21 **Abstract**

22 Geological study of the Khan Tengri and Pobedi massifs highlights two phases of
23 compressional fault displacements. A Late Permian/Triassic displacement phase is
24 highlighted (1) by biotite $^{40}\text{Ar}/^{39}\text{Ar}$ ages of 265–256 Ma, suggestive of cooling of Pobedi mid-
25 crustal granulites during >8 km of top-to-the-north motion of the Pobedi Thrust; (2) by
26 $^{40}\text{Ar}/^{39}\text{Ar}$ dating of syn-kinematic phengite at 249–248 Ma, which suggests a crystallization
27 age during top-to-the-south motion of the Khan Tengri Thrust shear zone; (3) by Apatite
28 Helium (AHe) ages of 280–240 Ma on the crystalline basement below the Mesozoic
29 peneplain, which gives insight into the final exhumation stage. Cenozoic reactivation of the
30 Pobedi Thrust is indicated by AHe thermochronology with a mean age of 8.3 ± 2.5 Ma, in
31 agreement with ~3 km exhumation and ~4.2 km of top-to-the-north motion in the Late
32 Miocene. Along a north-south transect of the west Tian Shan range from Issyk-Kul Lake to
33 Tarim Basin, compiled thermochronological data outline out-of-sequence deformation
34 beginning with the activation of north-directed crustal-scale faults at 22–15 Ma along the
35 northern margin of the north Tian Shan, followed by 20–10 Ma motion at the boundary
36 between the Middle and the South Tian Shan, and ending with the <10 Ma reactivation of the
37 Pobedi Thrust in the South Tian Shan. This latter coincided with south-directed motion on the
38 South Tian Shan Front (the Maidan Fault) and fold and thrust belt propagation towards the
39 Tarim Basin.

40 **1. Introduction**

41 Since the Early Cenozoic, deformation has propagated towards the core of the Eurasian
42 continent in response to the India-Asia collision (e.g., [Hu et al., 2016](#)). Collisional
43 deformation is now distributed over several thousand kilometres, from the Himalayan front to
44 the interior of the Siberian craton (e.g. [Avouac et al., 1993](#); [Tapponnier et al., 1986](#); [Sobel and](#)
45 [Dumitru, 1997](#)).

46 **Fig. 1.** (a) Location of Tian Shan within the Alpine-Himalayan collisional system. (b) Satellite image
 47 of the Tian Shan belt showing study areas. Insert: geographical situation of Tian Shan in Central Asia
 48 (Map data: Google, Image Landsat). (c) Tectonic map of Tian Shan (Cenozoic cover removed).
 49 Location of detailed geological map of Fig. 2 is shown, modified after Loury et al. (2017).
 50 Abbreviations used: CZ, Cenozoic; TFF, Talas-Fergana Fault; NL, Nikolaev Line; STS, South Tian
 51 Shan; NTS, North Tian Shan.

53 This deformation has given rise to the highest intra-continental orogen, the Tian Shan
54 mountain belt. The Tian Shan forms the south-western part of the Central Asian Orogenic
55 Belt (CAOB; [Fig. 1](#)), extending for 2500 km from Uzbekistan to western China and was built
56 up by successive continental accretionary events during the Palaeozoic (e.g. [Sengör et al.](#)
57 [1993](#); [Windley et al. 2007](#); [Kröner et al. 2014](#); [Loury et al., 2018b](#); [Han et al., 2011](#)). Active
58 deformation occurs along crustal scale faults inherited from the (post) collisional evolution of
59 the CAO in Late Carboniferous to Permian times, which have been reactivated during the
60 Cenozoic (e.g., [Sobel et al. 2006b](#); [Glorie et al. 2011](#); [Macaulay et al. 2013, 2014](#); [Loury et](#)
61 [al., 2017, 2018a](#); [Jourdon et al., 2018a-b](#); [Rizza et al., 2019](#)). Palaeozoic structures including
62 collisional sutures and transcurrent shear zones of the CAO have strongly localized
63 Cenozoic deformation, while the domains between these faults behaved as rigid blocks (e.g.,
64 [Jolivet et al., 2010](#); [Glorie et al. 2011](#); [Macaulay et al. 2013, 2014](#); [Jourdon et al., 2018a-b](#)).
65 Prominent reactivation since the Neogene has resulted in the highest topography of Central
66 Asia, with summits above 7000 m and large flat peneplains partly preserved from the Late
67 Palaeozoic to Early Cenozoic erosional stages (e.g., [Morin et al., 2019](#) and references
68 [therein](#)). Cenozoic erosion is spatially variable, focussed on the highest ranges, while the
69 formerly flat-lying Mesozoic peneplains are uplifted above 4000 m and form intra-orogenic
70 plateaus ([Jolivet, 2017](#); [Morin et al., 2019](#)). Reconstructing Cenozoic Tian Shan mountain
71 building and comprehending active tectonics requires precisely locating the major faults,
72 determining their crustal scale geometry and pin-pointing their activation throughout the
73 Cenozoic with respect to the previous tectonic stages (e.g., [Jourdon et al., 2018a-b](#)). It is thus
74 necessary to disentangle the relative contributions of the tectonic phases which affected the
75 area since the Palaeozoic.

76 Previous works based on thermochronology and basin sedimentology along the Tian Shan
77 belt have enabled quantifying several crustal compartments and along-belt uplift phases

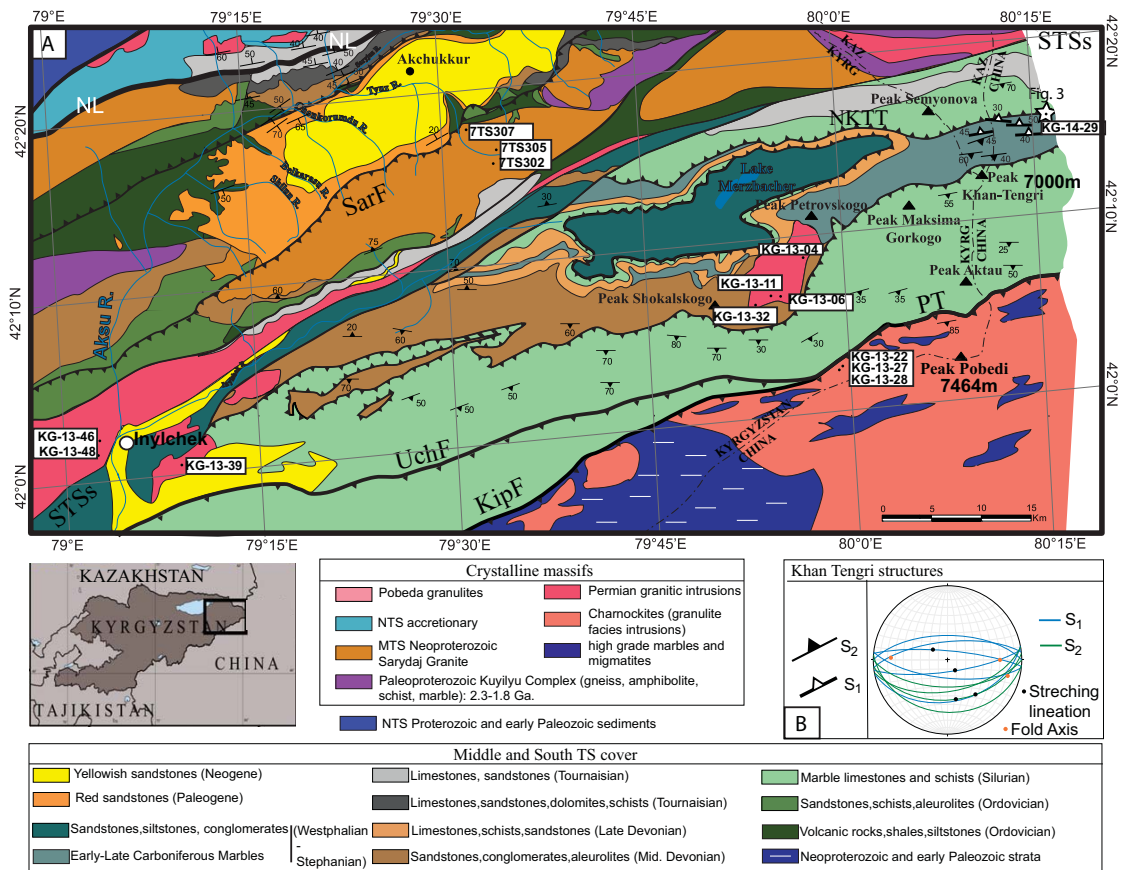

78 (Jolivet et al., 2010, 2015, 2018; Glorie et al. 2010, 2011, 2019; De Grave et al., 2007, 2011,
79 2012, 2013, 2014; Macaulay et al., 2013, 2014; De Pelsmaecker et al., 2017; Yin et al., 2018;
80 Zhao et al., 2019; Zhang et al., 2019). However, no such study was conducted in the highest
81 part of the South Tian Shan (STS): the Pobedi and Khan Tengri massifs, which culminate
82 above 7000 m. This most prominent Tian Shan topography is also a key zone to link the
83 history of mountain building in the Kyrgyz western Tian Shan to the frontal fold and thrust
84 belt and related foreland basin, the Tarim Basin, in NW China. For this, we have undertaken a
85 geological, $^{40}\text{Ar}/^{39}\text{Ar}$ geochronological and apatite (U-Th-Sm)/He (AHe) thermochronological
86 study. $^{40}\text{Ar}/^{39}\text{Ar}$ geochronology is applied to low-temperature mylonitic phengite in order to
87 constrain the time of ductile (Palaeozoic?) deformation (e.g., Sanchez et al., 2011). AHe
88 thermochronology is undertaken from underneath some major peneplains and on both sides of
89 major thrusts to constrain the time of the final (Palaeozoic to Cenozoic) stages of exhumation.
90 These data are integrated into a north-south crustal cross-section, and are used to reconstruct
91 the deformation sequence which gave rise to the western Tian Shan belt.

92

93 **2. Geological setting**

94 The main tectonic units of the Tian Shan belt correspond to at least three continental
95 blocks: the North Tian Shan (NTS), the Middle Tian Shan (MTS), the South Tian Shan (STS)
96 - Tarim basin, separated by two Palaeozoic sutures: the Nikolaev Line (NL) and the STS
97 suture (Figure 1; see a review of data in Loury et al., 2017). In China, the Yili-Central Tian
98 Shan (YCTS) is equivalent to the Kyrgyz NTS. It is separated from the Chinese STS by the
99 STS suture. The Kyrgyz MTS is not present in China (e.g., Jourdon et al., 2017). The main
100 faults that reactivate the Kyrgyz Tian Shan suture zones are highlighted by geophysical
101 (Makarov et al., 2010; Loury et al., 2017) and thermochronological data (De Grave et al.,
102 2012; Macaulay et al., 2013; 2014; Glorie et al., 2010; 2011). Along the northern border of

103 the Tarim basin, seismic activity indicates top-to-the-south thrusting of the Tian Shan over the
 104 Tarim basin, as also visible on the MANAS seismic profile (Makarov et al., 2010).

