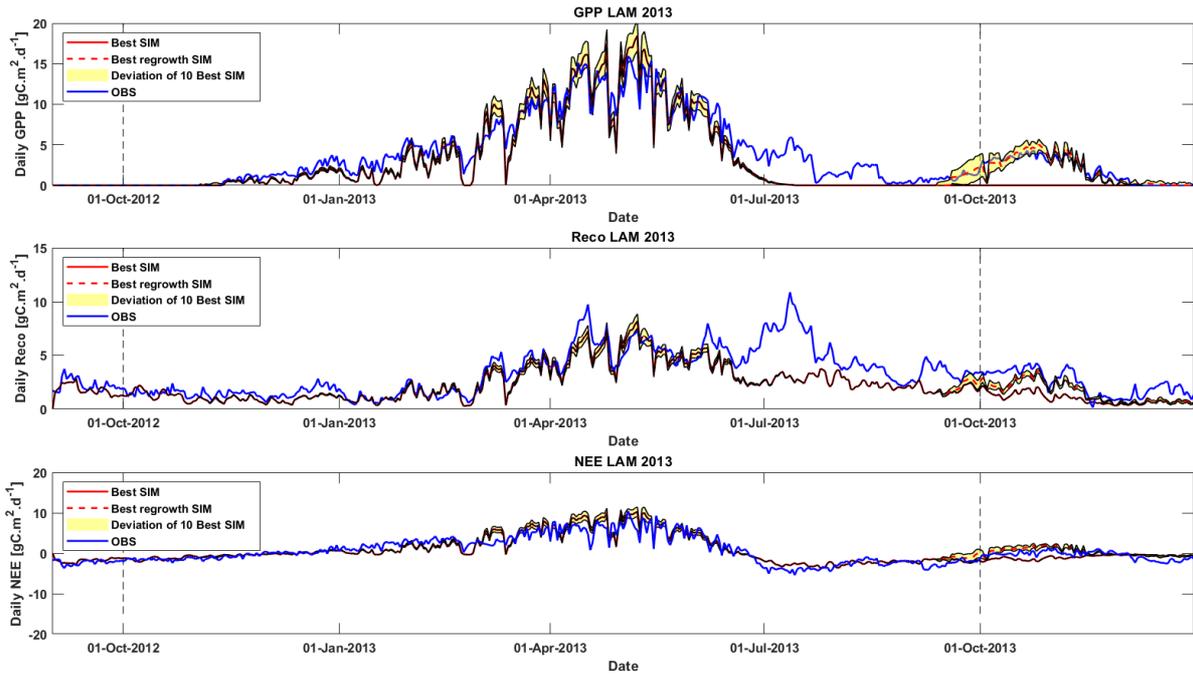

Figure 9b: Temporal evolution of the measured (in blue) and estimated (in red or red dashed lines) cumulated GPP, R_{eco} and NEE for LAM2013. The red/red dashed lines represent the simulations that do/do not account for the cover crop. The yellow envelopes represent the daily standard deviation of the 10 (/30) best simulations (i.e. smaller RMSE GAI error). The vertical dashed lines define the cropping year.

608 that is correctly reproduced by the model, in addition to the CO_2 fluxes ($\text{RMSE} = 0.68 \text{ gC.m}^{-2}.\text{d}^{-1}$ and $R^2 = 0.88$
 609 for GPP; $\text{RMSE} = 1.14 \text{ gC.m}^{-2}.\text{d}^{-1}$ and $R^2 = 0.62$ for NEE).

610 LAM2013 is also marked by an early winter wheat development that benefited from good climatic and soil
 611 conditions for emergence. Therefore, the final biomass is high (2298 g.m^{-2}) compared to that of other years
 612 (mean and standard deviation over the 8 studied years: $1566 \pm 453 \text{ g.m}^{-2}$). This site-year is also characterized
 613 by weeds that developed during the senescence of winter wheat. These weeds could not be observed by the
 614 considered satellites, and the model was not able to simulate their effects on the CO_2 fluxes (particularly on the
 615 GPP and the R_{eco}) observed just before and after harvest. The difference between the observed and simulated
 616 NEE dynamics is small, either because the “observed” GPP and R_{eco} partly balanced each other or because the
 617 increases in the “observed” R_{eco} and GPP are caused by errors in the NEE partitioning process.

618

619 **4.2. From the cumulated NEE to yearly carbon budget**

620 *4.2.1. Analysis of the cumulated NEE dynamics*

621 For the sake of conciseness, the analysis of the temporal behaviour of the cumulated NEE focuses on the same
 622 site-years (i.e., AUR2006 and LAM2009). These values are presented from October 1st until September 30th of
 623 the following year because this period corresponds to the agricultural cropping year in our area. The analysis of
 624 the cumulated NEE dynamics measured by the flux towers and modelled by SAFY- CO_2 allowed for the
 625 identification of the CO_2 net assimilation and release phases (Figure 10). A negative slope in the cumulated NEE
 626 curve (i.e., corresponding to net assimilation, with $\text{GPP} > R_{\text{eco}}$) is observed during the growing season and during
 627 crop re-growth or weed or cover crop development. A positive slope (i.e., corresponding to CO_2 release, with

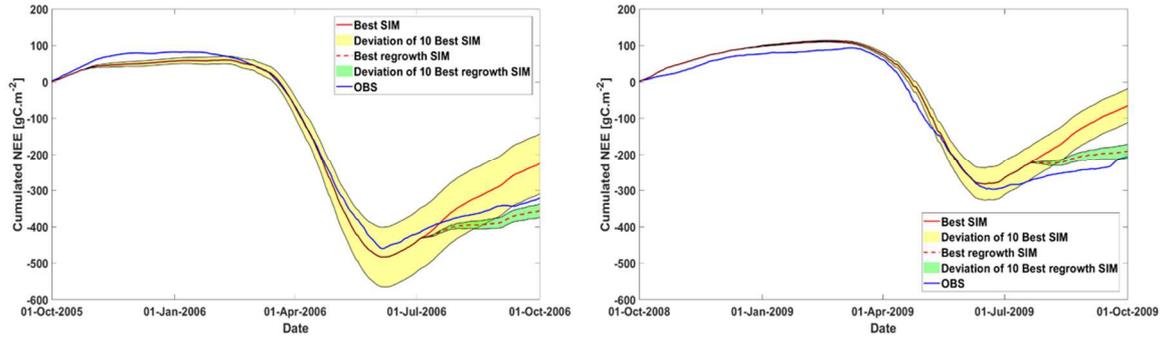

Figure 10: Temporal evolution of the measured (in blue) and estimated (in red and red dashed lines) daily values of the GPP, R_{eco} and NEE for 2 site-years: a) AUR2006 and b) LAM2009. The red/red dashed lines represent the simulations that do/do not account for re-growth and weed events. The yellow envelope represents the daily standard deviation of the 10 (/30) best simulations (i.e. smaller GAI RMSE).

