HIGHLIGHTS

- 32 Y-STR well-balanced mutation rate (CombYplex) and machine-learning program (PredYMaLe)
- Y-STR-based haplogroup prediction
- Best predictions using SVM and Random Forest classifiers
- Assignment accuracy scores (or prediction scores) using SVM: 97%
- Heterogeneous haplogroup predictions among classes
- Potential effects of small sample sizes and gene conversion

ABSTRACT

We developed a new mutationally well-balanced 32 Y-STR multiplex (**CombYplex**) together with a machine learning (ML) program **PredYMaLe** to assess the impact of STR mutability on haplogroup prediction, while respecting forensic community criteria (high DC/HD). We designed CombYplex around two sub-panels M1 and M2 characterized by average and high-mutation STR panels. Using these two sub-panels, we tested how our program PredYmale reacts to mutability when considering basal branches and, moving down, terminal branches. We tested first the discrimination capacity of CombYplex on 996 human samples using various forensic and statistical parameters and showed that its resolution is sufficient to separate haplogroup classes. In parallel, PredYMaLe was designed and used to test whether a ML approach can predict haplogroup classes from Y-STR profiles. Applied to our kit, SVM and Random Forest classifiers perform very well (average 97%), better than Neural Network (average 91%) and Bayesian methods (<90%). We observe

heterogeneity in haplogroup assignation accuracy among classes, with most haplogroups having high prediction scores (99-100%) and two (E1b1b and G) having lower scores (67%). The small sample sizes of these classes explain the high tendency to misclassify the Y-profiles of these haplogroups; results were measurably improved as soon as more training data were added. We provide evidence that our ML approach is a robust method to accurately predict haplogroups when it is combined with a sufficient number of markers, well-balanced mutation rate Y-STR panels, and large ML training sets. Further research on confounding factors (such as gene conversion) and ideal STR panels in regard to the branches analysed can be developed to help classifiers further optimize prediction scores.

Keywords: Y-STR, machine learning, assignation accuracy and haplogroup prediction (hg prediction), incremental mutation rates

Running title: Y-chromosome study: combined use of a 32 Y-STRs multiplex and machine learning methods for haplogroup prediction

INTRODUCTION

The Y-chromosome has been extensively used to identify male individuals in forensic communities (Kayser, 2017) and to reconstruct the family and evolutionary history of paternal lineages in geneticists (Jobling and Tyler-Smith, 2003) and genealogists communities (Calafell and Larmuseau, 2017). Questions related to the latter research topic are diverse and to address them on the Y-chromosome which is characterized by a low genetic diversity in human species, it can be advantageous to capture not only long-term but also short-term genomic information. It would help to optimally study not only the biogeographic informativeness of Y-haplotypes (Pardo-Seco et al., 2019) but also Y-specific migration paths and social structure, surname diffusion, paternal history of royal family members, and paternal lineage diffusion (Gill et al., 1994; Austerlitz and Heyer, 1998; King et al., 2014, 2007; Bowden et al., 2008; Chaix et al., 2008; Heyer et al., 2009, 2015; King and Jobling, 2009a, 2009b; Verdu et al., 2010; Martinez-Cadenas et al., 2016; Calafell and Larmuseau, 2017). But whatever the objectives and the technics used, the key problem remains the same: finding a good equilibrium between the resolution needs (markers and mutation rates) and the costs involved. Retrieving long-term genomic information has classically been completed using Y-SNaPshot analyses (for a review on Y-SNP typing see Sobrino, Brión and Carracedo, 2005), and very recently by using massively parallel sequencing (Ralf et al., 2019). Retrieving short-term genomic information has mainly consisted in Y-STR profiling in accessing the maximum of STRs variants and

polymorphism either by (i) designing Y-STR multiplexes including highly mutable markers to better discriminate closely related individuals (Purps et al., 2014; Gopinath et al., 2016) or (ii) by sequencing and extracting length-based Y-STR polymorphism STR loci from Next Generation Sequencing technologies as implemented in STRait Razor (Warshauer et al., 2013) to get rid of the excess of variants. To access short and long-term information while diminishing costs, some studies have chosen to generate high resolution Y-STR data and to use previously developed tools to predict haplogroup classes (Young et al., 2011; Mirabal et al., 2010, Šehović et al., 2017, Jannuzzi et al., 2020). Among these methods, Neural Network-based models (Felix Immanuel, 2013; <http://www.y-str.org/>) and Bayesian-allele frequency approaches (Athey 2006) were the first to have been developed, although ML approaches have been also tested (Schlecht et al., 2008) (see Supplementary data 1 for a review). However, the large bias in haplogroup prediction error (Jannuzzi et al., 2020) has urged the development of ready-to-use predictive tools, while considering more carefully the impact of STR mutation rates. The human Y-STR mutation rate spectrum is wide with a 1000 to 10000-fold of magnitude. Although this represents a powerful source of variation for designing tools in forensic genetics (from molecular to computational-based types), it is currently poorly explored.