105
 106 **Fig. 2.** A, Geological map of Inylchek-Khan Tengri-Pobedi area in Eastern Kyrgyz STS (modified after
 107 Jourdon et al., 2017a, and Kröner et al., 2017). MTF: Main Terskey Fault; CTF: Central Terskey Fault; PT:
 108 Pobedi Thrust; NKTT: North Khan Tengri Thrust; NL: Nikolaev Line; SarF: Sarajaz Fault; STSS: Southern Tian
 109 Shan Suture; UchF: Uchchat Fault; KipF: Kipchak Fault. The location of dated samples is shown. Note also
 110 the location of Fig. 3 pictures. B, Stereonet representing the structures measured to the north of Khan Tengri peak,
 111 along the NKTT. Note that the two foliations (S₁ and S₂, see Fig. 3 pictures) strike E-W and bear a down-dip
 112 lineation underlined by phengite (dated on Fig. 6), and gently dipping fold axes. These structural data can be
 113 interpreted as representative of nearly pure N-S shortening along the NKTT.

114
 115 The Pobedi and Khan Tengri massifs lie in SE Kyrgyzstan, in the STS domain (Figs. 1-2).
 116 It is still unclear if the STS formed a distinct tectonic block or if it corresponds to the northern
 117 margin of Tarim (see discussions in Loury et al., 2017; 2018b). The pre-Carboniferous
 118 basement of the STS is unknown; sedimentary series belong to the Silurian to Carboniferous
 119 periods (Tursungaziev and Petrov, 2008). These series are cross-cut by Late Carboniferous to
 120 Early Permian granitoid intrusions and charnockite bodies, which were emplaced during the

121 Tarim-CAOB collisional to post-collisional transcurrent tectonic context. U/Pb ages on
122 zircons from these granitoids range from 302 to 288 Ma (Konopelko et al., 2007; 2009; Glorie
123 et al., 2011; Loury et al., 2018a). The MTS has a Palaeoproterozoic (2.3–1.8 Ga) basement,
124 the Kuilyu Complex (Kröner et al., 2017). The STS suture was formed in the Late
125 Carboniferous following the collision of the MTS and YCTS with the Tarim craton (Fig. 1;
126 Loury et al., 2017; Jourdon et al., 2018a). This Carboniferous suture was then subjected to
127 several phases of reactivation from (1) the post-collisional evolution of the CAO in Permian
128 times and (2) several moderate tectonic pulses in Mesozoic times to (3) the Cenozoic uplift of
129 the belt.

130

131 *2.1. Late Palaeozoic tectonic evolution of the STS*

132 2.1.1. Formation of the belt during STS ocean subduction

133 Two distinct domains within the South Tian Shan belt, separated by 500 km along strike,
134 expose High Pressure (HP) rocks, which have similar timing and pressure-temperature
135 conditions: the Atbashi range in Kyrgyzstan and the Kebuerte-Kekesu area in China (e.g.
136 Klemm et al., 2005; Simonov et al. 2008; Hegner et al. 2010; Su et al., 2010; Li et al., 2011;
137 Loury et al., 2018b; Tan et al., 2019). The pressure-temperature-time data are consistent with
138 the end of oceanic subduction in the STS and thus the onset of accretion or collision between
139 Tarim and the CAO at 315-320 Ma (Hegner et al. 2010, Loury et al., 2016, 2018b). In
140 Kyrgyzstan, the structural and kinematic evolution related to this Late Carboniferous phase
141 corresponds to an intense reactivation of the MTS-STS boundary in a overall transpressional
142 context (Jourdon et al., 2017). In the western STS, nappe-stacking was expressed by top-to-
143 the-north thrusts and top-to-the-south detachments in the Atbashi Massif between 330 and
144 310 Ma, resulting in the exhumation of a large high-pressure unit along the STS suture (Loury

145 et al., 2018b). To the east of the STS, a pristine (S1) top-to-the-south deformation phase is in
 146 highlighted north of the Khan-Tengri massif (Jourdon et al., 2017, Fig. 3).

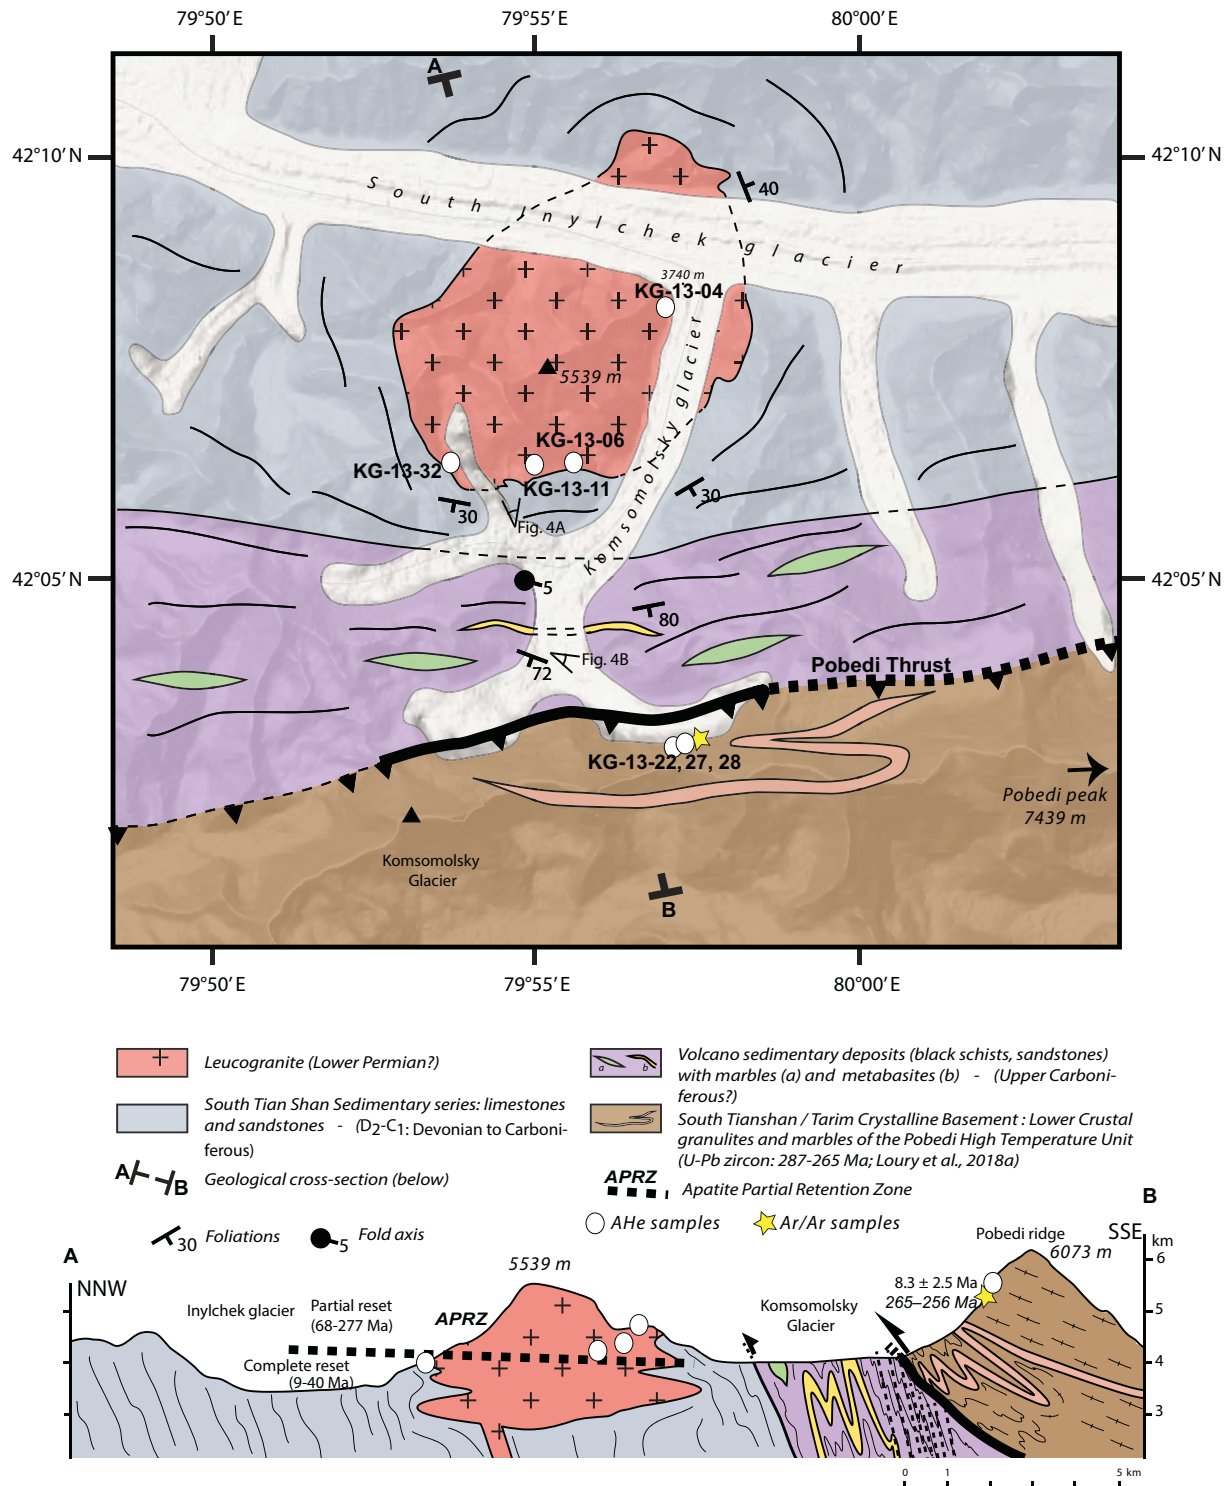

147
 148 **Fig. 3.** Field photographs of the North Khan Tengri Thrust. A, View towards the NW and B, interpreted sketch,
 149 of the North Khan Tengri Thrust (NKTT). Major folding and thrusting together with S1 foliation are in
 150 agreement with top-to-the-south sense of shear. More local retro-deformation (S2, top-to-the-North)
 151 locally transects the S1 structures (see f.i., picture B). C, Picture of the central part of the NKTT shear zone with D-E,
 152 kinematic indicators and location of sample KG-14-29, showing top-to-the-south shearing (S1). F,

153 Microphotograph of sample KG-14-29 showing a sheared marble with abundant calcite (Cal) and oxides.
 154 Phengite occurs along elongate and sheared quartz (Qtz) layers. Phengite crystallized along the lineation and
 155 thus is synchronous with ductile deformation of the central shear zone of the North Khan Tengri Thrust.
 156 Phengite from sample KG-14-29 is dated by $^{40}\text{Ar}/^{39}\text{Ar}$; results are displayed in Fig. 6.
 157
 158 This phase was followed by S2 top-to-the-north thrusting, which cross-cuts the S1 structures.
 159 The most prominent S1 structure which we were able to sample in the field is the North Khan
 160 Tengri Thrust (NKTT; Figs. 2, 3). The timing of this tectonic transport is still unconstrained.
 161 To the south of Peak Khan Tengri, the top-to-the-north Pobedi Thrust (PT) transported the
 162 deep and high-grade (granulite facies) crystalline basement of the Pobedi range on top of the
 163 Devonian-Carboniferous low grade complex (Loury et al., 2018a; Figs. 4, 5).