628 $GPP < R_{eco}$) is observed during the bare-soil periods and the senescence stages.

629 The modelled cumulated NEE for AUR2006 slightly diverges from the observations before the growing season
 630 because of the underestimation of the simulated R_{eco} during this period. The effect of the overestimation of the
 631 GPP at the end of the growing stage and beginning of the senescence stage (as discussed above) leads to an
 632 underestimation of the maximum simulated cumulated NEE value.

633 Finally, the slope becomes positive after harvest (when there is no more GPP). The modelled cumulated NEE is
 634 well estimated when re-growth and weeds considered (red dashed line) and diverges when they are not
 635 considered in the model (red solid line).

636 In 2009, the simulated cumulated NEE matches well with the observations before and during the vegetative
 637 period. Indeed, over this period, the model reproduces the GPP and the R_{eco} well, leading to a good estimation of
 638 the NEE. After harvest, not considering weeds causes the model to diverge from the observations, as in 2006,
 639 while modelling post-harvest vegetation development attenuates this bias (even if the simulated weed growth
 640 starts later here than on the field).

641 When the post-harvest vegetative events are simulated, the difference between the observed and the simulated
 642 NEP is improved from 95 and 140 $gC.m^{-2}$ to 33 and 16 $gC.m^{-2}$ for AUR2006 and LAM2009, respectively.

643 These results emphasize the need to include the effects of re-growth events, weeds and cover crops in the model
 644 because they represent non-negligible contributions to the NEP, which in turn could have an important impact on
 645 the final annual NECB values.

646

647 4.2.2. Carbon budget over 8 agricultural seasons of winter wheat

648 The NECB model estimates and its components (NEP, C_{exp}) are compared with those of the eight site-year
 649 measurements (Table 7). In this table, the effects of post-harvest vegetative events on NEE and NECB are
 650 considered. For FR-Lam, the C_{inp} is prescribed for the calculation of the modelled NECB, as the amount of C
 651 input as organic manure cannot be estimated by remote sensing. Also, C_{inp} corresponding to the amount of seeds
 652 brought to the plots are prescribed for both sites (even if very small compared to the other terms). The NEP
 653 values estimated by SAFY-CO₂, which vary from -191 $gC.m^{-2}.yr^{-1}$ (LAM2009) to -486 $gC.m^{-2}.yr^{-1}$ (LAM2011),
 654 are generally close to the measured values, which vary from -208 $gC.m^{-2}.yr^{-1}$ (LAM2009) to -410 $gC.m^{-2}.yr^{-1}$

(LAM2011). Table 7 shows that for all site-years, winter wheat is a CO₂ sink, and the model is able to reproduce the inter-annual variability in this sink activity. The years showing the largest difference in terms of NEP are AUR2014, AUR2012 and LAM2013, with differences of 30%, 24% and 22%, respectively, compared to observations. For AUR2014, this difference can be explained in different ways. First, the senescent phase is not well reproduced by the model because only one satellite image was available during this period, leading to an overestimation of the GPP. Second, after harvest, an increase in R_h is observed and is not reproduced by the model. This is due to the incorporation of straw into the soil, which leads to an increase in the soil microbial activity. The difference observed for AUR2012 is partly due to two post-harvest increases in R_h (priming effect) that could not be reproduced by the model. The first event, occurring at the beginning of July, was induced by rainfall. The second event followed ploughing that occurred at the beginning of August. Moreover, the NEP values of two of the three site-years where significant re-growth vegetative events occurred (during the cultural year) are better estimated once the re-growth is considered. Indeed, for AUR2006 and LAM2009, the differences between the simulated and observed NEP values are -30 and -68%, respectively, before taking re-growth into account and +10 and -7.8%, respectively, after taking re-growth into account. For LAM2011, NEP is first underestimated (-21%) and then overestimated (+19%).

The analysis of the amount of carbon exported from the ecosystem at harvest (C_{exp}) shows that this amount varies considerably from one site-year to another. The simulated C_{exp} varies from 253 gC.m⁻².yr⁻¹ (AUR2010) to 436 gC.m⁻².yr⁻¹ (LAM2013), while the observations range from 204 gC.m⁻².yr⁻¹ (AUR2010) to 488 gC.m⁻².yr⁻¹ (LAM2013). C_{exp} values are often larger at FR-Lam than at FR-Aur due to the export of grain and straw and the model tends to overestimate the C_{exp}. The differences between the observations and model estimates of C_{exp} vary between 5% and 46%. However, the comparison of the modelled C_{exp} and the observed C_{exp} should be performed with caution since the precision of the yield provided by the farmer is questionable (especially at the Lamasquère site where most of the straws are exported) since those values are averaged over several fields of the farm (see section 2.2.1.). For this reason, Béziat et al. (2009) concluded that the uncertainty of in situ C_{exp} is often higher than the uncertainty of the NEP at our sites. For AUR2012, for instance, the C_{exp} estimated from the farmer's data is 223 gC.m⁻².yr⁻¹, while our destructive measurements encompassing over 30 subplots of 3.75*10⁻² m² in the field suggest a C_{exp} of 406±53 gC.m⁻².yr⁻¹. When analysing the performance of the model against our own destructive field samples, the model generally performs much better (see Figure 6b and 6c). This indicates that our modelling approach may perform better for estimating C_{exp} (and therefore NECB) than what is presented in

| Site-Year | NEP | | | | Cinp | Cexp | | | | NECB | | | |

Table 7: Annual net ecosystem carbon budgets (NECB) and their components (NEP, C_{inp}, C_{exp}) derived from the in-situ (OBS) and modelled (SIM) data for 8 site-years. Uncertainties on observations are also shown (for more details see Béziat et al., 2009).