SUPPLEMENTARY DATA 1

In this paper, we assessed whether a well-balanced STR multiplex, associated with machine learning (ML) approaches can efficiently predict haplogroups, while still providing the high Discrimination Capacity (DC) index required in forensic genetics. We designed a 32 Y-STR-typing kit "CombYplex" around two panels of STRs (M1 and M2) mutating at various rates (selected from 3.85×10^{-04} to 1.45×10^{-02} mutation/locus/generation) to test the impact STR mutability on Hg prediction. Then, we designed "PredYMaLe" (Predicting Y-lineages using ML models), a program that includes various ML approaches to predict Y-haplogroup classes from a set of Y-STR markers.

First, for the CombYplex design, we assembled and typed a panel of 996 male individuals from three continents (Africa, Europe, and South America) available in our collections; we tested the discrimination power of CombYplex by computing both classic forensic and statistics parameters, e.g. Haplotype Diversity (HD), Discrimination Capacity (DC), Principal Component Analysis (PCA) and Linear Discriminant Analysis (LDA). Second, we tested whether the ML approaches implemented in the PredYMaLe program could efficiently predict the haplogroup lineages. We used a sub-panel of 503 chromosomes on four panels of STRs (the full 32-STR CombYplex, the Y-filer, and the CombYplex_M1 and M2 only) for which haplogroup data were available. We evaluated the impact of STR-assembly on assignment accuracy, by considering first seven main Hg classes (considered as basal Y-tree branches) and then 12 detailed Hg classes (including E-subdivided terminal-like branches) to test the impact of Hg subdivision. Although not all haplogroup lineages could be tested in this article, the wide range of coalescence ages associated with the Hgs tested here (from 5 KYA for R1b1a1a2a1a2a1b1a1-M167 to 45 KYA for Hgs I-170 or J-M304 (Kivisild et al. 2017) should give a good preview of the prediction scores for comparable clades existing in the Y-tree and of the associated divergence between the relative

haplotypes. Our results showed that: (i) the full and well-balanced STR profiles (CombYplex or Y-filer) give the best prediction scores using the SVM and Random Forest classifiers, whereas Neural Network or Bayesian approaches, the most currently used methods for Hg prediction, fall short; (ii) PredYMaLe and CombYplex can predict haplogroup classes with an average assignment accuracy of 97% using Support Vector Machines (SVM) and Random forest classifiers, but classifiers are sensitive to STR panel composition, STR number, and training dataset size. These results can be used in the future to design well-balanced STR panels with a high number of markers, featuring high discrimination capacity and accurate predictions of haplogroup lineages with appropriate ML methods.

MATERIALS AND METHODS

1. Database of Y-STR characteristics

For 220 Y-STRs, we collected information on Y-STR molecular characteristics, mutation rates, and polymorphisms for humans. This database is available in Supplementary data 2.

SUPPLEMENTARY DATA 2

2. Selecting Y-STRs and constructing multiplexes: CombYplex M1 and M2

We selected a set of 32 Y-STRs from our database to construct two complementary multiplexes: one with average-mutating markers (M1) and one with high-mutating markers (M2). These markers were chosen to be polymorphic and to have the simplest molecular structure as possible (see Table 1). M1 includes the following **18 Y-STRs**: DYS485, DYS588, DYS502, DYS461, DYS638, DYS643, DYS587, DYS575, DYS578, DYS632, DYS508, DYS640, DYS511, DYS577, DYS556, DYS517, DYS565 and DYS538. Their mutation rates range from 3.85×10^{-04} to 3.21×10^{-03} mutation/locus/generation. Their molecular structures, primers and conditions are detailed in Table 1 and an example of a M1_CombYplex profile is proposed in Figure 1a.

TABLE 1, FIGURE 1a

M2 includes a **sex-testing assay** (derived from Cadamuro et al., 2015) and the following **14 Y-STRs**: Y-GATA-A10, DYS570, DYS549, DYS460, DYS442, DYS510, DYS541, DYS576, DYS513, DYS458, DYS481, DYS612, DYS444, and DYS533. These markers were chosen to be highly polymorphic and to have the simplest molecular structure

as possible; however, when STR with pure molecular structures could not be selected, we compromised between a simple structure and high STR mutation rate (e.g. DYS612 and DYS533). Their mutation rates range from 3.32×10^{-03} to 1.45×10^{-02} mutation/locus/generation. Their molecular structures, primers and conditions are detailed in Table 1 and an example of a M2_CombYplex profile is proposed in Figure 1b.

TABLE 1, FIGURE 1b

The multiplexes were designed using the shortest amplicons as possible, with a maximum size of 356 bp for DYS533 (M2). They were designed to be used independently or combined, according to the degree of resolution required. The cost of a full CombYplex reaction (32 Y-linked STRs + three sex-typing markers) is only 4.3 € (in France and based on public prices for all the reagents), and one of the assets of this multiplex in regard to its resolution. This tool was developed on an ABI Prism 3730 DNA Analyzer 48-capillary array system (Life Technologies), due to contextual and logistic reasons, but its design strategy can be transposed to Next Generation Sequencing.