164
 165
 166 **Fig. 4.** Field photographs of the southern part of Kyrgyz STS. A, view of the southern flank of the ‘5539 m
 167 peak’, showing an intrusive Permian granite cross-cutting the Devonian-Carboniferous low grade complex
 168 (schists, black shales, metagabbros). B, view towards the east of the Pobedi Thrust, which placed the high-grade
 169 (granulite facies) STS formation on top of the Devonian-Carboniferous low-grade complex. Location of photos
 170 is shown on Fig. 5. C, View towards the East showing the high Khan Tengri-Pobedi chain, from above Inylchek
 171 (location on Fig. 2). The Pobedi Thrust transports the southern STS onto the Mesozoic peneplain and the
 172 overlying Cenozoic basin.
 173

174
 175 **Fig. 5.** Geological map of the northern flank of Pobedi Massif, with the location of samples dated by $^{40}\text{Ar}/^{39}\text{Ar}$
 176 and AHe, and the position of the supposed lower limit of the apatite helium partial retention zone (see
 177 discussion). Position of pictures of Fig. 4 is also indicated.

178
 179 The age of this tectonic transport is indirectly constrained by $^{40}\text{Ar}/^{39}\text{Ar}$ biotite ages between
 180 265–256 Ma, which suggests a rapid cooling of the Pobedi granulites after the metamorphic

181 peak (287-265 Ma constrained by U-Pb on zircon and $^{40}\text{Ar}/^{39}\text{Ar}$ on amphibole; Loury et al.,
182 2018a). Without any direct dating of deformation, it remains difficult to estimate which part
183 of the thrust displacement is related to the Carboniferous/Permian and which could be related
184 to Mesozoic or Cenozoic deformation events.

185

186 2.1.2. Post collisional evolution of the STS

187 After the last collisional phase that affected the CAOBS in the Late Carboniferous, subduction
188 continued to the south of the Tarim block (e.g., [Metcalf, 2013](#) and references therein). In the
189 CAOBS, a transition towards a transcurrent deformation regime along several roughly equally
190 spaced NW-SE-trending large-scale faults occurred mostly in Permian times (e.g. the Talas
191 Ferghana Fault or TFF in Kyrgyzstan and the Dzhungarian Fault in eastern Kazakhstan;
192 [Rolland et al. 2013](#); [Konopelko et al. 2013](#)). Sinistral strike-slip motion along the ENE-
193 striking STS suture is supposed to be coeval to dextral strike-slip along the NW-striking TFF
194 ([Alekseev et al. 2007](#); [Jourdon et al., 2017](#)). The TFF was activated during the collision of
195 Tarim with the Kazakh Platform at ca. 317 Ma, but remained active in Permian to Lower
196 Jurassic times ([Rolland et al. 2013](#); [Konopelko et al. 2013](#); [Morin et al., 2019](#)), with up to 70
197 km of right-lateral slip in the Permian-Triassic ([Alexeiev et al., 2017](#)). During this phase of
198 transcurrent deformation, the Tarim Basin experienced a significant phase of subsidence
199 ([Carroll et al. 1995](#)). Intense magmatism affected the Tian Shan belt and northern Tarim
200 during Early to Middle Permian times (290-260 Ma) (e.g. [Biske et al., 2013](#); [Chen et al.,](#)
201 [1999, 2009](#); [Li et al., 2011](#); [Wang and Liu, 1991](#); [Yang et al., 2006](#); [Yu et al., 2011](#); [Zhang et](#)
202 [Zou, 2013](#)). Magmatic emplacement is controlled by regional scale strike-slip faults (e.g. [de](#)
203 [Jong et al., 2009](#); [Shu et al., 1999](#); [Wang et al., 2007](#); [2009](#); [2014](#); [Loury et al., 2018a](#)); the
204 source of these alkaline OIB-like magmatic rocks (e.g. [Zhang et Zou, 2013](#); [Zhou et al., 2009](#))

205 is ascribed to mantle plume activity (e.g. Yang et al., 2005, 2006, 2013, Yu et al., 2011; Biske
206 et al. 2013; Loury et al., 2018a).

207

208 *2.2. Mesozoic reactivation of the STS*

209 Mesozoic transcurrent tectonic activity along the TFF is evidenced by Late Triassic to Early
210 Jurassic $^{40}\text{Ar}/^{39}\text{Ar}$ ages (Rolland et al. 2013; Konopelko et al. 2013). This brittle reactivation
211 occurred in a transtensional regime, and resulted in pull-apart basins with up to 70 km of right
212 lateral slip in the Jurassic (Alexeiev et al., 2017). Furthermore, sedimentary deposits and
213 thermochronological data suggest that at least one and up to three exhumation stages occurred
214 in the Tian Shan during the Mesozoic (e.g. De Grave et al., 2007, 2011, 2013, 2012; Dumitru
215 et al., 2001; Glorie et al., 2011; Hendrix, 2000; Hendrix et al., 1992; Jolivet et al., 2010;
216 Macaulay et al., 2014).

217 A first exhumation stage of the STS during the Late Jurassic at ca. 160–145 Ma is suggested
218 based on Apatite Fission Track (AFT) and apatite or zircon (U-Th)/He ages (Hendrix et al.,
219 1992; Dumitru et al., 2001; De Grave et al., 2007, 2013; Glorie et al., 2011; Jolivet et al.,
220 2010; Chang et al., 2019). This event is also emphasized by a major alluvial conglomerate in
221 the sedimentary record of the Tarim, Turpan and Junggar basins (Hendrix, 2000; Hendrix et
222 al., 1992; Li et al., 2004; Jolivet et al., 2013), and is possibly related to collisional processes
223 along the southern boundary of Eurasia, such as the accretion of the Lhasa block to the
224 Eurasian margin (e.g. Hendrix et al., 1992; Yin and Harrison, 2000; Yang et al., 2017).

225 In the Late Jurassic-Early Cretaceous, a period of thermal stability is well-documented, with
226 cooling rates lower than $1^\circ\text{C}/\text{Myr}$ (e.g. Bullen et al., 2003, 2001; Jolivet et al., 2010;
227 Macaulay et al., 2014). This long period of tectonic quiescence is also supported by the
228 formation of large peneplains and alluvial fans in western Central Asia (Hendrix et al., 1992;

229 Dumitru et al., 2001; Jolivet et al., 2007, 2009, 2015; Vassallo et al., 2007; Jolivet, 2015;
230 Morin et al., 2019).

231 A second pulse of Tian Shan exhumation in the Late Jurassic/Early-Mid Cretaceous is
232 emphasized by numerous AFT ages, which are concentrated around ~120–95 Ma (Glorie and
233 De Grave, 2016). This event, or slow cooling between significant events, corresponds with a
234 major hiatus in the sedimentary record of the Tarim Basin (e.g., Dumitru et al., 2001 and
235 references therein).

236 Several studies (De Grave et al., 2007, 2011, 2012, 2013; Glorie et al., 2011; Hendrix et al.,
237 1992; Jolivet et al., 2010) suggest that a third and last Mesozoic Tian Shan exhumation phase
238 occurred during the Late Cretaceous-Early Paleogene at ~75–60 Ma. Indeed, AFT and (U-
239 Th)/He ages are obtained for this time range in the Narat and Bohoro ranges of Chinese Tian
240 Shan (Jolivet et al., 2010), and especially in the southern part of CAO (Gillespie et al.,
241 2017). In Kyrgyzstan, similar ages are obtained from intrusions bordering the south Tian Shan
242 suture (Glorie et al., 2011), in the Song-Kul plateau (De Grave et al., 2011), in the Issyk-Kul
243 basement (De Grave et al., 2013), in the Altai mountains (De Grave et al., 2012) and in
244 Central STS (Macaulay et al., 2014). However, these ages could clearly correspond to
245 partially reset ages Macaulay et al. (2014), and may have no geological significance. Several
246 tectonic events occurred during this time range, such as Kohistan-Ladakh arc accretion to
247 Eurasia (Rolland et al., 2000; De Grave et al., 2007; Hendrix et al., 1992; Jolivet et al., 2010)
248 and the collision of Siberia with the Mongolia-North China Block following the closure of the
249 Mongol-Okhotsk Ocean (e.g. Jolivet et al., 2010; Lin et al., 2008; Metelkin et al., 2007);
250 cooling within the Tian Shan has been correlated with these events (REFS).

251

252 2.3. Cenozoic reactivation of the STS

253 Little exhumation occurred in the Cenozoic until the Early Miocene (e.g., [Jolivet et al., 2018](#)).
254 A period of renewed cooling is highlighted by widespread AFT, ZHe, AHe Early Palaeogene
255 ages (ca. 55–45 Ma; see [Glorie and De Grave, 2016](#) for a review), or might again reflect
256 some partial age resetting, as suggested by [Macaulay et al. \(2014\)](#). This potential event occurs
257 at the scale of the Tian Shan belt ([Jolivet et al., 2010](#)). These cooling ages are only found in
258 close proximity to major fault zones, which suggests that Palaeogene resetting or cooling is
259 mainly controlled by fault reactivations. However, this phase resulted in minor exhumation as
260 Late Palaeozoic and Mesozoic exhumation ages are widely preserved. This transient
261 deformation phase could be attributed to the onset of India-Asia collision (e.g., [Hu et al.,](#)
262 [2016](#)).