684 Table 7.

685 The NECB estimated from in situ data or from SAFY-CO₂ characterize all of the site-years as carbon sinks. The
686 modelled NECB estimates vary from -304 gC.m⁻².yr⁻¹ (LAM2007) to -6 gC.m⁻².yr⁻¹ (AUR2010), while the in situ
687 NECB estimates vary from -439 gC.m⁻².yr⁻¹ (LAM2007) to -29 gC.m⁻².yr⁻¹ (AUR2014). The FR-Lam site-years
688 present the greatest variations between years, and the carbon inputs (NEP + C_{inp}) are stronger than those of FR-
689 Aur, partly because of organic fertilization.

690 As shown in Table 7, the relative differences between the modelled and in-situ NECB vary from 6% (AUR2014)
691 to 355% (LAM2013). In absolute terms, these differences vary from 2 gC.m⁻².yr⁻¹ (AUR2014) to 135 gC.m⁻².yr⁻¹
692 (LAM2007) but the sign of NECB is always similar between both approaches. Regarding all simulated years, the
693 model shows RMSE of 77 gC.m⁻².yr⁻¹. Note however that, the modelled NECB match to that observed for five
694 simulated years out of eight if the uncertainties are considered. Indeed, the uncertainties on the in-situ NECBs
695 (derived from uncertainties on the observed NEP, C_{inp}, C_{exp}) range from 40 to 105 gC.m⁻².d⁻¹. These results
696 highlight the importance of precisely estimating each of the terms that compose the NECB to obtain accurate
697 estimations of the annual crop carbon budgets (both with the in-situ and the modelling approaches).

698

699 5. DISCUSSION

700 5.1. Performances and benefits of our approach

701 In this study, our objective is to evaluate the potential of high resolution GAI products assimilation into a simple
702 crop model for simulating the biomass, the yield, the net CO₂ fluxes components and the annual C budget of
703 winter wheat crops at plot scale. The main advantage of this approach is that it requires few input data and little
704 or no external information about management practices. Also, even with a limited number of equations and
705 parameters compared to more complex crop models that require data on management practices, SAFY-CO₂
706 achieves equivalent or better performances regarding estimates of key components of the C budget: CO₂ fluxes,
707 biomass and yield (see sections 4.1.1. and 4.1.2.).

708 Next, we demonstrated the ability of the model to reproduce winter wheat dynamics, production and CO₂ fluxes
709 under contrasted climatic and management conditions with the same parametrization. It shows the ability of such
710 a remote sensing driven diagnostic approach (*e.g.* for calculating GPP) to account implicitly for the main stresses
711 (N, drought, temperature...) and the main crop development limiting factors.

712 Finally, our methodology allows accounting for the effect of post-harvest spontaneous re-growth, weeds and
713 cover crops on the CO₂ fluxes. As showed by Ceschia et al., (2010) this is essential for estimating accurately
714 cropland C budgets and only remote sensing based approaches allow characterizing the dynamics and the spatial
715 heterogeneity of the various post-harvest vegetative events. Therefore, in spite of a generic parameterization of
716 the SAFY-CO₂ model for those post-harvest vegetative events, the overall performances of the model for
717 simulating CO₂ fluxes and C budgets always increase when they are accounted for. The performances should
718 improve thanks to the higher temporal resolution of the Sentinel missions. Next step could be to apply a specific
719 parametrization, depending on the nature of those events or on their species composition (*e.g.* for cover crops),
720 provided that the information is given by the farmer or can be retrieved by remote sensing (*e.g.* through cover
721 crop classification).

722

5.2. Potential limitations of this approach and drawbacks for large scale application

The first main limitation of this approach based on optical remote sensing is that gaps in optical remote sensing observations during crucial periods of the crop development could lead to wrong estimates of the GAI dynamics, biomass and CO₂ fluxes or could even make our approach inoperative (*e.g.* in 2007-2008). Fortunately, recent Sentinel 2 satellite missions provide observations at high spatial resolution (10m) every 5 days all over the globe which could partially solve this problem. Also, it was shown that the combined use of optical and Synthetic Aperture Radar (SAR) satellite data, like Sentinel 1, can overcome this issue (see Ameline et al., 2018; Baup et al., 2019; Betbeder et al., 2016; Remy Fieuzal et al., 2017; Revill et al., 2013). Indeed, the signal of the SAR satellites is not affected by clouds and they can even observe the surface at night. Another limitation of this optical remote sensing approach is that it cannot detect understorey vegetation (*e.g.* weeds) and their effect on the CO₂ fluxes. Here again SAR data may overcome this issue as microwave signal are associated to deeper penetration capabilities (compared to optical reflectance), depending on the considered wavelength, and providing a valuable information on vegetation structure and water content (Brown et al., 2003).

The second main limitation of this approach concerns the availability of plot scale information regarding straw management and organic fertilization. Those practices cannot be detected or quantified by remote sensing at this stage and therefore the uncertainty on the C budgets estimates in areas where animal farming occurs is high. This issue may be overcome in the future if data from the Farm Management Information Systems (FMIS) become more easily and more widely accessible. Another limitation for applying our approach concerns the size and the shape of the agricultural plots. As mentioned above, the contours of the plots must be eroded so that the signal is not influenced by surrounding landscape elements. Thus, we consider that for plots below 0.5-1 ha, GAI products may not be of good enough quality to apply our approach. Also high resolution GAI and crop maps are needed in our approach. In Europe, the later can be obtained via the Land Parcel Identification System (LPIS) and both data inputs should be available in a near future via the High Resolution Layers Copernicus Land Monitoring Service (<https://land.copernicus.eu/pan-european/high-resolution-layers>). The last limitation of our approach is that it cannot be used for forecasting, since it is based on satellite observations, although it is possible to test the effect of some scenarios on the C budgets (*e.g.* accounting or not for the effects of the post-harvest vegetative events or for the impact of exporting or not the straw from the plot).