3. Population samples

Samples, available from collaborations and internal collections, were obtained from healthy human volunteers with consent forms. They were extracted from various substrates including saliva and whole blood. A total of **996** samples were used in this study (plus one male control, one female control and 1 *AZFc* deleted Y-chromosome male to control for deletion) and genotyped with the CombYplex kit. This dataset includes **six native West African** populations: three populations from Benin: 59 Bariba (Parakou region), 47 Yoruba (Ketou region), and 68 Fon (Cotonou and Ouidah regions), two populations from Ivory Coast:

47 Ahizi (Nigui-Saff region) and 37 Yacouba (Danané region), and one population from Mali: 13 Bwa (Segou region), **three native South African** populations (97 Xhosa, 90 Zulu, and 33 Tswana), **three admixed African-descendant** populations (52 French Guyana and Suriname Noir Marron, 56 Ketou-Yoruba, 35 Brazil - Rio de Janeiro, 20 Colombia), **one native American** population (6 Palikour), and **11 European populations** (30 Spain Barcelona, 19 Spain Galicia, 24 Spain Granada, 25 Spain Huelva, 46 France Loire-Atlantique, 50 France Vendée, 21 France Sarthe, 30 France Maine and Loire, 81 France Ariège-Pyrénées, and 57 France Haute-Garonne).

4. Analysis of grouped samples

DNA samples were grouped based on two criteria: geographic ("GEO" sample) and phylogenetic ("HAPLO" sample).

In the "**GEO sample**" the geographic location of individuals is based on two generations of residence. All the 996 male individuals are included in this sample, to evaluate forensic parameters and control the discrimination power of the sample.

The "**HAPLO sample**", a haplogroup-based sample, is a subset of the GEO sample, used to evaluate haplogroup predictions with ML methods. It includes 503 individuals for whom Y-SNP haplogroup and Y-filer profiles were also available. Since many studies have already tested the added value of PPY23 and Y-filer plus, we did not type these these additional products due to the costs involved. We used Y-filer, a mutationally relatively balanced Y-STR kit for which we already had data in our database. We removed DYS385a/b and analysed only 15-STRs from the Y-filer panel since we have found evidence of conversion and outlier alleles in previous work (Balaesque et al., 2014). Eight main Hgs were first considered to calculate forensics parameters (E1a, E1E1a, E1b1b, F, G, I, J, R1b1a1a2). However, haplogroup classes represented by a very low number of individuals were not included in the

subsequent ML analyses (7 individuals in Hg F-M213*/F-M89*, and 2 individuals in Hg E1b1b1b1a-M81 included in E1b1b for 12-classes analyses): 7-Main and 12 detailed classes were considered in ML-analyses. Hg G and E1b1b had the lowest sample sizes, with 9 and 12 individuals respectively; we kept these Hgs in the 7-main classes to test the potential impact of a low number of individuals. The results for these two Hgs will have to be considered carefully due to the effect of small training sets reported in the ML literature.

First, the HAPLO sample was used to test the efficiency of CombYplex using classic forensics parameters (Haplotype diversity, Gene Diversity, Discrimination Capacity and Match Probability) and to test whether CombYplex could discriminate haplogroup classes using discriminant analyses (PCA). Second, it was used to test whether haplogroups could be predicted from the full 32 Y-STR, from the M1 and M2 only (lower number of markers and contrasted mutation rate), or from the Y-filer Y-STR profiles using an ML program. The HAPLO sub-sample includes six European populations (n=201; 26 Spain Barcelona, 14 Spain Galicia, 19 Spain Granada, 22 Spain Huelva, 64 France Pyrenees, 56 France Haute-Garonne), five native African populations (n=191; 52 Benin Parakou Bariba, 60 Benin Cotonou Fon, 36 Ivory-Coast Ahizi, 30 Ivory-Coast Yacouba, 13 Mali Bwa), and five admixed African-descendant populations (n=111; 8 French Guyana Aluku, 50 Ketou-Yoruba, 27 Noir-Marron, 12 Brazil-Rio de Janeiro, and 14 Colombia).

5. DNA extraction

The DNA extraction method was chosen according to the sample substrate. DNA was extracted from: (i) **whole blood**, using the QiaAmp DNA Blood mini-kit (Qiagen), (ii) **serum**, using the i-genomic DNA Blood mini-kit (Euromedex), and (iii) **saliva**, using the OG-300 Oragene DNA Self-Collection Kit (DNA Genotek) following the respective manufacturer's

instructions. The quantity and quality of DNA extracted was estimated using a NanoDrop Spectrophotometer 2000C (LabTech).

6. PCR amplification conditions: CombYplex M1 and M2

CombYplex M1 and M2 were amplified in a reaction volume of 12.5 μ l with 6.25 μ l of QIAGEN Multiplex PCR Plus Kit (Qiagen), 1.25 μ l Q-solution (Qiagen), 4 μ l of the CombYplex M1 or M2 primer mix (see Tables 1a and 1b for concentrations) and 5 ng of DNA template (limit of detection tested: 2-2.5 ng). Thermal cycling was conducted on a GeneAmp PCR System 2700 (Applied Biosystems) using the following conditions: 95°C for 5 min; 30 cycles: 95°C for 30 sec, 62°C for 90 sec, 72°C for 30 sec; 68°C for 30 min, 10°C hold. To ensure that the resultant PCR amplicons were A-tailed (thereby avoiding the split peak phenomenon when visualized), a 2 μ l reaction mix incorporating 0.125 U Taq polymerase (Fisher BioReagents) and a 1X PCR buffer system was added to 5 μ l of PCR products prior to incubation for a further 45 min at 72°C.