263 In the Kyrgyz Tian Shan, it is suggested that the onset of the modern orogeny occurred during
264 the Early Miocene (~30–22 Ma) with an apparent intensification in the Late Miocene (~12–8
265 Ma) and in the Plio–Pleistocene (<5 Ma; see for [Macaulay et al., 2014](#) for a review). There,
266 Cenozoic exhumation is clearly documented since the Oligocene around 25–20 Ma ([Hendrix](#)
267 [et al., 1994](#); [Sobel et Dumitru, 1997](#); [Yin et al., 1998](#); [Bullen et al., 2001](#); [Sobel et al., 2006a-](#)
268 [b](#); [Heermance et al., 2008](#); [De Grave et al., 2007, 2011](#); [Glorie et al., 2010, 2011](#); [Macaulay et](#)
269 [al., 2014, 2013](#); [Glorie and De Grave, 2016](#); [Bande et al., 2017](#)). The onset of exhumation is
270 linked to a progressive transfer of compressional stresses of India-Asia collision into the
271 Asian continent (e.g., [Molnar et Tapponnier, 1975](#)) after the closure of marginal basins and a
272 significant thickening of the Himalayan collision zone. Diffuse regional exhumation was
273 likely followed by focussed exhumation due to the activation of major thrusts in relation to a
274 soft to hard collision of India with Eurasia ([Heermance et al., 2007](#); [Glorie and De Grave,](#)
275 [2016](#)). In parts of the Tian Shan, Cenozoic deformation was out-of-sequence ([Jolivet et al.,](#)
276 [2010](#); [Macaulay et al., 2014](#)), with a significant lateral variation along major reactivated

277 structures. This out-of-sequence activation could be explained by the dip and nature of the
278 inherited structures that were more or less susceptible to reactivation (e.g. Macaulay et al.,
279 2014; Jourdon et al., 2018a). To the north, the NTS basement over-thrusts the Issyk-Kul
280 Cenozoic basin along the Main Terskey Fault (MTF) (Macaulay et al., 2013).
281 Thermochronological data show that this structure was activated during the Late Oligocene
282 (~25 Ma ago) and propagated eastward during the Miocene (Macaulay et al., 2013). In the
283 central part of the belt, the STS suture was reactivated by a top-to-the-north thrust, which
284 uplifted the STS units over the MTS from 20 to 8 Ma (Macaulay et al., 2014; Glorie et al.,
285 2011). An increase in exhumation rates occurred during Miocene times (12-8 Ma and <5 Ma),
286 as documented by abundant thermochronological data (e.g. Bullen et al., 2001; 2003; De
287 Grave et al., 2007, 2011; Glorie et al., 2010, 2011; Macaulay et al., 2014, 2013; Sobel et al.,
288 2006b). The exhumation rate is estimated at 0.1–0.4 mm/yr in the Terskey Range of the NTS
289 during the Miocene (Macaulay et al., 2013). Acceleration of tectonic uplift and erosion are
290 also suggested by magnetostratigraphic data and sedimentary records in the Tarim foreland
291 Basin (e.g. Abdrakhmatov et al., 1996; Charreau et al., 2006; Heermance et al., 2007, 2008;
292 Chang et al., 2012, 2017). An increase in deformation and the activation of new faults in the
293 Tian Shan range since ca. 12 Ma may explain the anomalously high topography in the
294 southern Tian Shan, particularly summits above 7400 m in the Pobedi and Khan Tengri
295 massifs. However, data have not yet been reported from the highest mountains within the Tian
296 Shan in order to relate its formation to the rest of the belt.

297

298 **3. Methods and dating results**

299 *3.1. $^{40}\text{Ar}/^{39}\text{Ar}$ dating*

300 3.1.1. Analytical methods

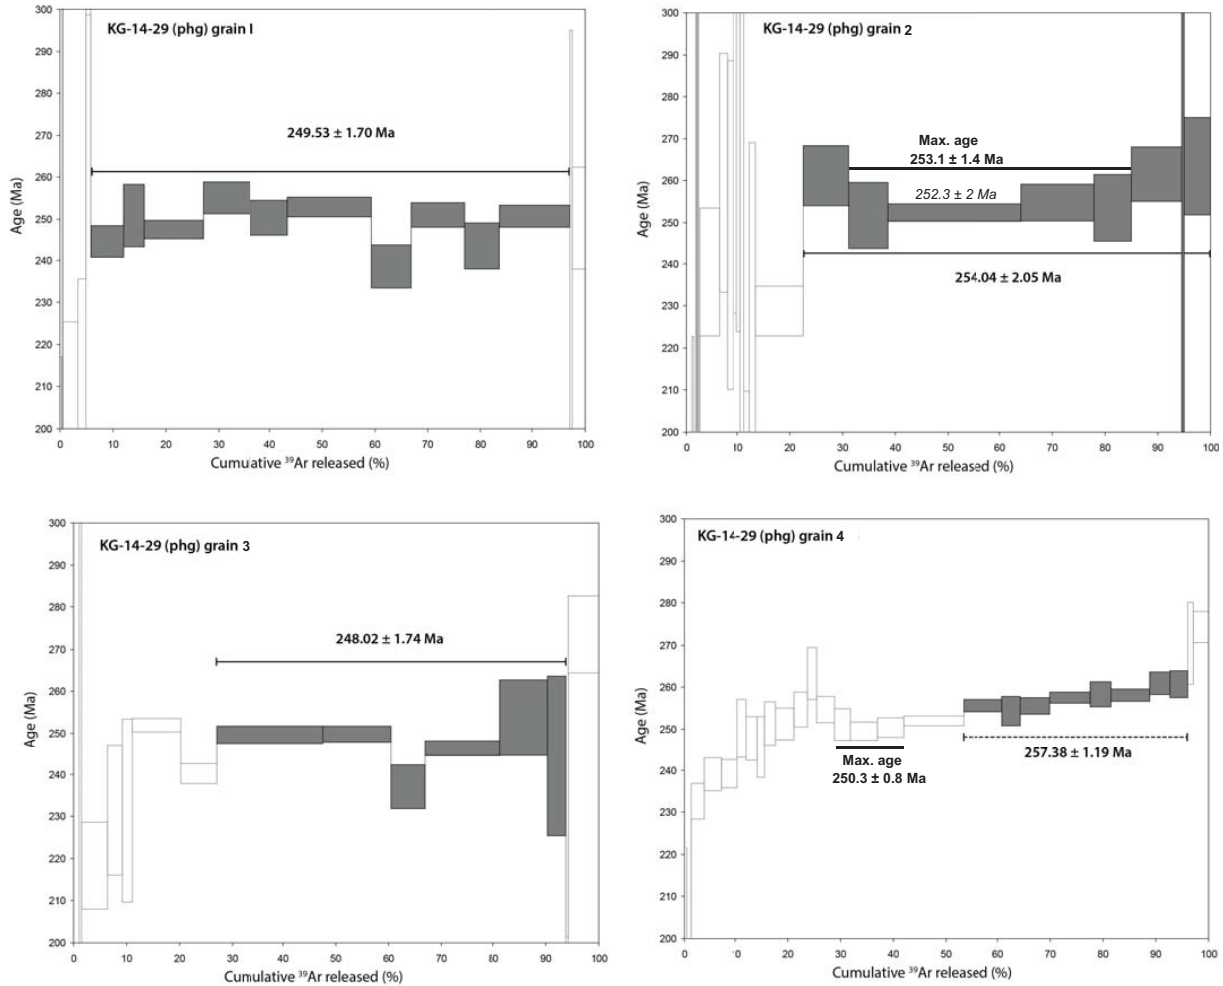

301 In order to constrain the tectonic and cooling history of the STS basement in eastern
302 Kyrgyzstan, $^{40}\text{Ar}/^{39}\text{Ar}$ dating was performed on a marble mylonite (sample KG-14-29) of the
303 North Khan Tengri Thrust (NKTT; [Figs. 2-3](#)) to provide an age constraint for tectonic motion
304 on this thrust. Sample KG-14-29 was crushed to a size fraction of 500-800 μm and cleaned in
305 an ultrasonic bath. Phengites were carefully handpicked under a binocular microscope to
306 select only grains without evidence of alteration or inclusions. Phengite aggregates from
307 elongated syn-kinematic pressure-shadows were less than 800 μm in size ([Fig. 3F](#)). Selected
308 grains and aggregates were packed in aluminum foil and irradiated for 40 hours in the Triga
309 Mark II nuclear reactor of Pavia University in Italy together with Fish Canyon sanidine grains
310 as flux monitor (28.03 ± 0.08 Ma, Jourdan and Renne, 2007). For this reactor, the following
311 correction factors for argon nuclear interferences were applied after irradiation of pure salts of
312 KF and CaF_2 : $(^{36}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.000288 \pm 0.000016$; $(^{39}\text{Ar}/^{37}\text{Ar})_{\text{Ca}} = 0.000727 \pm 0.000041$;
313 $(^{40}\text{Ar}/^{39}\text{Ar})_{\text{k}} = 0.00969 \pm 0.00038$; $(^{38}\text{Ar}/^{39}\text{Ar})_{\text{k}} = 0.01297 \pm 0.00045$. All samples were
314 analyzed by single-grain infrared CO_2 laser fusion analysis, and isotopic ratios were measured
315 using an ARGUS VI multi-collector mass spectrometer at Geoazur institute of the University
316 of Nice. System blanks were measured every three experiments. Mass discrimination for the
317 mass spectrometer was monitored by regularly analyzing air pipette volumes. The ArArCalc
318 © software v2.5.2 was used for data processing. Decay constants are those given by [Steiger
319 and Jäger \(1977\)](#). Uncertainties on apparent and plateau ages are given at the 1σ level
320 including the error on the $^{40}\text{Ar}^*/^{39}\text{Ar}_{\text{k}}$ ratio of the monitor. The criteria we used for defining a
321 plateau age are: (1) it should contain at least 70% of total ^{39}Ar released, (2) it should contain
322 at least three successive step-heating fractions, (3) the integrated age of the plateau, calculated
323 by a weighted average of apparent ages of individual fractions comprising the plateau, should
324 be consistent with each apparent age of the plateau within a 2σ error. A detailed table of
325 results is given in [Table 1](#).

326

327 3.1.2. Marble mylonite (sample KG-14-29) phengite $^{40}\text{Ar}/^{39}\text{Ar}$ dating results

328 4 phengite aggregates from the KG-14-29 marble mylonite were analyzed and results are

329 presented in Fig. 6 and Table 1.

330

331

332 **Fig. 6.** North Khan Tengri Thrust shear zone mylonite sample KG-14-29 $^{40}\text{Ar}/^{39}\text{Ar}$ phengite dating results. The
333 location, field relationships and petrological features of the dated sample are shown in Figs. 2-3.