Of course the question of the transposability of our approach and of its domains (spatial and temporal) of validity should be considered with caution. Indeed, the current parametrization of the SAFY-CO₂ model is adapted to the pedoclimatic conditions where it has been set and it should be adapted to other crop species. Also the boundaries of the calibrated winter wheat phenological parameters are set for our pedoclimatic conditions. Applying this approach to areas where winter wheat has different periods of emergence and senescence would require to redefine those boundaries (*e.g.* in Northern countries). Note however that 1) the future High Resolution Phenology Copernicus Land Monitoring Service should provide, all over Europe since 2017, the dates of emergence and end of the growing for the crops and cover crops at plot scale for each cropping year by the end of this year and that 2) the transposability of the original SAFY model has already been tested in contrasted pedoclimatic conditions (France, Mexico and Morocco; see (Claverie et al., 2012; Duchemin et al., 2015, 2008; respectively) and for different crop species (corn, soybean, sunflower and wheat).

Also, the parametrisation of the Q₁₀ based approach for estimating heterotrophic respiration is well adapted to the type of soils and climates similar to the ones found in our area of study but it should probably be adapted to

763 other soil types (*e.g.* organic or sandy soils) and climatic conditions. Still, with a similar approach, Delogu et al.,
764 (2017) obtained good R_h estimates (RMSE comprised between 0.15 and 0.73 $\text{gC}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$ and R^2 between 0.42 and
765 0.92 depending on the site) over contrasted pedoclimatic conditions. Another potential issue concerning our
766 approach relates to the simplistic method for estimating R_h which should be considered as a first step for
767 estimating R_h . In the future, this method could be improved, with little changes in the formalisms, by considering
768 a R_{10} parameter that depends on top soil slow carbon content as it is proposed in Delogu et al., (2017). Another
769 step of improvement could be to account for the priming effect following the incorporation of fresh organic
770 matter into the soil (Kuzyakov et al., 2000). Indeed, with our modelling approach we could already estimate the
771 amount of crop residues, cover crop, weeds and spontaneous re-growth incorporated in the soil. However
772 accounting for the effect of organic fertilization is not an option at this stage, since this kind of information is not
773 yet available at plot scale over large areas. For similar reasons, we did not account for the effect of soil work on
774 soil respiration and also because it was shown that it has no significant effect on soil respiration (Eugster et al.,
775 2010) and no clear effect on SOC mineralisation (*e.g.* in Dimassi et al., 2014; Powlson et al., 2016; Virto et al.,
776 2012). Also, a potential drawback of our approach for estimating R_h is that the effect of the soil water content is
777 not accounted for. As for the SAFY model (Battude et al., 2017; Duchemin et al., 2015), we have already tested
778 the coupling of a soil water module (FAO56; Allen et al., 1998) to the SAFY-CO₂ model (see Veloso, 2014).
779 Such a coupling allows accounting for soil water content effects on photosynthesis and on heterotrophic
780 respiration, and requires that accurate data concerning soil properties (*e.g.* texture, depth) at the plot scale are
781 available. Unfortunately, the current products mapping soil properties (*e.g.* GlobalSoilMap, SoilGrids) either
782 have a too coarse resolution for our area of study (250 m, for SoilGrids) or have too little accuracy to meet the
783 needs of a SAFY-CO₂ – soil water module coupled approach at plot scale (*e.g.* the performances of
784 GlobalSoilMap in France are $R^2 = 0.27$ and $\text{RMSE} = 128 \text{ g}\cdot\text{kg}^{-1}$ for clay content). Therefore, in the perspective
785 of up-scaling our current approach for estimating annual cropland C budgets, we chose to rely only on currently
786 available and sufficiently accurate data at plot scale. This is the reason why we chose a simple Q_{10} approach for
787 estimating heterotrophic respiration at this stage. Of course, if this choice is likely suitable for plot scale annual
788 C budget estimates, at crop rotation scale or over longer periods of study, the coupling of the SAFY-CO₂ model
789 with a soil organic matter model (*e.g.* RothC, Coleman and Jenkinson, 1996; AMG, Saffih-Hdadi and Mary,
790 2008) should be considered. Such a step would benefit from 1) the improvement of the current soil products (*e.g.*
791 GlobalSoilMap) which could be achieved by developing the current methods of inversion based on high
792 resolution multi-spectral or hyperspectral remote sensing data (see Castaldi et al., 2019; Vaudour et al., 2019)
793 and 2) from an easier and more systematic access to the FMIS data.

794 Another limitation of our modelling approach is that it tends to underestimate the highest biomass values at the
795 end of the season and therefore also the yield, impacting the C budgets estimates. These underestimations may
796 be partly due to the underestimation of satellite-derived GAI (Claverie et al., 2012). In such a context, the
797 assimilation of both GAI derived from optical images and dry biomass estimated from SAR images into the
798 agro-meteorological model overcomes the limitation, as presented by Betbeder et al., (2016) in the specific case
799 of soybean. Furthermore, taking into account the clumping effect in radiative transfer model would make it
800 possible to limit the underestimation of GAI values (derived from optical images) when vegetation becomes
801 dense.

802 Still, we show that, within the limit of its domain of application, our approach was able to reproduce correctly

803 the GAI, biomass and CO₂ flux dynamics and it was able to estimate the NEP with a satisfactory level of
804 accuracy. The relatively large error of prediction on the C budgets (mean RMSE of 77 gC.m⁻².yr⁻¹ and rRMSE of
805 56 %) has to be tempered considering the uncertainties on the NECB calculated from the in-situ data. Indeed,
806 besides the inherent uncertainties on the NEP associated to measurements errors and data processing, there is a
807 strong uncertainty on the in-situ C_{exp} term for the two ICOS sites as mentioned previously. Considering the
808 resulting uncertainties on the in-situ NECB, we conclude that the modelled NECB match the observations for
809 five years out of eight. Also, section 4.1.2.4 showed that the model was able to estimate the yield with a rather
810 good precision, suggesting that the error on the NECB could be reduced when comparing our estimates with in-
811 situ NECB calculated with more accurate yield data. Still, even if SAFY-CO₂ provided accurate estimations of
812 the annual components of the NECB we cannot claim at this stage that the model can reproduce accurately
813 carbon budgets, especially over the long term. More accurate in-situ data, a larger dataset of validation and/or
814 simulations on longer periods evaluated against estimates of soil C stock changes based on soil analysis would
815 be needed to conclude.