7. Detection and analysis of PCR products

Diluted A-tailed PCR products were mixed to 8.8 μ l Hi-Di™ formamide (Applied Biosystems) and 0.2 μ l GS600LIZ Size Standard (Applied Biosystems). After incubation at 95°C for 5 min, the samples were loaded onto an ABI Prism 3730 and a 3500 DNA Analyzer 48-capillary array system (Applied Biosystems). The G5 matrix filter DS-33 was used to detect the five dyes 6-FAM™ (blue), VIC™ (green), NED™ (yellow), PET™ (red) and LIZ™ (orange). The samples were injected for 15 sec at 1,600 V. Separations were performed at 15,000 V for 30 min with a run temperature of 63°C using the POP™-7 Polymer for 3730 (Applied Biosystems), run through a 50 cm capillary array (Applied Biosystems). Following data collection, samples were analysed with GeneMapper v4.0 (Applied Biosystems).

8. SNP genotyping methods

The populations Fon, Bariba, Yoruba, Ahizi and Yacouba were genotyped using 96 Y-SNPs on a BioMark™ HD system (Fluidigm, USA) as described in (Fortes-Lima et al., 2015). Y-SNP haplogroups were assigned according to ISOGG Y-DNA Haplogroup Tree 2015 (<http://www.isogg.org/tree/>) updated in April 2015. All other populations were genotyped using classic SNaPshot technics using a hierarchical approach. In total, 14 haplogroup lineages were detected and grouped in 7-Main and 12-Detailed classes for ML-analyses (Supp Data 6); they were used in combination with 4 sets Y-STR profiles (full CombYplex, Y-filer, CombYplex_M1 and CombYplex_M2) in PredYmale program to calculate how accurately a haplogroup lineage could be assigned.

9. Sequencing

Each locus was sequenced for the Male 1 control sample. Primers for sequencing are reported in Supplementary data 3. Each PCR product was sequenced in two reactions using forward and reverse PCR primers. The sequence reaction was performed with the BigDye Terminator v3.1 Cycle Sequencing Kit (Applied Biosystems). Sequence products were run on an ABI 3730 DNA Analyzer (Applied Biosystems). Sequences were analysed using Sequence Scanner Software v1.0 (Applied Biosystems) and BioEdit Sequence Alignment Editor version 7.2.5.

SUPPLEMENTARY DATA 3

10. Forensic parameters and discrimination indexes: population grouping and comparative analyses

For GEO and HAPLO grouped samples, the following diversity parameters were calculated: haplotype diversity (HD) was calculated using $HD = \frac{n}{n-1} (1 - \sum xi^2)$, where n = the number of haplotypes in the dataset and xi = the frequency of the i th haplotype (Nei et al., 1981), gene diversity (GD) was calculated analogously to HD where n and xi denote the total number of samples and the relative frequency of the i th allele (Nei, 1973), discrimination capacity (DC) was defined as the ratio between the number of different haplotypes and the total number of haplotypes: $DC = \frac{N_{diff}}{N}$ where N_{diff} was the number of different haplotypes, N was the sample size, and match probability (MP) was calculated as the sum of squared haplotype frequencies $MP = \sum pi^2$ where pi was the frequency of the i th haplotype. Haplotype number (n) and haplotype frequencies were estimated using Arlequin v 3.5.2.2 (Excoffier and Lischer, 2010). We represented the distribution of Y-STR haplotypes according to their haplogroup class by PCA: analyses were carried out using R software v 2.15.3 (R CoreTeam, 2017) and ade4 packages (Dray and Dufour, 2007). In addition, we performed Linear Discriminant Analyse (LDA) using the MASS package (Venables and Ripley, 2002) to estimate the proportion of haplogroups that were classed to a satisfactory precision. For LDA analysis, about 75% of individuals per haplogroup class taken randomly are used to train the model, while the remaining 25% is used to validate the trained classifier by testing its efficiency. This procedure was run 100 times. Given that the ML training and the split between training and validation datasets are heuristic, all the scores are averaged over 100 trials. We tested haplogroup prediction on the most represented haplogroup classes in our sample: E1a, E1a1a, E1a1b, G, I, J, and R1a1a1 (and on the collapsed root E group, including E1a, E1a1a and E1a1b).

11. Predicting haplogroups using machine-learning approaches: PredYMaLe

Haplogroups are usually defined by a given set of SNPs, but here, we explore whether they could also be recovered from the phylogenetic information contained in the Y-STR haplotype profiles alone. Different methods have been developed to predict haplogroups based on STRs, such as the Bayesian-based haplogroup predictor (<http://www.hprg.com/hapest5/index.html>) or Nevgen (<https://www.nevgen.org>), but neither of these is based on generalized ML models such as those proposed here. Here, similarly to the work of Schlecht et al., (2008), albeit with a higher resolution, we developed a generalist ML-based approach to the problem of haplogroup assignment from Y-STR profiles, then applied it to the particular case of the CombYplex profiles. We also assessed whether it performs better than the more common linear discriminant analysis.