334

335 Aggregate 1 yields a well-defined plateau age of 249.5 ± 1.7 Ma (MSWD = 1.44) including

336 10 steps and 91% of ^{39}Ar released. An inverse isochron age of 251.6 ± 1.6 Ma (MSWD =

337 1.58) is calculated, which is consistent within errors with the plateau age. Aggregate 2 shows

338 a more disturbed spectrum in the low-temperature steps, which might represent some outer

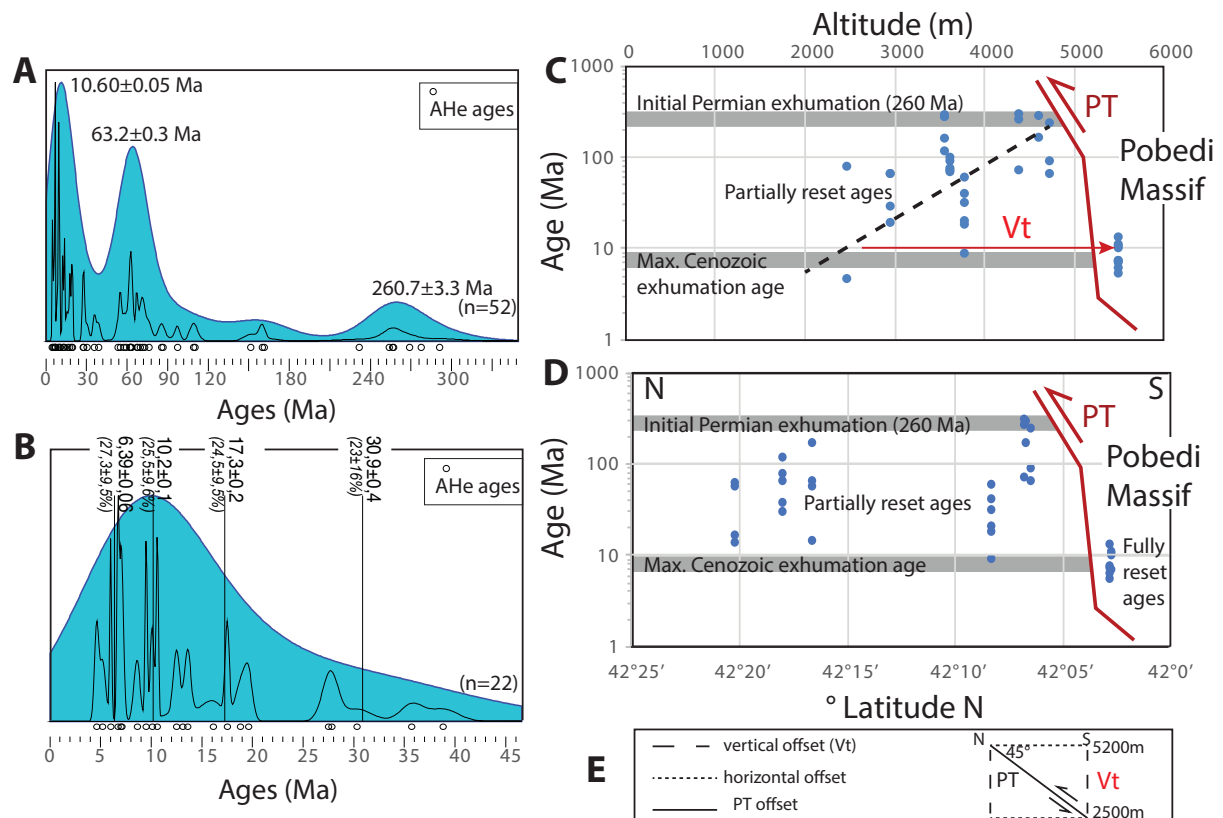

339 grain alteration. At higher temperatures, a plateau age is obtained at 254.0 ± 2.1 Ma (MSWD

340 = 0.54), corresponding to 77% of ^{39}Ar released in 8 steps. However, its slight “U” shape

341 might be indicative of some (relatively minor) excess argon (e.g., [Arnaud and Kelley, 1995](#)),
342 so the central part of the spectra might be regarded as a maximum age (253.1 ± 1.4 Ma with
343 the central four steps or 252.3 ± 2 Ma with the lower central one).

344 Aggregate 3 shows a pattern with increasing apparent ages for the low-temperature steps.
345 Then a plateau age of 248.0 ± 1.7 Ma (MSWD = 1.45) is obtained, including 6 steps and 67%
346 of released ^{39}Ar .

347 Finally, the last phengite aggregate (Aggregate 4) shows a staircased shape with apparent ages
348 continuously increasing. A pseudoplateau age is obtained for high-temperature steps (19 to
349 26) of 257.4 ± 1.2 Ma (MSWD = 1.00), including 44% of ^{39}Ar released in 9 steps. However,
350 this age is not considered geologically meaningful because (i) this part of the spectra is not
351 flat and shows a steady increase from 255 to 261 Ma, and (ii) the last two steps increase
352 significantly up to 274 Ma. Therefore, it seems that this part of the spectra is influenced by
353 some inherited argon released in the higher temperature steps, which may be hosted in
354 mineral inclusions such as epidote or titanite (e.g., [Simon-Labric et al., 2009](#)) in the grain
355 core. If we retain the hypothesis of some (relatively minor) inherited argon in this sample,
356 then the central portion of the spectra is the closest to the crystallization age (and thus
357 represents a maximum age) of 250.3 ± 0.8 Ma, which is similar within error to the three other
358 ages.

359

360 **Fig. 7.** Distribution of obtained AHe in this paper. A, Plot of all obtained AHe dates in this study, which shows a
 361 broad trimodal distribution, with Permian (260±5 Ma), Late Mesozoic-Early Cenozoic (~63.2 Ma), and Miocene
 362 (~10.6 Ma) peaks. This plot shows the spread in the obtained AHe dates, which are not all considered to be
 363 geologically meaningful (some of the ages are explained by partial resetting and inheritance, see the text for
 364 details). B, enlargement of the 0-50 Ma time range, which displays the equal weight of four age peaks in the age
 365 distribution at 6.4, 10.2, 17.3 and 30.9 Ma. C, Distribution of ages versus altitude along STS (including the
 366 Naryntoo Range). D, Distribution of ages versus latitude of samples of the Khan Tengri-Pobedi massifs. In the
 367 Pobedi Thrust (PT) footwall domain, the minimum age of the Late Palaeozoic exhumation is constrained by the
 368 older AHe ages, while the maximum age of the Cenozoic exhumation is constrained by the younger ages. The
 369 spread between these two ages is interpreted to reflect partial resetting of the apatite helium system during the
 370 Cenozoic. Vt represents the minimum vertical offset deduced for the Pobedi Thrust (PT) at ca. 8-10 Ma rocks. E,
 371 sketch of relative offsets on the PT inferred from Vt and the 45° dip of the thrust.
 372

373 3.2. U-Th-Sm/He ages of Apatites

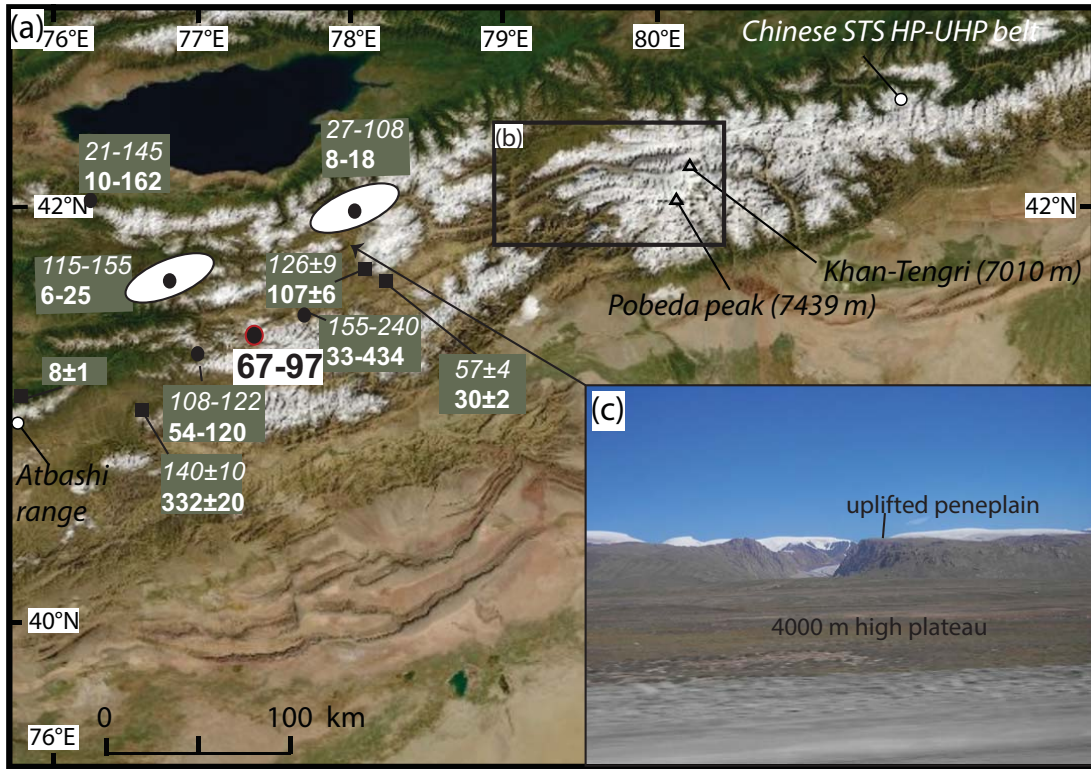

374 3.2.1. Strategy & Methodology

375 13 new apatite samples have been analyzed by U-Th-Sm/He (AHe) in this study. Samples
 376 were gathered from Palaeozoic basement lithologies from the STS, from the highest Pobedi
 377 Massif in the east (from which no thermochronological data has previously been published) to
 378 the flat region of the STS uplifted peneplain. These data are combined with published data
 379 (Glorie et al., 2011; De Grave et al., 2013; 2014; Macaulay et al., 2013; 2014). In this work,

380 AHe analyses were conducted on two to six single crystal aliquots per sample, depending on
381 sample quality (Table 2). Apatite grains were extracted using standard mineral separation
382 techniques and packed in platinum tubes for U, Th, Sm, and He isotopic analysis at the
383 University of Potsdam and GFZ German Research Centre for Geosciences, Potsdam,
384 Germany. Average AHe ages of Durango apatite standards analyzed were 29.1 ± 1.1 , 30.7 ± 2.4 ,
385 and 29.0 ± 0.8 , which are comparable to published averages of replicate analysis (e.g., $31.0 \pm$
386 1.0 and 32.1 ± 1.1 Ma; McDowell et al., 2005; Min et al., 2006). The Ft correction factor is
387 calculated using the grain size (e.g., Farley, 2002). Any aliquot differing by more than 75%
388 from the mean value of the other aliquots of a given sample was considered erroneous and
389 was thus discarded from the data set. The 2 sigma standard error is representative of the
390 uncertainties associated with the method and the natural reproducibility of the AHe system
391 than the analytical error on individual aliquots. For more details on the methodology used for
392 AHe dating, the reader is referred to Zhou et al. (2017).

393

394 3.2.2. AHe dating results

395

396 **Fig. 8.** Satellite image showing the AHe dating results obtained in the STS. A, Results of dating in the Naryn
 397 River area. B, Results obtained in the Pobedi - Khan Tengri - Pobedi area. AHe and AFT data from the literature
 398 are also shown.