816 Of course other approaches allowing to estimate carbon budget exist, such as soil organic matter models which
817 are designed to simulate the evolution of soil C stocks. The two most widely used and validated SOM are Roth-
818 C (Coleman and Jenkinson, 1996) and CENTURY (Parton et al., 1987). Those models estimate soil C stock
819 changes have been evaluated against long term experiments. Contrary to the proposed approach, they need
820 information about soil texture, management practices or residue quality. Their relative error in estimating soil C
821 stock changes is comprised between 2-30% (Falloon and Smith, 2006; Guo et al., 2007; Smith et al., 1997) for
822 Roth-C model and between 1.8-16.4% for CENTURY (Cong et al., 2014; Falloon and Smith, 2003). These
823 results, which are more accurate than those achieved with SAFY-CO₂ model should be tempered by the fact that
824 they represent two different approaches, requiring different input and designed for different purposes and time-
825 scales.

826 Also, as in other studies (Ceschia et al., 2010; Schmidt et al., 2012) our results showed that for all cropping years
827 the plots behave as a net CO₂ sinks and our results concerning the potential C storage of winter wheat crop are
828 consistent with other studies (*e.g.* Aubinet et al., 2009; Ceschia et al., 2010). In addition, our results show that, in
829 soils with low SOC content, post-harvest vegetative events (*e.g.* cover crops) increase soil organic carbon
830 storage which is consistent with other studies (Kaye and Quemada, 2017; Pellerin et al., 2019; Poepflau and Don,
831 2015; Tribouillois et al., 2018).

832 Finally, in spite of the limitations and potential drawbacks of this approach, it seems to be a good compromise
833 for estimating the components of the annual C budgets over large areas at this stage and we think that it offers
834 great perspectives of development and applications at large scale thanks to the new satellite missions and
835 Copernicus services.

836

837 **6. CONCLUSION**

838 In this work, we demonstrate the potential of high-resolution remote sensing data assimilation in a semi-physical
839 crop model (SAFY-CO₂) to successfully provide estimates of some of the main components of cropland annual
840 carbon budgets (*i.e.*, net CO₂ flux components and yield). While this modelling approach is promising because it
841 requires few input parameters and no management data for estimating crop production and net CO₂ fluxes, this
842 approach should be considered a first step for filling the gap in obtaining spatially explicit representation of the

843 main components of cropland carbon budgets at the regional scale for a crop rotation or longer. Indeed, the main
844 limitation of this approach is that, in areas concerned with animal farming, the calculation of the carbon budget
845 requires data on i) organic amendments and ii) the fraction of straw exported at harvest, which presently cannot
846 be retrieved by remote sensing at this stage. The second main limitation relates to the fact that the simple Q_{10}
847 based approach for estimating heterotrophic respiration does not allow us to estimate accurately the C budget for
848 periods longer than the cropping year. For longer periods of study, the benefit of coupling our model with a soil
849 module should be investigated. Another limitation concerns the availability of satellite observations, since our
850 approach is data driven. However, because of recent HTRS satellite missions (Sentinel 2 and Landsat-7&8), this
851 type of approach could be generalized and more accurate and robust. Synthetic aperture radar satellites (*e.g.*,
852 Sentinel 1) could also be used to overcome cloudy conditions (Veloso et al., 2017). In addition, our results show
853 that the performance of the model in estimating net CO₂ fluxes and thus C budgets are significantly improved by
854 considering the development of weeds and crop re-growth after harvest. These events, as well as the presence of
855 cover crops in crop rotations, are rarely or never accounted for in regional or global modelling of CO₂ fluxes,
856 although they significantly impact cropland carbon budgets.

857 In the perspective of future global-scale applications, our approach could be strengthened (validated for a wider
858 range of climates and management regimes) and extended to other crops by using data from international flux
859 networks (*e.g.*, ICOS and FLUXNET) and from recent HTRS satellite missions.

S.1 Effect of diffuse radiation on the ELUE

1235

The fraction of diffuse radiation affects photosynthesis (Béziat et al., 2009) and should be accounted for when
1236 simulating GPP. Furthermore, because the photosynthetic rate of leaves is usually saturated under high incoming
1237 radiation, leaves with lower irradiance will be more efficient than those with higher irradiance, and a reduction in
1238 the volume of shade leaves within the canopy should result in an increase in the efficiency of the canopy in the
1239 presence of low and diffuse radiation (Roderick et al., 2001). Thus, the photosynthetic efficiency is expected that
1240 to increase as the diffuse solar radiation increases. To quantify this effect, we used data from 5 European flux
1241 sites, including the Lamasquère and Auradé sites. The 3 other sites were Lonze (LON) in Belgium, Grignon
1242 (GRI, located near Paris) in France and Oensingen (OEN) in Switzerland. For all sites, the ELUE increased non-
1243 linearly with the ratio of diffuse over total global radiation. As a consequence, the relationship between the
1244 effective light-use efficiency and the ratio between diffuse and direct radiation at ground level was defined as an
1245 exponential function, with parameter “b” fixed to 1.34 and parameter “a” calibrated based on the assimilation of
1246 GAI derived from satellite observations. The relationship seemed relatively generic; the correlation coefficient of
1247 the regression was 0.63.