We ran a pre-pilot study to test the efficiency of seven ML models (detailed in Bishop, 2006) so the fittest ML models could be implemented in PredYmale (details of pre-pilot study in Supplementary Data 4). Three models were eventually selected: Support Vector Machines (SVM), Random Forest Classifiers and k-Nearest Neighbors (kNN). These models follow the same concept: they build a classifier (a function) that maps a point in the problem space (here, a sample defined by its repeat counts for a given set of STRs) to a given class (here, a haplogroup). It should be noted that naive Bayes classifiers, a common method to address the problem of linking a set of STR markers to a haplogroup, and tested in a pilot run, have been constantly outperformed by SVMs and Random Forest Classifiers.

SUPPLEMENTARY DATA 4

Support Vector Machines (SVM) are classifiers that linearly partition the problem space by determining the frontier of the hyperplane maximizing its distance to the training samples (Cortes and Vapnik, 1995). Although SVMs were originally designed to discriminate between only two classes, they can be used in multi-class classification problematics (Chih-Wei Hsu

and Chih-Jen Lin, 2002), the problem being then divided in as many one-versus-all sub-problems as there are classes, which are solved independently. These partial classifiers are then merged to define the final classifier. Concretely, each sample in the training set is represented in the problem space by a point whose coordinates are the number of repetitions for each STR. Samples with close characteristics will cluster together. The SVM will determine a set of hyperplanes maximizing the margin between the classes. New points (i.e. unlabelled samples) are classified in either class depending on where they find themselves with regards to these hyperplanes.

Random Forest Classifier decision trees (Breiman, 1993) are linear classifiers that partition the problem space by defining a tree of binary conditions based on the features of a sample. Each new sample is then run through this tree of questions until it reaches a leaf, containing its predicted haplotype. Since a decision tree tends to over-fit the dataset it has been trained with, it might encounter difficulties generalizing when confronted with new samples. The random forest model (Ho, 1995) was developed to alleviate this limitation. At first, it trains multiple independent trees on several distinct subsets of the training data. Then, their outputs are averaged to define the final classifier. To improve the efficiency of random forests, we trained them with the AdaBoost boosting algorithm (Freund and Schapire, 1997). AdaBoost successively trains several copies of a base classifier (here a random forest) on the same dataset, and the training is adapted over generations to force the classifier to focus on hard to classify samples. Finally, all the generated classifiers over the generations are weighted according to their performances and combined to produce the final classifier. In our case, the learning process generates a decision tree defining questions on the number of repetitions of each STR. Depending on the answer, the sample to be classified will fall in one of the haplogroups. A notable advantage of this method is that its architecture (a sequence of questions) is easy for a human to understand, making the classification process transparent.

The **k-nearest neighbour** algorithm (also known as k-NN) is a non-parametric classification method. To produce a prediction for an unlabelled point, the algorithm combines the labels of the k closest points from the learning dataset according to a voting system. There are many ways to adapt the algorithm to the problem at hand, for instance by choosing the distance used, by applying a preliminary dimension reduction, by weighting the votes and so on. An advantage of the k-NN is that its error rate in a multi-class classification problem is proved to be bounded as an expression of the Bayes error rate, giving it a solid theoretical ground.

Implementing PredYMaLe

We developed PredYMaLe (Predicting Y-lineages using machine learning models), a graphical interface to our automatic labelling solution, available at <https://gitlab.com/delehef/predymale/>. It is implemented in Python using the scikit-learn machine learning library and the Qt5 GUI library, and is available for GNU/Linux, macOS and Windows. PredYMaLe can be used on any Y-STR dataset where every sample is represented as a set of numerical repeat values (*e.g.* CombYplex, PPY23, etc.). Empty or null values are deliberately not supported in PredYMaLe: to avoid biases stemming from an imperfect dataset, we advise users to remove or insightfully fix erroneous profiles. The predicted labels can be exported to a CSV file for easy interoperability with other programs.

Procedure

We tested whether haplogroups could be predicted using the three selected ML models implemented in the PredYMaLe program, and the three different Y-STR profiles (CombYplex full, CombYplex_M2, and Y-filer). Each model was trained and evaluated using the HAPLO dataset (503 individuals, 7 Main and 12 Detailed Hg classes considered, 19 populations) and

according to the same protocol. The dataset was normalized in the [0; 1] range to avoid numerical discrepancies influencing the final result. Similar to the LDA analyses, 75% of the samples were used to train the model, while the remaining 25% were used to evaluate the trained classifier by testing its efficiency. Given that ML training, as well as the split between training and validation datasets are heuristic, all the scores are averaged over 100 trials. This also alleviates score outliers and offers a better interpretation of the performances of multiple models on real datasets. For that purpose, we performed two runs of analyses: for the first run, individuals were considered to belong to one of seven major haplogroup classes (E1a-M33, E1b1a-M2*, E1b1b-M215, G-M201, I-M170, J-M304, and R1a1a1-M269 called *MainHg*), and for the second run, to one of twelve more detailed haplogroup classes (E1a-M33, E1b1a1-M2*, E1b1a7-M191, E1b1a7a-U174, E1b1a8a-U209, E1b1a8a1-U290, E1b1b1-M35*, G-M201, I-M170, J-M304, R1b1a1a2-M269, and R1b1a1a2a1a2a1b1a1-M167 called *DetailedHg*). The poorly represented haplogroup classes (e.g. F-189, and E1b1b1b1a-M81) could not be included in the procedure.