399 AHe results are displayed in [Table 2](#) and the main results are shown in [Figs. 8-9](#). Most of our
400 AHe samples yielded over-dispersed single crystal aliquot ages. Such AHe age variability
401 may be related to differences in the diffusion characteristics between aliquots caused by grain
402 size variations, radiation damage, or the number of intact crystal terminations (e.g., [Farley,](#)
403 [2000](#); [Reiners et al., 2004](#); [Flowers et al., 2009](#); [Brown et al., 2013](#)), and to subsequent
404 incomplete resetting due to burial within the apatite partial retention zone (e.g., [Macaulay et](#)
405 [al., 2013, 2014](#)). Therefore, variations in AHe ages within a given sample could be accurate
406 and potentially provide informations about its thermal history. Plotting age versus Ft (Suppl.
407 Fig. 1) shows that KG-13-48 and KG-13-11 and possibly KG-13-27 may have a positive
408 relationship between closure temperature and grain size. There are no obvious relationships
409 between age and eU (Suppl. Fig. 1); however, aliquots of samples KG-13-27 and -28 have
410 extremely high eU values and therefore may have anomalously high closure temperatures.
411 Alternatively, erroneous ages can reflect inclusions, (healed/unhealed) fractures, ^4He
412 implantation and U-Th(-Sm) zonation (e.g., [Farley, 2002](#); [Dobson et al., 2008](#); [Macaulay et](#)
413 [al., 2014](#)).

414 Significant variations are observed in the spread of thermochronological ages obtained in our
415 samples from different parts of the STS, which mainly relate to their structural situation
416 within the study area ([Fig. 8](#)). These variations are considered to be significant in the light of
417 previous data and of this structural situation. Four different geochronological configurations
418 can be inferred from the distribution of AHe ages:

419 - (i) in zones lying directly below the Mesozoic peneplain:

420 In the central STS, in the Naryntoo Range (sample KG13-78, [Fig. 8A](#)), all aliquots are
421 spread within 18% of the average age, and thus an average age of ca. 78 Ma is
422 retained for this sample, which is considered as geologically meaningful. This age

423 could correspond to cooling of the sample below ca. 60°C (e.g., [Farley, 2002](#)). We
424 relate this age to a period of slow erosion during formation of the erosion surface.
425 South of Inylchek ([Fig. 8B](#)), sample KG13-39 presents three aliquot ages of 256-269
426 Ma, and two aliquots of 109 and 151 Ma. The group of three Late Permian aliquots is
427 close to the granite protolith U-Pb age of 285-305 Ma obtained by [Konopelko et al.](#)
428 ([2007](#)). These granites must have been emplaced at a very shallow level as they
429 intrude low grade schists ([Loury et al., 2018a](#)), and therefore the 256-269 Ma AHe
430 ages are considered to be geologically meaningful. Both <200 Ma AHe aliquots have
431 two broken ends and therefore the Ft correction may be less precise; therefore, we
432 discard these two ages.

433 - (ii) To the north of the STS suture, north of Inylchek village ([Fig. 8B](#)), Cenozoic ages
434 are obtained in samples KG13-46 & 48, in agreement with previous datings by [Glorie](#)
435 [et al. \(2011\)](#) and [Macaulay et al. \(2014\)](#). However, there is a large spread in ages from
436 4.6 to 63 Ma, which also reflects the spread in ages of previous studies in the same
437 area. For sample KG13-48, the age spread may reflect a Ft relationship. These
438 dispersed ages could suggest that this zone has remained within the helium partial
439 retention zone after a mid-Cenozoic phase of uplift initiated at > 19 Ma ([Macaulay et](#)
440 [al., 2014](#)), with a possible increase of exhumation after 10 Ma.

441 - (iii) in the high Pobedi-Khan Tengri massifs ([Fig. 8B](#)), two different zones have been
442 dated, which both record incomplete Cenozoic resetting. In this domain, the AHe data
443 are dispersed which is ascribed to an incomplete reset of this chronometer: (1) to the
444 north, SE of Akchukkur basin, in the hanging wall compartment of the NKTT and
445 SarF, two samples (7TS302 and 305), from elevations of 3818 and 3540 m,
446 respectively, show a spread of ages between 13 and 160 Ma, which is in agreement
447 with incomplete resetting during the Cenozoic tectonic phase. It is also compatible

448 with monotonic slow cooling, as modeled by Macaulay et al (2014, Fig. S3). Sample
449 7TS307, which comes from the direct vicinity of SarF at a lower elevation of 3200 m,
450 was strongly reset during the Cenozoic and gives ages of 13 to 59 Ma. However, the
451 large amount of single aliquot dispersion argues for prolonged residence within the
452 apatite partial retention zone. (2) The second sampled zone lies in the footwall
453 compartment of the PT. Samples KG13-04, 06, 11, and 32 were collected along
454 Inylchek Glacier, at high elevations (3790-4800m) on the northern flank of Peak
455 Pobedi. These samples display a high variation in ages, ranging from 9 to 291 Ma.
456 Many of these aliquots have extremely low eU values, suggesting that these results
457 may be less reliable; however, all aliquots which yielded Cenozoic ages have higher
458 eU values. For samples above 4000 m, all ages lie between the Permian and the
459 Cenozoic (291-62 Ma). Only sample KG13-04, collected at 3785 m, displays
460 Cenozoic ages (58-9 Ma). We interpret the age pattern of samples collected between
461 4000 and 4800 m as reflecting partial resetting of AHe ages within the apatite partial
462 retention zone due to underthrusting and hence reheating (Jourdon et al., 2018a-b), as
463 this zone corresponds to the footwall compartment of the PFT thrust and also exhibits
464 a thick Cenozoic cover south of Inylchek (Fig. 4C).

465 - (iv) In the hanging-wall part of the Pobedi Thrust, at an elevation > 5500 m, samples
466 KG13-27 & 28 display a narrow age variation within 5.2-12.5 Ma, which is
467 considered geologically meaningful. Two average ages could be calculated, of $7.6 \pm$
468 1.8 Ma for KG13-27, and 9.2 ± 2.9 Ma for KG13-28, or 8.3 ± 2.5 Ma combining the
469 two samples, which are very near from each other. As compared to the footwall
470 compartment of Pobedi Thrust, which has an incompletely reset AHe age, we interpret
471 this 8.3 ± 2.5 Ma age as resulting from the significant differential exhumation of the
472 two compartments in response to the PT activation at <10 Ma.

473 **4. Discussion**

474 *4.1. Tectonic significance of the Permian $^{40}\text{Ar}/^{39}\text{Ar}$ and AHe ages*

475 $^{40}\text{Ar}/^{39}\text{Ar}$ dating on phengite of the Khan-Tengri Thrust mylonitic marble provides
476 chronologic constraints on an episode of compressional tectonics within the STS belt in the
477 Late Permian - Early Triassic. The $^{40}\text{Ar}/^{39}\text{Ar}$ technique has been widely used to date
478 deformation-induced neo-crystallized K-white mica (e.g. Dunlap, 1997; Rolland et al., 2008;
479 2013; Sanchez et al., 2011; West et Lux, 1993). In this paper (section 3.1 and Fig. 6), four
480 phengite aggregates yield plateau ages between 257 and 248 Ma. All the grains show partly
481 disturbed ^{39}Ar releasing patterns with staircase shapes for the low-temperature steps, which is
482 generally ascribed to radiogenic argon loss during post-crystallization fluid flow or brittle
483 reactivation (e.g. Berger, 1975; McDougall and Harrison, 1999; Rolland et al., 2008; Sanchez
484 et al., 2011; Tartèse et al., 2011; Lanari et al., 2014). As the temperature for brittle-ductile
485 deformation in marbles (~200-300°C; e.g., Ashby and Verrall, 1978) is lower than the closure
486 temperature of K-Ar system in phengite (>400°C, Villa, 1998), the ages obtained for these
487 minerals are thus interpreted as ages for dynamic crystallization in the shear zone. All four
488 age spectra from marble mylonite sample KG-14-29 phengites are consistent with a single
489 crystallization event, bracketed, if we retain the two most meaningful plateau ages (aggregates
490 1 and 3), between 249 ± 1.7 and 248 ± 1.7 Ma. Thus, the phengite age range likely represents
491 a single or several shearing events at 249-248 Ma, during south-directed thrusting on the
492 NKTT. In regard to kinematics, this deformation is related to a N-S shortening phase
493 involving the activity of several thrusts in the STS, including the Pobedi and the North Khan
494 Tengri thrusts, in a global transpressional context (e.g., Jourdon et al., 2017; Fig. 9). Similar
495 to slightly older ages (240–290 Ma) have been obtained by Konopelko et al. (2013) and
496 Rolland et al. (2013) for dextral displacement of the TFF. Therefore, the tectonic context in
497 the Middle-Late Permian is in agreement with a phase of N-S shortening + sinistral motion in

498 the STS coeval with dextral deformation along the TFF (Figs. 1, 9).
N-S to NW-SE shortening

499

500 **Fig. 9.** Sketch of Tian Shan tectonic context at c. 260-240 Ma. Synchronous right-lateral motion of TFF and
501 transpressional sinistral deformation along the South Tien Shan (STS) suggests a main N-S compression context.
502 Middle Tien Shan (MTS) squeezes out towards the east in the eastern part of Kyrgyz STS close to the border
503 with China. At this location, the termination of the MTS and the E-W strike of the STS give rise to a mainly
504 compressional flower-type structure along the STS.

505

506 This tectonic phase directly followed a major phase of sinistral deformation along the STS,

507 coeval with HT metamorphism and magmatism in the Early-Middle Permian at 287-265 Ma

508 in the Pobedi Range and along strike in the Chinese STS (e.g., [Loury et al., 2018a](#); [Yu et al.,](#)

509 [2017](#); [Wali et al., 2017](#); [Zhong et al., 2017](#)). These main compressional shear zone phases

510 occurred after 265 Ma, in agreement consistent with the $^{40}\text{Ar}/^{39}\text{Ar}$ age of 256–265 Ma

511 obtained on biotites in the Pobedi HT unit ([Loury et al., 2018a](#)). $^{40}\text{Ar}/^{39}\text{Ar}$ ages obtained from

512 amphiboles are similar to the U-Pb ages on zircon of 265-287 Ma in this unit, and thus

513 represent the age of the metamorphic peak, while the biotite ages could be interpreted as a

514 cooling age for the Pobedi HT unit (through $\sim 300^\circ\text{C}$; [Loury et al., 2018a](#)). We thus propose

515 that the N-S shortening phase is responsible for the exhumation of the HT Pobedi HT unit by

516 the activation of the PT at a minimum age of 265 Ma. This compressional phase lasted until

517 the Late Permian - Early Triassic, as shown by phengite $^{40}\text{Ar}/^{39}\text{Ar}$ ages of 248-249 Ma in the

518 North Khan Tengri Thrust, when a transpressive tectonic regime affected the entire study area
519 (de Jong et al., 2009; Laurent-Charvet et al., 2003; Rolland et al., 2013; Konopleko et al.,
520 2013). Such a fast cooling rate due to exhumation during transcurrent tectonics at that time is
521 also described in the Chinese Tien-Shan and Altai along the Main-Tien-Shan and Erqishi
522 shear zones (Laurent-Charvet et al., 2003). As shown by the Permian AHe ages of 260 ± 5 Ma
523 (Fig. 7A), and similar ages obtained across the Tian Shan range (e.g., Glorie et al., 2019, and
524 references therein), exhumation related to the transpressive tectonics lasted probably less than
525 10 Ma. Exhumation ended at c. 250 Ma, and deformation might have evolved as pure strike-
526 slip with little exhumation in the Early Triassic until c. 240 Ma (Rolland et al., 2013;
527 Konopelko et al., 2013).