1248

1249

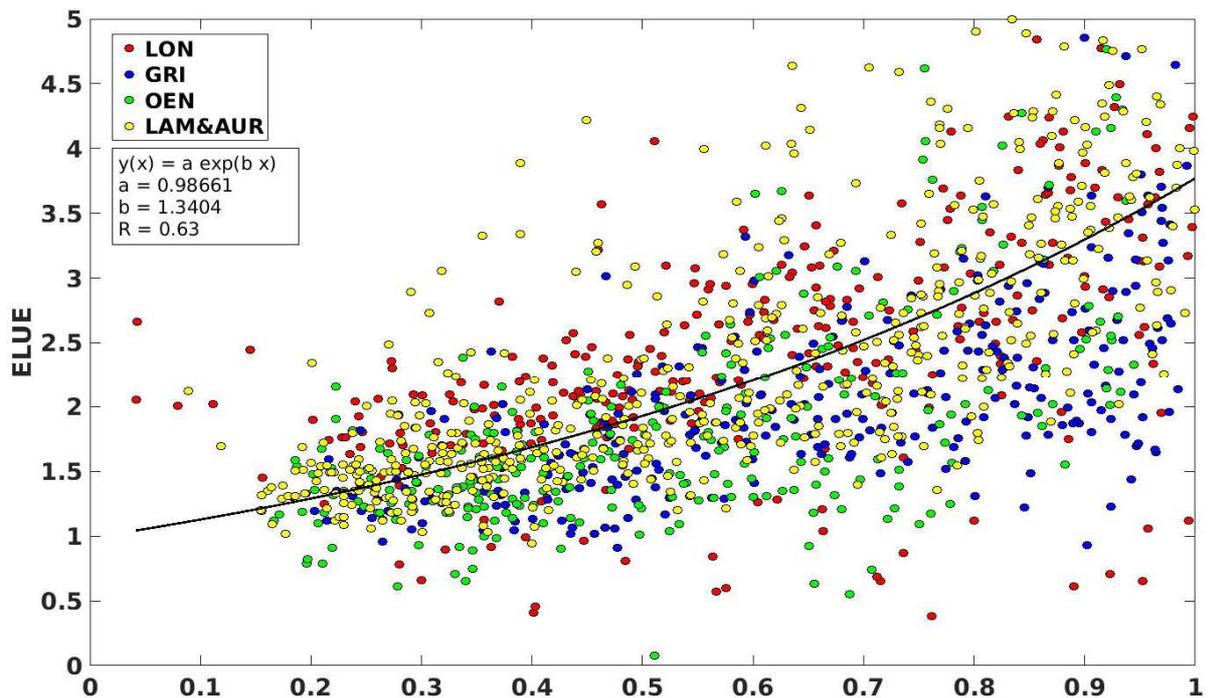

Figure S.1: Relationship between the ELUE and the ratio between diffuse (Rdf) and global (Rg) radiation measured at 5 European flux sites (Lonze, Grignon, Oensingen, Lamasquère & Auradé)

1252

1253 **S.2 Temporal evolutions of the in-situ and simulated net CO₂ flux components**

1254 The purpose of this section is to compare the temporal evolutions of in-situ and simulated CO₂ fluxes (GPP, R_{eco},
1255 NEE and cumulated NEE) at FR-Lam and FR-Aur for the site years discussed in the text but not shown.