Validation: The evaluation process gives a score to a model, reflecting the efficiency of its predictions. We used the standard success score defined as $s = n_C / n_T$, where n_C is the number of successfully labelled validation samples and n_T the total count of validation samples. One success rating noted ‘score’ considers prediction as correct only if the predicted label of the validation sample matches the expected one.

RESULTS

1. CombYplex: from polymorphisms to discrimination power

The CombYplex polymorphism was assessed based on 996 samples. All CombYplex profiles are available in Supplementary data 5. As expected, we observed an increasing level of polymorphisms from the less discriminative set of M1 markers (mean allele number: 6; Table 1) to the most discriminative M2 set (mean allele number: 9; Table 1). Forensic parameters were calculated for the GEO and HAPLO sample groups defined above (Table 2). GD and HD were greater than 0.999 for all GEO and HAPLO sub-groups using full CombYplex profiles. As expected, when M1 and M2 were analysed independently, M2 was always more discriminant than M1, with MP values oscillating from 0.001 (all populations) to 0.003 (Europe) using the GEO sample, and from 0.007 (Hg R) to 0.14 (Hg F) using the HAPLO sample. Indexes of discrimination capacity and match probability were observed in line with these values.

SUPPLEMENTARY DATA 5

TABLE 1, TABLE 2

Inter-haplogroup comparative analyses: PCA and LDA

We tested whether CombYplex and Y-filer profiles could easily discriminate between haplogroup classes using the HAPLO sample (Supplementary 6). For this aim, we performed a PCA with seven haplogroup classes (MainHg) and a LDA (Table 3). PCA results based on CombYplex showed that haplogroup classes are well-discriminated along the two first axes (Figure 2a, especially R1b1a1 and E1a1a), but also along the second and third axes (Figure 2b, G, and I). LDA scores reach 94% in average, and oscillate from excellent (100 for E1a-

M33, E1b1a-M2, G-201, J-M304, R1b1a1a2-M269), to very good (95 for I-M170), correct for one of the less represented classes (62% for E1b1b-M35*).

SUPPLEMENTARY DATA 6

FIGURE 2a,b

In comparison, discrimination of haplogroup classes appears less efficient using Y-filer profiles, both on F1xF2 and the F2xF3 axes (Figure 3a, b) but also using LDA (81% on average).

FIGURE 3a,b

These results provide evidence of the high resolving power of the 32 Y-STR CombYplex profile, not only for investigating paternal lineages but also for discriminating among haplogroups. Based on these encouraging results, we assessed whether haplogroup classes can be predicted using an ML approach based on CombYplex, Y-filer, CombYplex_M1 Y-STR and CombYplex_M2 Y-STR profiles.

2. Haplogroup prediction (HP) using Y-STR profiles and PredYMaLe program

We tested whether haplogroup classes can be predicted using an ML-based approach on CombYplex, Y-filer, CombYplex_M1 Y-STR and CombYplex_M2 Y-STR profiles. Results from the first run (seven major haplogroup classes (E1a-M33, E1b1a-M2*, E1b1b-M215, G-M201, I-M170, J-M304, and R1a1a1-M269 called *MainHg*) were very informative on the three methods and the four datasets tested. Although HP scores using SVM and Random Forest are similar, SVM performed slightly better than Random Forest (Table 3); on average,

these two methods gave much better results than kNN: Random Forest/SVM HP average 3 methods 90-97%; kNN HP average 3 methods: 52-73%; Table 3).

TABLE 3

Compared to classic LDA (73 - 94%), SVM and Random Forest models perform systematically better, whatever the STR dataset, and especially using CombYplex. This results illustrates the combined impact of the marker number and the mutation rate range chosen on assignment accuracy. However, LDA performs better than kNN also for the three methods tested here. From the four STR datasets tested, we noted a noticeable performance of CombYplex (SVM: 97%) compared with M1 (SVM: 96%) and Y-filer (SVM: 95%), the M2 subset being systematically declassified (SVM: 92%, RF: 90%, kNN: 52%); when all E classes are collapsed, HP scores are very high (SVM et RF: 96-100%). A strong heterogeneity in HP scores is observed between haplogroup classes, even when the best method (SVM) is considered with the best STR combination (CombYplex): the G (67%) and E1b1b (67%) branches give the lowest HP scores compare to all others branches (100%). These two haplogroup classes represent the least represented ones (respectively N=9, 12), thus, suggesting the strong influence of sample size on the efficiency of HP. By analyzing confusion matrices for the best combination SVM/CombYplex and the worst combination kNN/M2, we observe clear differences in misclassification profiles (Figure 4): for the best combination, only two misclassifications are observed: E1b1a for E1b1b, and R for G. In contrast, 5 miss-targeted classifications are observed for kNN/M2, illustrating the incapability of this model/STR panel to associate an STR profile to a defined haplogroup class (especially for G: 0% HP).