528

529 *4.2. Significance of the Permian – Early Cenozoic planation surface*

530 Following the pioneering works of Afonichev and Vlasov (1984); Makarov (1977); Chediya
531 (1986); Hendrix et al. (1992) and Dumitru et al. (2001) and more recent compilations of De
532 Pelsmaeker et al. (2017), Chen et al. (2017), Jolivet et al. (2018), the planation surfaces
533 developed through ongoing erosion during the Mesozoic in the entire western CAOB.
534 Thermochronological data from the Song-Kul plateau, the Alai, Trans-Alai and Terskey
535 ranges and from the central and western Chinese Tian Shan show slow basement cooling
536 during most of the Jurassic (e.g. Dumitru et al., 2001; Sobel et al., 2006a; Jolivet et al., 2010;
537 De Grave et al., 2011, 2012; Tang et al., 2015; Glorie and De Grave, 2016; Zhang et al., 2016;
538 Gillespie et al., 2017a-b; Wang et al., 2017; Morin et al., 2019). The Permian-Cretaceous
539 peneplain is recognized in the landscape in regions neighbouring the Pobedi range; therefore,
540 in these areas, Cenozoic tectonics have resulted in surface uplift with very limited erosion.
541 However, some slight differences in exhumation ages could reflect several tectonic phases, or
542 a long lasting tectonic context punctuated by slight, distinct, along-belt exhumation episodes

543 during the Mesozoic (e.g., [Jolivet, 2017](#)). Permian-Triassic (280–210 Ma) titanite fission track
544 and zircon (U-Th)/He data ([Glorie et al., 2011](#)) along the southern margin of STS are
545 diagnostic of significant exhumation until the Triassic. In agreement with these data, we
546 document several AHe ages, which remained unreset in the Cenozoic, spanning 256-269 Ma
547 (sample KG-13-11) at Inylchek, to the west of the Pobedi-Khan Tengri massif. This age range
548 for the initial exhumation of the southern STS to a temperature <60°C ([Ehlers and Farley,](#)
549 [2003](#)) is in good agreement with the Late Permian tectonic phase evidenced by $^{40}\text{Ar}/^{39}\text{Ar}$
550 dating (see previous section 4.1.). As the AHe and $^{40}\text{Ar}/^{39}\text{Ar}$ ages overlap, this tectonic phase
551 is suggested to have resulted in rapid exhumation and vertical motions, which seemingly
552 stopped shortly after 250 Ma in that area. The Permian transpressional phase thus appears to
553 have been short-lived and laterally heterogeneous, and matches relatively well with the
554 ending of the Early to Middle Permian magmatic phase (~260 Ma; e.g. [Wang et Liu, 1991](#);
555 [Chen et al., 1999, 2009](#); [Yang et al., 2006](#); [Li et al., 2011](#); [Yu et al., 2011](#); [Biske et al., 2013](#);
556 [Zhang et Zou, 2013b](#)).

557 At the large scale, to the west, the neighbouring STS preserves some younger exhumation
558 ages. This article extends the work of [Macaulay et al. \(2014\)](#) and [Glorie et al. \(2011\)](#),
559 documenting a ~100-60 Ma planation surface preserved in the central Kyrgyz STS, to the
560 west of the Pobedi Massif, highlighted by Late Cretaceous (67-97 Ma) AHe ages in the Naryn
561 Valley and an age peak of ~ 63 Ma documented in the entire AHe dataset ([Figs. 7-8 & Table](#)
562 [2](#)). Similar Late Cretaceous / Early Cenozoic ages were also obtained in the Chinese TS to the
563 east (e.g., [Jolivet, 2017](#)) and reflect slow cooling at the scale of the STS. This age is rarely
564 documented in the Northern Tian Shan ([De Grave et al. 2011](#)), while it largely occurs within
565 the southern rim of CAOBS ([Gillespie et al., 2017a-b](#)). SW of the Tian Shan in the South
566 Pamir, some authors propose that significant crustal thickening occurred in that time range

567 (Aminov et al., 2017), although there are still few direct constraints to tie Tian Shan
568 exhumation to this Late Mesozoic tectonic event.

569

570 *4.3. Respective parts of Permian and Cenozoic motions on major faults*

571

572 Regarding the evolution of STS, a major question is how to estimate the relative contributions
573 of Permian tectonics and Cenozoic structural reactivation to the net displacement of major
574 faults? Direct and indirect constrains can be derived from geological analysis and
575 thermochronology. (i) First, considering the Permian activity of the PT, the thrust places the
576 hangingwall granulite facies unit on top of the footwall greenschist facies unit, which
577 represents a significant metamorphic jump (Loury et al., 2018a). Cooling below 300°C of the
578 hanging-wall compartment, constrained by biotite $^{40}\text{Ar}/^{39}\text{Ar}$ dating, occurred at 256-265 Ma.
579 Given that high-temperature metamorphism in this hanging-wall is constrained at 6 kbar-
580 850°C and is dated at 276.2 ± 2.0 Ma (Loury et al., 2018a), the maximum initial Permian
581 offset of the PT should be > 8 km to explain its emplacement on top of the shallow footwall
582 domain, with a geothermal gradient of 40°C.km^{-1} . In this paper, we obtain a peak of Permian
583 AHe ages, which record exhumation of the PT footwall at 260.7 ± 3.3 Ma (Fig. 7A). This age
584 is in agreement with an exhumation of the STS following transpressional tectonics at 290-260
585 Ma (see discussions on the timing of collision in Loury et al., 2018b), after the termination of
586 PT motion.