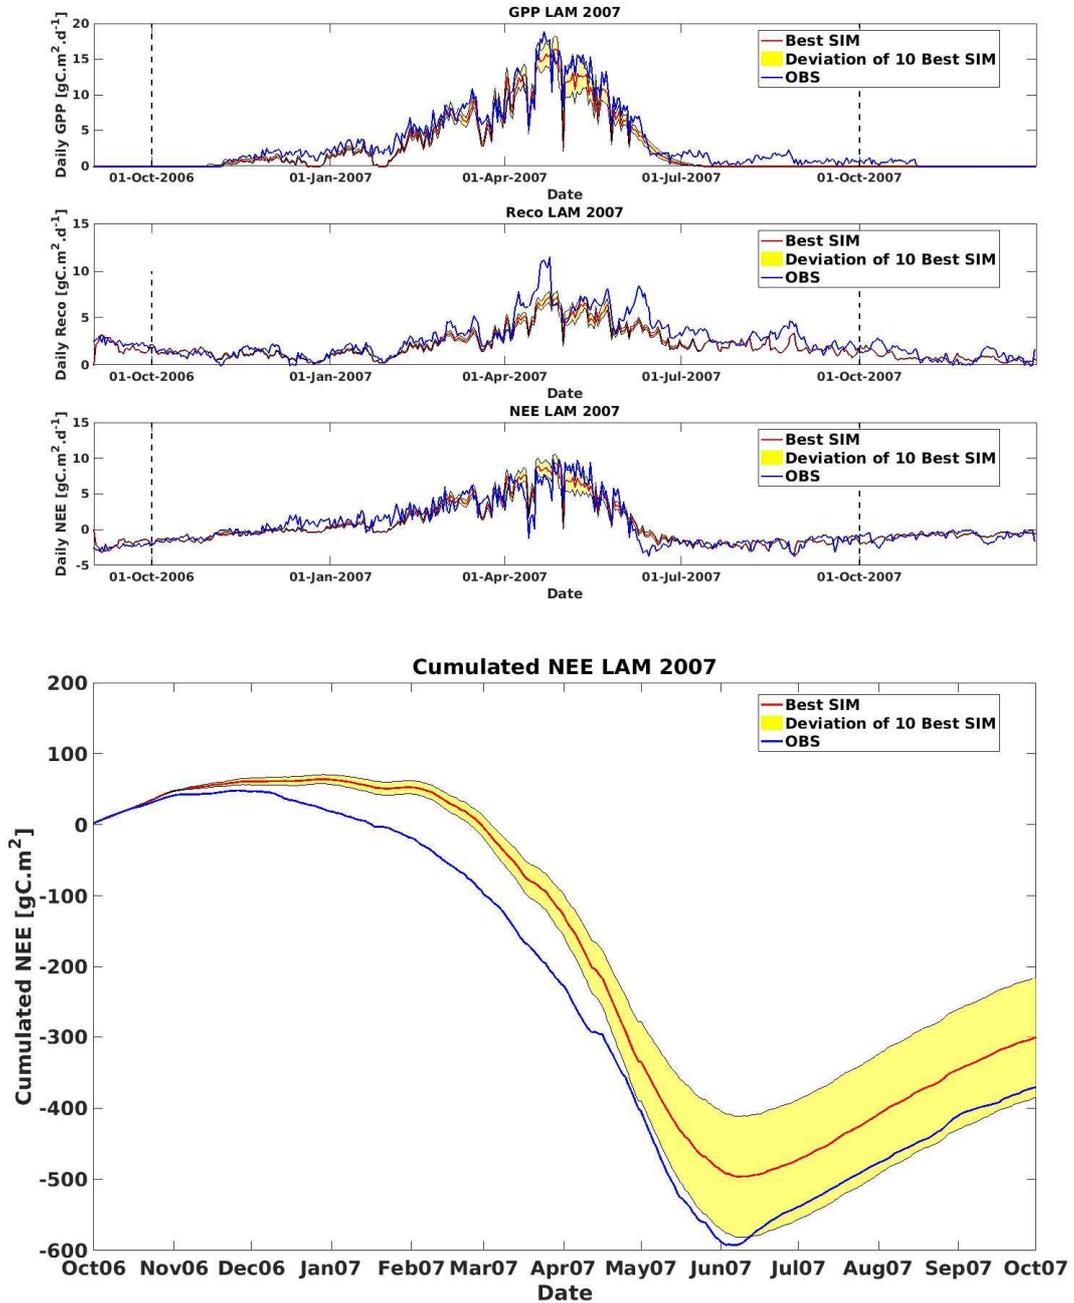

Figure S.3.1: Temporal evolution of the measured (in blue) and estimated (in red) GPP, R_{eco} and NEE, top, and cumulated NEE, bottom, for LAM2007. The yellow envelopes represent the daily standard deviation of the 10 (/30) best simulations (i.e. smaller RMSE GAI error). The vertical dashed lines define the cropping year.