FIGURE 4

No classifier exhibits a particularly skewed behavior regarding either of the metrics; all of them, on both datasets, follow the same pattern: F1-score and markedness stay close, while the informedness tends to score lower, denoting conservative classifiers. Therefore, defining the best classifier as the one with the best overall scores is straightforward. For a more detailed insight, Supplementary Data 7 (Supp tables 7a-7c) contain the per-class, per-dataset and per-classifier precisions, recalls, F1-scores, informednesses and markednesses.

Supplementary Data 7 (Supp table 7a à 7c)

The second run aimed to test the impact of sub-branch on haplogroup assignation accuracy score. We used a maximum resolution by considering the 12 most represented haplogroup branches (E1a-M33, E1b1a1-M2*, E1b1a7-M191, E1b1a7a-U174, E1b1a8a*-U209, E1b1a8a1-U290, E1b1b1-M35*, G-M201, E1b1b1b1a, I J, R1b1a1a2-M269, R1b1a1a2a1a2a1b1a1-M167) and the two best models selected from the first run: SVM and Random Forest (Table 4). Per-class, per-dataset and per-classifier precisions, recalls, F1-scores, informednesses and markednesses are given in Supplementary Data 7 (Supp tables 7d-7f).

TABLE 4

Supplementary Data 7 (Supp tables 7d à 7f)

The average HP scores are high for both models and the four datasets, but they are lower than those from the first run, probably due to the smaller sample sizes and the close genetic affinity

of the different classes. Better prediction performances are observed for Random Forest, all STR datasets considered, with the highest average HP score obtained for CombYplex. The lowest scores are observed for M2 with an average HP score of 71% for Random Forest; this Y-STR dataset also has higher heterogeneity in HP scores between classes (from 27% for E1b1a1 to 100% E1a-M33; Table 4). By analyzing the confusion matrices for the best combination (Random Forest/CombYplex) and the worse (SVM/M2), we noticed that misclassification profiles are different (Figure 5). For Random Forest/CombYplex, misclassifications occur mainly across phylogenetically neighbors E1b1a and R1b1a1a2 branches. In contrast, for SVM/M2, misclassifications are associated with very diverse branches on the whole Y-chromosome phylogenetic tree (e.g. hg G), reflecting the impact either of highly mutating markers, the lower number of STR loci in this panel or the lack of association between STR profile and Y-haplogroup due to the impact of additional molecular mechanism as gene conversion.

FIGURE 5

DISCUSSION

In this paper, we assess whether a panel of well-balanced Y-STR mutations, built around two sub-STR panels (from 3.85×10^{-04} to 1.45×10^{-02} mutation/locus/generation), associated with machine learning (ML) approaches can efficiently predict haplogroups. We developed the 32 Y-STR panel "CombYplex" and genotyped it on 996 male individuals from three continents (West and South Africa, West Europe, South America) to explore and confirm the discrimination capacity of the full, M1 and M2 panels, using classing forensic and statistics parameters. Then, we developed the ML approach PredYMaLe (Predicting Y-lineages using

ML models) and tested it on an assembled panel of 503 individuals, for which Hg and Y-filer information were also available in our database allowing a direct comparison of Y-STR assemblies.

STR panels and ML classifiers: an ideal association?

We have demonstrated noticeable differences in prediction scores between STR panels and ML methods. Among all ML classifiers, SVM and Random Forests give better and more homogeneous prediction scores (90-97%) compared with kNN (52-97%) for this dataset, independently of the panels analysed.

When performing basal branch analyses (7-classes), mutationally well-balanced panels (CombYplex, Y-filer) and mutationally average panels (M1) performed better than the M2 panel, which was systematically outperformed. This result suggests that mutationally well-balanced or average STR panels should be preferred when analysing basal branches. The lower performance of M2 could imply either that assignment accuracy is affected by homoplasia using M2, due to the high mutation rate of the panel, or by the low number of STRs analysed (14 STRs). The latter argument is less probable since the 15 selected STRs of the Y-filer profiles gave better results.

When moving toward terminal branches (12-classes), mutationally well-balanced STR panels (CombYplex, Y-filer) performed better than M1 and M2 panels. M1 composed solely of average mutating STRs (18 STRs) were less performant due to its lack of discrimination power, giving equivalent results to M2 with four additional STR loci. Assignment accuracies for M1 and M2 decrease for the less represented classes, reflecting the need for the largest training set possible, and also a well-balanced STR panel with a sufficient number of STR loci when exploring closely related phylogenetic branches.

Variation in performance accuracies across Hg classes

We showed that some haplogroups (e.g. E1a, I, J) have very distinct and unambiguous Y-STR profiles leading to 100% assignment accuracy scores, while others haplogroups (e.g. G, E1b1b) are more prone to misclassification within the STR panels and datasets analysed here. The impact of complexifying molecular mechanisms, such as gene conversion (Rozen et al., 2003), which potentially affect these profiles cannot be excluded (Balaresque et al., 2014) and could be further investigated. However the consistently worst scores of misclassification for the G and E1b1b haplogroups is likely to be the simple consequence of their small sample size. If the low accuracy of less well represented classes is problematic, empirical trends suggest that results are instantly improved when more training data are available. By running PredYmale with 10 additional G profiles collected recently, we observed that the prediction accuracy score reaches 83%, illustrating that prediction accuracy is significantly improved when more training data are available. We encourage users to train and use PredYmale on their own datasets, to learn about the prediction scores expected for the part of the tree explored. Given that PredYmale computations are rather fast, users should not hesitate to use larger datasets, or to adapt their STR panels to attain the best prediction scores.