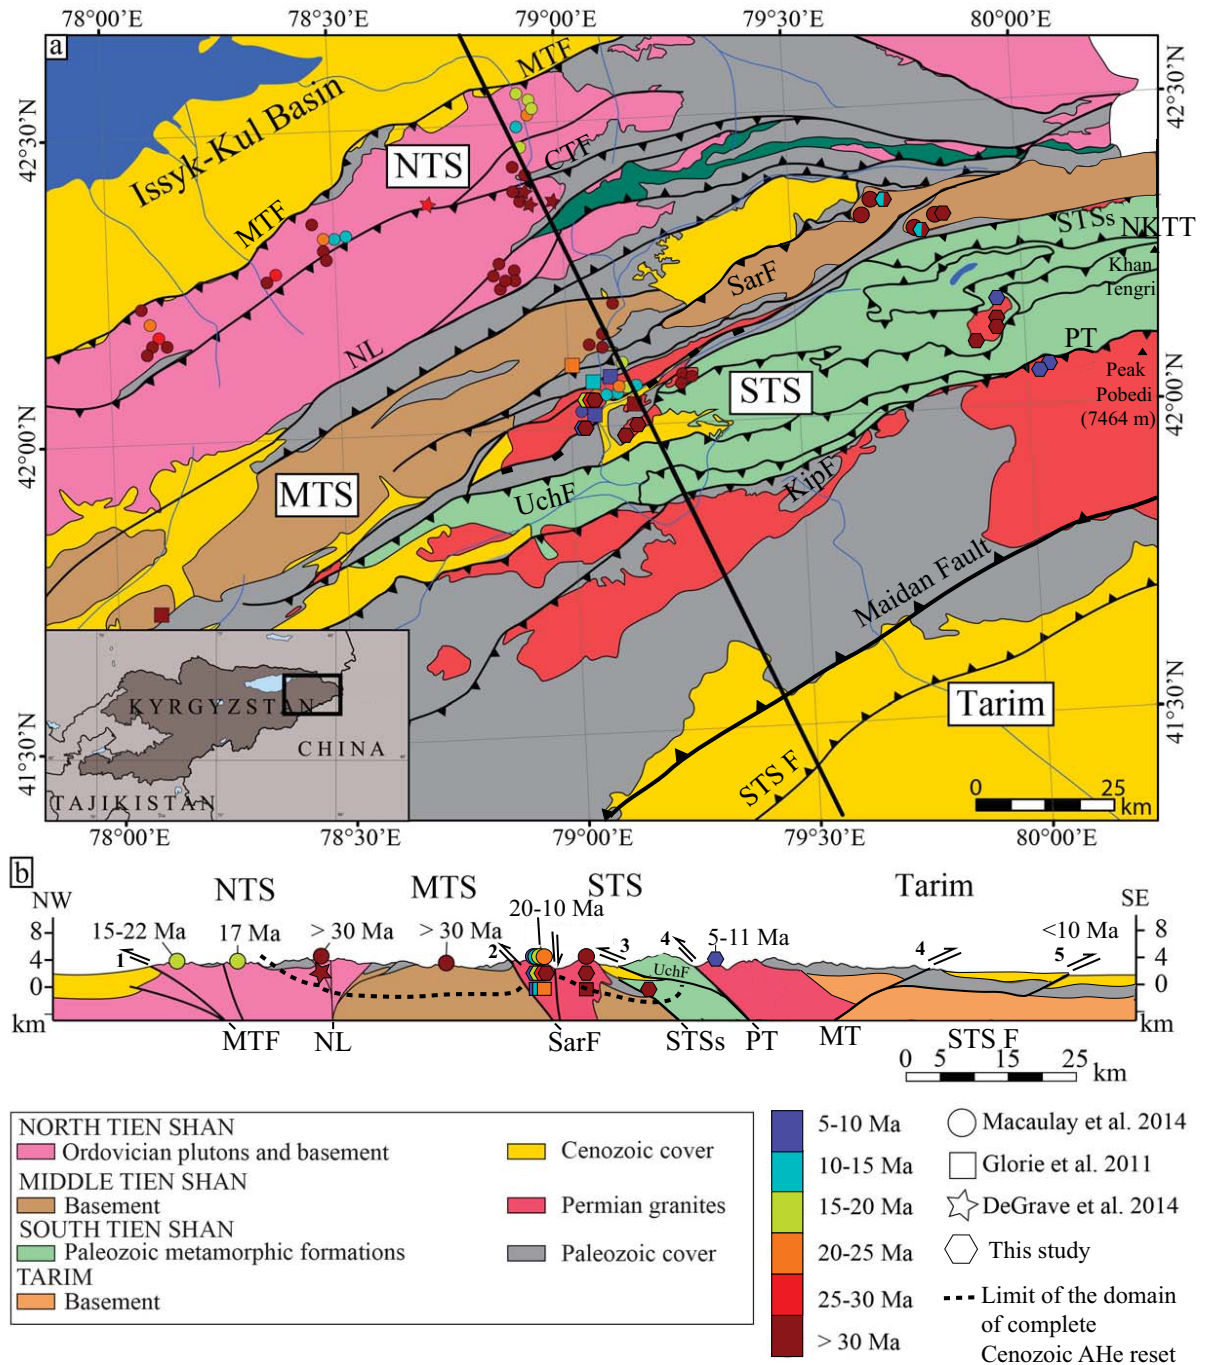

587 (ii) Considering the Cenozoic offset of the PT, we obtained partly reset/unreset AHe ages in
588 the northern footwall part of the PT, while AHe ages were reset and lie within 8.3 ± 2.5 Ma in
589 its southern hanging-wall part. We interpret this age difference as resulting from the Cenozoic
590 top-to-the-north tectonic displacement of the PT. A $\sim 60^\circ\text{C}$ blocking temperature for the U-
591 Th-Sm/He system in apatite (for a cooling rate of $\sim 10^\circ\text{C/Ma}$; Reiners and Brandon, 2006),
592 and a geotherm of 25°C/km for this period of time (Vinnik et al., 2004; Makarov et al., 2010;

593 Jourdon et al., 2018a), implies that 8.3 ± 2.5 Ma reflects the time of exhumation through a
594 depth of $\sim 3 \pm 0.5$ km. The presence of Permian biotite $^{40}\text{Ar}/^{39}\text{Ar}$ ages shows that the
595 hanging-wall compartment was not subjected to temperatures above the cooling temperature
596 of biotite of $\sim 300^\circ\text{C}$ (Harrison et al., 1985) during the Cenozoic, corresponding currently to
597 an equivalent depth of ~ 12 km in the Tian Shan. Therefore, the Pobedi HT unit hanging wall
598 has experienced between ~ 3 and < 12 km of Cenozoic exhumation. In the PT footwall domain,
599 Permian AHe ages from below the peneplain imply that the samples were exhumed close to
600 the earth surface at ~ 260 - 250 Ma, and were then buried to a depth equivalent to $< 60^\circ\text{C}$ in the
601 Mesozoic-Cenozoic. Along strike to the east, at higher elevations in the PT footwall
602 compartment, Cenozoic reset AHe ages are found at an elevation of < 3800 m, and, in this
603 domain a 7-8 Ma age would broadly correspond to an altitude of 2000-2500 m following the
604 age – elevation correlation (Fig. 7C). In this area, the maximum peak elevation is 5500 m.
605 This age pattern is in agreement with (i) little burial during the Cenozoic (less than 2-3 km, as
606 sediments were continuously removed from Tien Shan during thrusting (Jourdon et al.,
607 2018b), and (ii) with a minimum Cenozoic differential uplift of about 3 km (Vt in Fig. 7C),
608 and hence an approximate 4.2 km north-directed offset along the PT, given its 45° dip
609 towards the south (Fig. 7E). Since ~ 8.3 Ma, the average offset rate along this thrust would
610 thus be of about 0.3-0.7 mm/yr. This slip rate is much lower than those recorded on
611 ‘emblematic’ collisional thrusts like the Main Central Thrust of Himalayas for instance (> 10
612 mm/yr, e.g., Catlos et al., 2001).

613

614 *4.4. Out-of-sequence Late Miocene activation of deformation in the South Tian Shan*

615 In agreement with a previous compilation of thermochronological ages in the Kyrgyz Tian
616 Shan proposed by Macaulay et al. (2014), a north to south ‘out-of-sequence’ Cenozoic
617 deformation is suggested.

618

619 Fig. 10. A, Eastern Kyrgyz sketch geological map and compilation of main thermochronological results. B,
 620 Geological cross-section showing the major thrusts and their age of tectonic (re)activation during the Cenozoic.
 621 CTF: Central Terskey Fault; KipF: Kipchak Fault; MT: Maidan Thrust; MTF: Main Terskey Fault; NKTT:
 622 North Khan Tengri Thrust; NL: Nikolaev Line; PT: Pobedi Thrust; SarF: Sarajaz Fault; STS F: Southern Tian
 623 Shan Front; STSs: Southern Tian Shan Suture; UchF: Uchchat Fault.
 624

625 Overall, the numerous AFT and FT ages compiled along the Issyk-Kul-Pobedi Massif transect
 626 (Fig. 10) highlight a top-to-the-north deformation event that likely started in the north (Main
 627 Terskey Fault, MTF) in the Late Oligocene-Early Miocene. Here, several points of evidence

628 suggest that the highest and southern part of the Tian Shan belt, the Pobedi Massif, was
 629 uplifted after the MTS, which argues for a progressive propagation of deformation in the belt
 630 towards the Tarim basin in the south (Figs. 10-11):

631
 632 **Fig. 11.** Crustal-scale geological cross-section of the Kyrgyz-Chinese Tian Shan (79°E) after Jourdon et al.
 633 (2018b), showing the ages of the Cenozoic re-activation of major thrusts and their probable geometry at depth.
 634 The cross-section was built by coupling geological and geophysical data and numerical models (Jourdon et al.,
 635 2018b).
 636

637 (i) At the scale of the Tian Shan belt, combined thermochronological data define a
 638 Cenozoic exhumation event starting at ca. 30 Ma (e.g., Bande et al., 2017 and
 639 references therein). The ages obtained by Macaulay et al. (2014) in the hanging
 640 wall of the MTF are within 15-22 Ma, which argues for Early-Middle Miocene
 641 activity of this fault. This event is correlated with synchronous tectonic activity
 642 along the TFF (Bande et al., 2017), implying that both strike-slip and north-
 643 directed thrust motions acted simultaneously at the onset of Cenozoic
 644 compressional deformation. In turn, these faults were synchronous with the
 645 Maidan and adjacent faults bounding Tarim (Heermance et al., 2008; Sobel et al.,
 646 2011). Therefore, the locus of deformation has shifted within the Tian Shan with
 647 an out-of-sequence style.

- 648 (ii) The ages obtained by [Macaulay et al. \(2014\)](#), [Glorie et al. \(2011\)](#) and this study for
649 the hanging wall of the Sarajaz Fault, at the boundary between the Middle and
650 North Tian Shan, mostly range between 20 and 5 Ma, which argues for its main
651 activity during the Middle-Late Miocene. To the north of the Sarajaz Fault, the
652 south NTS and MTS mostly preserve Mesozoic ages, and in any case ages older
653 than 30 Ma, which is in good agreement with a north vergence for the Sarajaz
654 Fault thrust and relative downthrow of this compartment.
- 655 (iii) The STS domain exhibits older, Permian ages (256-269 Ma, to the west at
656 Inylchek) unreset during the Cenozoic, or variable partly reset ages (to the east
657 between Khan Tengri and Pobedi peaks). This zone of older AFT ages is in
658 agreement with a relative subsidence of that compartment accommodated by
659 extensional displacement on the STS suture at the back of a possible anticline
660 ramp structure.
- 661 (iv) The southern flank of the STS domain is uplifted by the top-to-the-north motion of
662 the Uchchat and Kipchak faults, which merge into the PT ([Figs. 2, 11](#)). In this
663 study, the new set of ages obtained in the high part of the Pobedi Massif suggest a
664 Cenozoic reactivation of the PT after 10 Ma. This Late Miocene age for the PT
665 reactivation is also supported by the geometry and polarity of the Aksu River
666 drainage network ([Fig. 8](#)). This deeply incised, meandering river cuts across the
667 high topography of the Pobedi Massif, flowing from north (MTS) to south (Tarim
668 Basin), in agreement with a later uplift of the STS.
- 669 (v) The <10 Ma activation age of the PT is in good agreement with the net coeval
670 increase in sedimentary rates documented in the north Tarim foreland basin all
671 along the southern edge of the Tian Shan belt (e.g., [Wu et al., 2019a-b](#); [Chang et](#)
672 [al., 2019](#); [Jia et al., 2020](#)). West to our study area, at the border with the Pamirs, a

673 marked increase in sedimentation rates at ~7 Ma, and a further rapid increase after
674 2.6 Ma, have been documented (Heermance et al., 2007; Chen et al., 2015; Qiao et
675 al., 2017; Liu et al., 2017). Similarly, to the south and east of our study area,
676 several studies show a marked increase in sedimentation rates after 20 Ma, and
677 especially between 12 and 5 Ma (Chang et al., 2012; 2017; Huang et al., 2006;
678 Charreau et al., 2006; Sun et al., 2009). These increased rates could be related to
679 the joint activation of the Pobedi and Maidan thrusts in a “flower-type” structure
680 (Figs. 10-11). Towards the south, the Maidan Thrust connects with a flat cover-
681 basement décollement, forming the Kalpin fold and thrust belt in the north Tarim
682 basin (e.g., Chang et al., 2019; Wu et al., 2019a-b; Figs. 10-11).

683 **Conclusions**

684 This study highlights two (Permian and Cenozoic) main phases of deformation related to the
685 activity and further reactivation of major thrusts within the STS: the Pobedi and the North
686 Khan Tengri Thrusts.

- 687 • $^{40}\text{Ar}/^{39}\text{Ar}$ dating of biotite and phengite at ca. 260-250 Ma agree with a maximum 12
688 km offset of the Pobedi Thrust and brittle-ductile deformation of the North Khan
689 Tengri Thrust.
- 690 • The AHe ages decrease from west to east. Towards the west, the importance of Late
691 Miocene uplift decreases sharply, while Late Permian exhumation ages (260-250 Ma)
692 are partly preserved below the Mesozoic unconformity at Inylchek, about 70 km to the
693 west of Pobedi Peak. In contrast, AHe ages obtained in the highest part of the massif,
694 in the Pobedi Thrust hangingwall highlight its Cenozoic re-activation at 8.3 ± 2.5 Ma,
695 with a differential uplift of 3 km along the thrust and a slip rate of 0.3-0.7 mm/yr.
696 Together with previous thermochronologic results from the Issyk-kul - Tarim transect,
697 these ages agree with a north to south ‘out-of-sequence’ thrust reactivation history,

698 which started about 20-30 Ma on several major faults such as the Main Terskey Fault
699 in the north and the Maidan Fault in the south, and ended with the joint reactivation of
700 the Pobedi Thrust and acceleration on the Maidan - STS frontal thrust.