1258

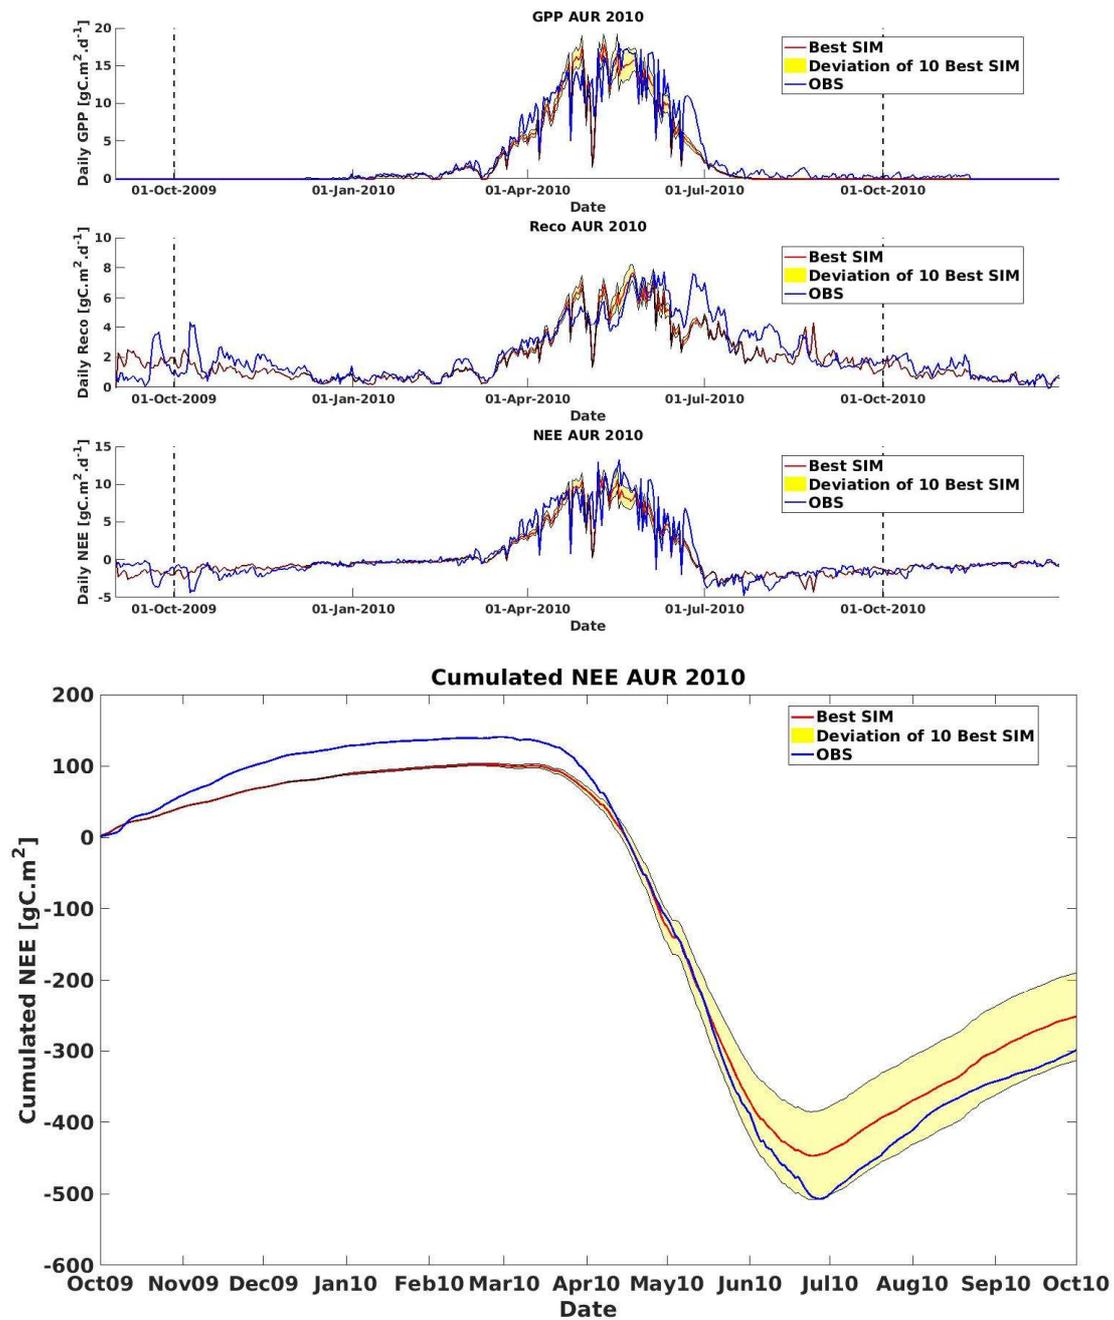

Figure S.3.2: Temporal evolution of the measured (in blue) and estimated (in red) GPP, R_{eco} and NEE, top, and cumulated NEE, bottom, for AUR2010. The yellow envelopes represent the daily standard deviation of the 10 (/30) best simulations (i.e. smaller RMSE GAI error). The vertical dashed lines define the cropping year.

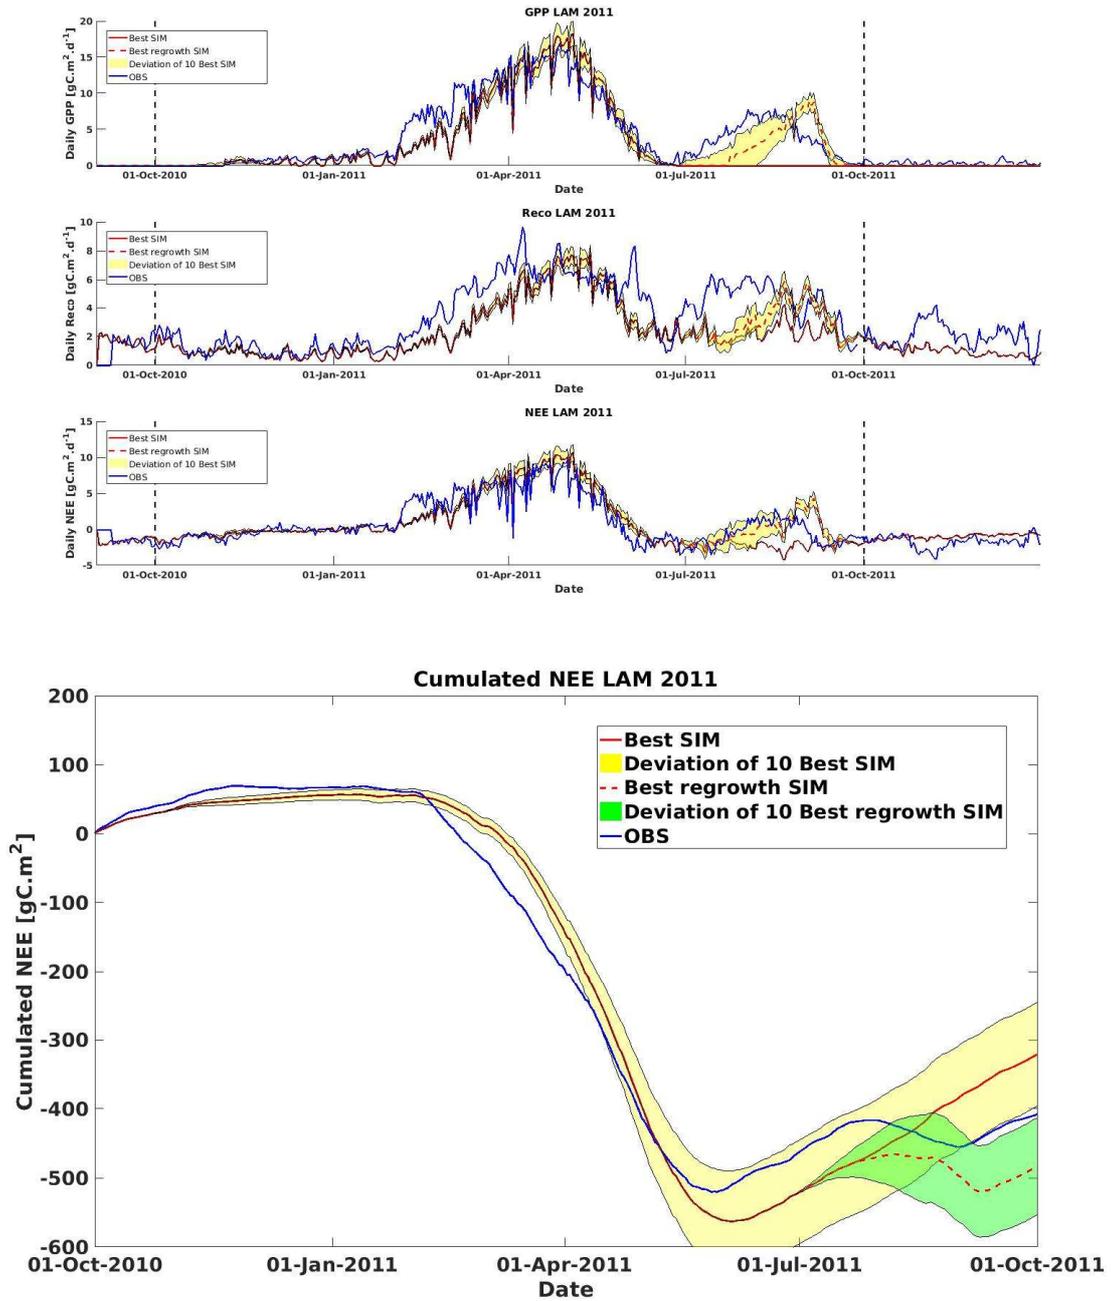

Figure S.3.3: Temporal evolution of the measured (in blue) and estimated (in red or red dashed lines) GPP, Reco and NEE, top, and cumulated NEE, bottom, for LAM2011. The red/red dashed lines represent the simulations that do/do not account for re-growth and weed events. The yellow envelopes represent the daily standard deviation of the 10 (/30) best simulations (i.e. smaller RMSE GAI error).