Using PredYMaLe with other STR panels

Our results demonstrate the need to find a good equilibrium between the number of markers, their mutability and the sample size of the training set according to the tree structure

considered. When analysing basal branches, well-balanced STR panels or average mutating STR panels can be selected preferably with SVM or Random Forest classifiers to ensure higher prediction scores. The M1 panel, an average mutating STR panel, gives very good results. Since these STRs have generally simpler motifs or low repeat counts, they can be extracted from whole-genome sequencing data using pre-existing tools (STRait Razor, Warshauer et al., 2013) and used to predict basal branches.

When moving toward terminal branches, mutationally well-balanced STR panels associated with SVM or Random Forest classifiers can be selected. In both cases, a minimal number of markers (> 20 -30 STRs) is required to guarantee the best prediction scores possible. In forensic genetics, two commercial kits are commonly used, PPY23 (Purps et al., 2014) and Y filer[®] Plus (Gopinath et al., 2016). We have briefly tested whether our program could be confidently used with these panels by running PredYmale on published data. Based on our previous conclusions, we have only included the most represented classes ($N > 20$). We analysed 451 individuals from five basal branches (E1b1b, G, I, J, R) for PPY23 (Pamjav et al., 2017, Heraclides et al., 2017), and 282 individuals from four basal branches (G, I, J, R1) for Y filer[®] Plus (Lacerenza et al., 2017). The average prediction scores obtained with SVM and Random Forest reached 98.5% for PPY23 and 97% for Y-filer plus (equiv. sample for ComBYplex reaches 98.5%). These results confirm the high prediction scores obtained with the SVM and Random Forest classifiers, for the three mutationally well balanced panels, for basal branches and sufficiently large training sets.

Predicting Hg using ML approaches: SVM, random forest and nearest neighbours classifiers

By developing an ML program (PredYMaLe), designed to predict haplogroups using any Y-STR profiles, we show that ML models, especially SVM and Random Forest, give much

better HP results compared to alternative ML methods, including Bayesian, or Neural Network-based models. Interestingly these two classifiers have been reported to perform quite well for many other biological data (Fernández-Delgado et al., 2014). An interesting observation resides in the large variance of scores depending on the algorithm used: naive Bayes methods giving the worst results, while SVMs reach excellent precisions. The low accuracy of naive Bayes-based methods, in this case, can be explained by the fact that these algorithms consider features independently, and so cannot capture the information contained in their covariance patterns. SVMs, on the other hand, by maximizing the margin between the training classes, typically give excellent results as long as first, the problem is linearly well separable, which seems to be the case in this study, and second, that there is no consequent overlap between the different classes. Were it not the case, one can apply the “kernel trick” (Aizerman et al., 1964), which uses Mercer’s theorem to computationally cheaply immerse the dataset in a much larger space, where classes that are not linearly separable in the original space might become linearly separable.

In conclusion, support vector machines, random forests and nearest-neighbors classifiers are interesting alternatives to Bayesian or Neural networks classifiers to predict Y-haplogroups. Future users should note that although we developed and mostly used PredYmale with datasets featuring Y-STR profiles sampled with the CombYplex kit, the underlying ML concepts in our tool can be used on any STR panel (using STR repetition counts). We encourage users to train and use PredYmale on their own datasets regardless of the typing method.

ACKNOWLEDGMENTS

We thank all DNA donors and volunteers associated with the sampling sessions. We also warmly thanks Prof. Maria Cátira Bortolini for giving us access to Brazilian samples, to Prof. Antoine Gessain for the Guyanese Noir Marrons. This work was supported by a Maturation research grant (CB's post-doctoral position), Research and Post-graduate Teaching Pole (PRES), the University Toulouse III (11.007), the LABEX DRIIHM (Investing in a future programme, ANR-11-LABX-0010), the OHM Haut Vicdessos, the Spanish Ministry of Economy and Competitiveness's grants (CGL2010-15191/BOS and CGL2014-53985-R) and the National Research Foundation Grant IFR160623173836 (MED). This work was performed using HPC resources from CALMIP (grant P1434). FD was supported by a PhD studentship (INSA, France), AM by a PhD studentship (Ministry of research, French government), NS by La Estancia de Otoño HOCR Cia. Ltda. (grant number 201509), CLH by a Spanish's research contract. CFL was supported by the EUROTAST Marie Curie Initial Training Network (EU FP7/2007-2013, grant no. 290344) and the Sven and Lilly Lawski's Foundation (N2019-0040). N = Number of samples; n = number of distinct haplotypes; HD: haplotype diversity (gene diversity); DC: discrimination capacity; MP, match probability

Table 3. Prediction scores (%) for seven haplogroup classes using three machine learning methods (SVM, Random Forest, k Nearest Neighbors) and LDA on four Y-STR datasets (CombYplex, M1, M2, Y-filer kit). For LDA, 10 individuals have been removed for Y-filer kit due to missing data; DYS502 has been removed from M1 analyses due to the lack of polymorphism.

Table 3.
